mance on the standard CTB test set. Table 2 shows the performance of the parser trained on the optimized projected treebank. Unexpectedly, we find that the constituent F_1-value of the parser trained on the optimized treebank drops sharply from the baseline, although the span F_1-value remains nearly the same. We assume that the EM procedure gives the original projected treebank more consistency between each single tree while the revised treebank deviates from the CTB annotation standard, but it needs to be validated by the following experiments.

4.2 Boost an Traditional Parser

The projected parser is used to help the reranking of the k-best parses produced by another state-of-the-art parser, which is called the baseline parser for convenience. In our experiments we choose the revised Chinese parser (Xiong et al., 2005) based on Collins model 2 (Collins, 1999) as the baseline parser.[2]

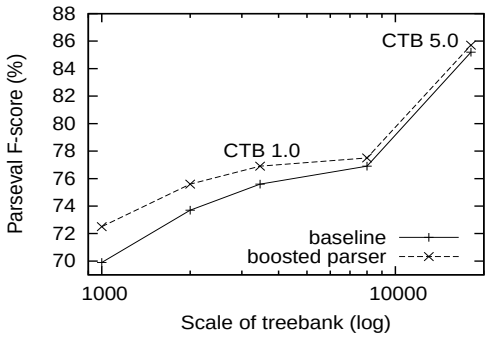

Figure 2: Boosting performance of the projected parser on a series of baseline parsers that are trained on treebanks of different scales.

The baseline parser is respectively trained on CTB 1.0 and CTB 5.0. For both corpora we follow the traditional corpus splitting: chapters 271-300 for testing, chapters 301-325 for development, and else for training. Experimental results are shown in Table 3. We find that both projected parsers bring significant improvement to the baseline parsers. Especially the later, although performs worse on CTB standard test set, gives a larger improvement than the former. This to some degree confirms the previous assumption. However, more investigation must be conducted in the future.

We also observe that for the baseline parser trained on the much larger CTB 5.0, the boosting performance of the projected parser is relatively lower. To further investigate the regularity that the boosting performance changes according to the scale of training treebank of the baseline parser, we train a series of baseline parsers with different amounts of trees, then use the projected parser trained on the optimized treebank to enhance these baseline parsers. Figure 2 shows the experimental results. From the curves we can see that the smaller the training corpus of the baseline parser, the more significant improvement can be obtained. This is a good news for the resource-scarce languages that have no large treebanks.

[2]The Berkeley Parser fails to give k-best parses for some sentences when trained on small treebanks, and these sentences have to be deleted in the k-best reranking experiments.

4.3 Using in Machine Translation

We investigate the effect of the projected parser in the tree-based translation model on Chinese-to-English translation. A series of contrast translation systems are built, each of which uses a supervised Chinese parser (Xiong et al., 2005) trained on a particular amount of CTB trees.

We use the FBIS Chinese-English bitext as the training corpus, the 2002 NIST MT Evaluation test set as our development set, and the 2005 NIST MT Evaluation test set as our test set. We first extract the tree-to-string translation rules from the training corpus by the algorithm of (Liu et al., 2006), and train a 4-gram language model on the Xinhua portion of GIGAWORD corpus with Kneser-Ney smoothing using the SRI Language Modeling Toolkit (Stolcke and Andreas, 2002). Then we use the standard minimum error-rate training (Och, 2003) to tune the feature weights to maximize the system's BLEU score.

Figure 3 shows the experimental results. We find that the translation system using the projected parser achieves the performance comparable with the one using the supervised parser trained on CTB 1.0. Considering that the F-score of the projected parser is only 22.8%, which is far below of the 75.6% F-score of the supervised parser trained on CTB 1.0, we can give more confidence to the assumption that the projected parser is apt to describe the syntax structure of the counterpart language. This surprising result also gives us an inspiration that better translation would be achieved by combining projected parsing and supervised parsing into hybrid parsing schema.

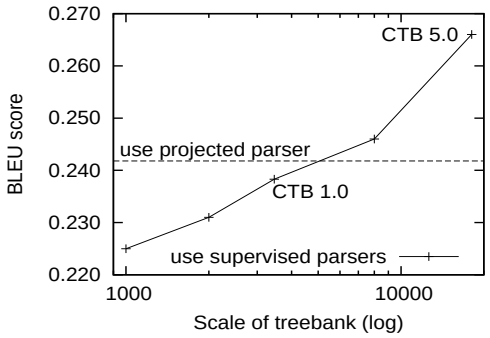

Figure 3: Performances of the translation systems, which use the projected parser and a series of supervised parsers trained CTB trees.

5 Conclusion

This paper describes an effective strategy for constituent projection, where dependency projection and constituent projection are consequently conducted to obtain the initial projected treebank, and an constraint EM procedure is then performed to optimized the projected trees. The projected parser, trained on the projected treebank, significantly boosts an existed state-of-the-art supervised-trained parser, especially trained on a smaller treebank. When using the projected parser in tree-based translation, we achieve the translation performance comparable with using a supervised parser trained on thousands of human-annotated trees.

As far as we know, this is the first time that the experimental results are systematically reported about the constituent projection and its applications. However, many future works need to do. For example, more energy needs to be devoted to the treebank optimization, and hybrid parsing schema that integrates the strengths of both supervised-trained parser and projected parser would be valuable to be investigated for better translation.

Abstract

This paper presents a comparative study on two key problems existing in extractive summarization: the ranking problem and the selection problem. To this end, we presented a systematic study of comparing different learning-to-rank algorithms and comparing different selection strategies. This is the first work of providing systematic analysis on these problems. Experimental results on two benchmark datasets demonstrate three findings: (1) pairwise and listwise learning-to-rank algorithms outperform the baselines significantly; (2) there is no significant difference among the learning-to-rank algorithms; and (3) the integer linear programming selection strategy generally outperformed Maximum Marginal Relevance and Diversity Penalty strategies.

1 Introduction

As the rapid development of the Internet, document summarization has become an important task since document collections are growing larger and larger. Document summarization, which aims at producing a condensed version of the original document(s), helps users to acquire information that is both important and relevant to their information need. So far, researchers have mainly focused on extractive methods which choose a set of salient textual units to form a summary. Such textual units are typically sentences, sub-sentences (Gillick and Favre, 2009), or excerpts (Sauper and Barzilay, 2009).

Almost all extractive summarization methods face two key problems: the first problem is how to rank textual units, and the second one is how to select a subset of those ranked units. The ranking problem requires systems model the relevance of a textual unit to a topic or a query. In this paper, the ranking problem refers to either sentence ranking or concept ranking. Concepts can be unigrams, bigrams, semantic content units, etc., although in our experiment, only bigrams are used as concepts. The selection problem requires systems improve diversity or remove redundancy so that more relevant information can be covered by the summary as its length is limited. As our paper focuses on extractive summarization, the selection problem refers to selecting sentences. However, the selection framework presented here is universal for selecting arbitrary textual units, as discussed in Section 4.

There have been a variety of studies to approach the ranking problem. These include both unsupervised sentence ranking (Luhn, 1958; Radev and Jing, 2004, Erkan and Radev, 2004), and supervised methods (Ouyang et al., 2007; Shen et al., 2007; Li et al., 2009). Even given a list of ranked sentences, it is not trivial to select a subset of sentences to form a good summary which includes diverse information within a length limit. Three common selection strategies have been studied to address this problem: Maximum Marginal Relevance (MMR) (Carbonell and Goldstein, 1998), Diversity Penalty (DiP) (Wan, 2007), and integer linear programming (ILP) (McDonald, 2007; Gillick and Favre, 2009). As different methods were often evaluated on different datasets, it is of great value to systematically compare ranking and selection strategies on the same dataset. However, to the best of our knowledge, there is still no work to compare different ranking strategies or compare different selection strategies.

In this paper, we presented a comparative study on the ranking problem and the selection

Coling 2008: Poster Volume, pages 525–533,
Beijing, August 2010

problem for extractive summarization. We compared three genres of learning-to-rank methods for ranking sentences or concepts: SVR, a pointwise ranking algorithm; RankNet, a pairwise learning-to-rank algorithm; and ListNet, a listwise learning-to-rank algorithm. We adopted an ILP framework that is able to select sentences based on sentence ranking or concept ranking. We compared it with other selection strategies such as MMR and Diversity Penalty. We conducted our comparative experiments on the TAC 2008 and TAC 2009 datasets, respectively. Our contributions are two-fold: First, to the best of our knowledge, this is the first work of presenting systematic and in-depth analysis on comparing ranking strategies and comparing selection strategies. Second, this is the first work using pairwise and liswise learning-to-rank algorithms to perform concept (word bigram) ranking for extractive summarization.

The rest of this paper is organized as follows. We introduce the related work in Section 2. In Section 3, we present three ranking algorithms, SVR, RankNet, and ListNet. We describe the sentence selection problem with an ILP framework described in Section 4. We introduce features in Section 5. Evaluation and experiments are presented in Section 6. Finally, we conclude this paper in Section 7.

2 Related Work

A number of extractive summarization studies used unsupervised methods with surface features, linguistic features, and statistical features to guide sentence ranking (Edmundson, 1969; McKeown and Radev, 1995; Radev et al., 2004; Nekova et al., 2006). Recently, graph-based ranking methods have been proposed for sentence ranking and scoring, such as LexRank (Erkan and Radev, 2004) and TextRank (Mihalcea and Tarau, 2004).

There are also a variety of studies on supervised learning methods for sentence ranking and selection. Kupiec et al. (1995) developed a naive Bayes classifier to decide whether a sentence is worthy to extract. Recently, Conditional Random Field (CRF) and Structural SVM have been employed for single document summarization (Shen et al., 2007; Li et al., 2009).

Besides ranking sentences directly, there are some approaches that select sentences based on concept ranking. Radev et al. (2004) used centroid words whose *tf***idf* scores are above a threshold. Filatova and Hatzivassiloglou (2004) used atomic event as concept. Moreover, summarization evaluation metrics such as Basic Element (Hovy et al., 2006), ROUGE (Lin and Hovy, 2003) and Pyramid (Passonneau et al., 2005) are all counting the concept overlap between generated summaries and human-written summaries.

Another important issue existing in extractive summarization is to find an optimal sentence subset which can cover diverse information. Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998) and Diversity Penalty (Wan, 2007) are most widely used approaches to reduce redundancy. The two methods are essentially based on greedy search. By contrast, ILP based approaches view summary generation as a global optimization problem. McDonald (2007) proposed a sentence-level ILP solution. Sauper and Barzilay (2009) presented an excerpt-level ILP method to generate Wikipedia articles. Gillick and Favre (2009) proposed a concept-level ILP, but they used document frequency to score concepts (bigrams), without any learning process. Some recent studies (Gillick and Favre, 2009; Martins and Smith, 2009) also modeled sentence selection and compression jointly using ILP. Our ILP framework proposed here is based on these studies. Although various selection strategies have been proposed, there is no work to systematically compare these strategies yet.

Learning to rank attracts much attention in the information retrieval community recently. Pointwise, pairwise and listwise learning-to-rank approaches have been extensively studied (Liu, 2009). Some of those have been applied to document summarization, such as SVR (Ouyang et al., 2007), classification SVM (Wang et al., 2007), and RankNet (Svore et al., 2007). Again, there is no work to systematically compare these ranking algorithms. To the best of our knowledge, this is the first time that a listwise learning-to-rank algorithm, ListNet (Cao et al., 2007), is adapted to document summarization in this paper. Moreover, pairwise and listwise learning-to-rank algorithms have never been used to perform concept ranking for extractive summarization.

3 Ranking Sentences or Concepts

Given a query and a collection of relevant documents, an extractive summarization system is required to generate a summary consisting of a set of text units (usually sentences). The first problem we need to consider is to determine the importance of these sentences according to the input query. We approach this ranking problem in two ways: the first way is to score sentences directly using learning-to-rank algorithms, and thus the goal of summarization is to select a subset of sentences, considering both relevance and redundancy. The second way is to score concepts within the document collection, and then the summarization task is to select a sentence subset that can cover those important concepts maximally. The problem of sentence selection will be described in Section 4.

Suppose the relevant document collection for a query q is D_q. From this collection, we obtain a set of sentences or concepts (e.g., word bigrams), $S=\{s_1,s_2,...,s_n\}$ or $C=\{c_1,c_2,..., c_n\}$. Before training, each s_i or c_i is associated with a gold standard score, y_i. A feature vector, $x_j=\Phi(s_j/c_j,q,D_q)$, is constructed for each sentence or concept. The learning algorithm will learn a ranking function $f(x_j)$ from a collection of query-document pairs $\{(q_i,D_{qi})|i= 1, 2,...,m\}$.

We investigated three learning-to-rank methods to learn $f(x_j)$. The first one is a pointwise ranking algorithm, support vector regression (SVR). This algorithm treats sentences (or concepts) independently. The second method is a pairwise ranking algorithm, RankNet, which learns a ranking function from a list of sentence (or concept) pairs. Each pair is labeled as 1 if the first sentence s_i (or concept c_i) ranks ahead of the second s_j (or c_j), and 0 otherwise.

The listwise ranking algorithm, ListNet, learns the ranking function $f(x_j)$ in a different way. A list of sentences (or concepts) is treated as a whole. Both RankNet and ListNet take into account the dependency between sentences (or concepts).

3.1 Support Vector Regression

Support Vector Regression (SVR), a generalization of the classical SVM formulation, attempts to learn a regression model. SVR has been applied to summarization in (Ouyang et al., 2007; Metzler and Kanungo, 2008). In our work, we train the SVR model to fit the gold standard score of each sentence or concept.

Formally, the objective of SVR is to minimize the following objective:

$$\Im(w,b,\xi) = \left\{\frac{1}{2}\| w\|^2 + C\left(v\cdot\xi + \frac{1}{N}\sum_{x_i} L(y_i - f(x_i))\right)\right\} \quad (1)$$

where $L(x)=|x|-\xi$ if $x > \xi$ and otherwise $L(x)=0$; y_i is the gold standard score of x_i; $f(x) =w^Tx+b$, the predicted score of x; C and v are two parameters; and N is the total number of training examples.

3.2 RankNet

RankNet is a pairwise learning-to-rank method (Burges et al., 2005). In this algorithm, training examples are handled pair by pair. Given a pair of feature vectors (x_i, x_j), the gold standard probability $\overline{P}_{ij}$ is set to be 1 if the label of the pair is 1, which means x_i ranks ahead of x_j. The gold standard probability is 0 if the label of the pair is 0. Then the predicted probability P_{ij}, which defines the probability of x_i ranking ahead of x_j by the model, is represented as a logistic function:

$$P_{ij} = \frac{\exp(f(x_i) - f(x_j))}{1+\exp(f(x_i) - f(x_j))} \quad (2)$$

where $f(x)$ is the ranking function. The objective of the algorithm is to minimize the cross entropy between the gold standard probability and the predicted probability, which is defined as follows:

$$C_{ij}(f) = -\overline{P}_{ij}\log P_{ij} - (1-\overline{P}_{ij})\log(1-P_{ij}) \quad (3)$$

A three-layer neural network is used as the ranking function, as follows:

$$f(x_n) = g^3\left(\sum_j w_{ij}^{32} g^2\left(\sum_k w_{jk}^{21} x_{nk} + b_j^2\right) + b_i^3\right) \quad (4)$$

where for weights w and bias b, the superscripts indicate the node layer while the subscripts indicate the node indexes within each layer. And x_{nk} is the k-th component of input feature vector x_n. Then a gradient descent method is used to learn the parameters. For details, refer to (Burges et al., 2005).

3.3 ListNet

ListNet takes a list of items as input in the learning process. More specifically, suppose we have

a list of feature vectors ($x_1, x_2, ..., x_n$) and each feature vector x_i has an gold standard score y_i, which has been assigned before training. Accordingly, we have a list of gold standard scores ($y_1, y_2, ..., y_n$). We also have a list of scores assigned by the algorithm during training, say, ($f(x_1), f(x_2), ..., f(x_n)$). Given a score list $S=\{s_1, s_2, ..., s_n\}$, the probability that x_j will rank the first place among the n items is defined as follows:

$$P_s(j) = \frac{\Phi(s_j)}{\sum_{k=1}^{n}\Phi(s_k)} = \frac{\exp(s_j)}{\sum_{k=1}^{n}\exp(s_k)} \quad (5)$$

It is easy to prove that ($P_s(1), P_s(2), ..., P_s(n)$) is a probability distribution, as the sum of them equals to 1. Therefore, the cross entropy can be used to define the loss between the gold standard distribution $P_y(j)$ and the distribution $P_f(j)$, as follows:

$$L(y, f) = -\sum_{j=1}^{n} P_y(j)\log P_f(j) \quad (6)$$

where y represents the gold standard score list ($y_1, y_2, ..., y_n$) and $f=(f(x_1), f(x_2), ..., f(x_n))$ is the score list output by the ranking algorithm.

The function f is defined as a linear function, as follows:

$$f_w(x_i) = w^T x_i \quad (7)$$

Then the gradient of loss function $L(y,f)$ with respect to the parameter vector w can be calculated as follows:

$$\Delta w = \frac{\partial L(y, f_w)}{\partial w} = -\sum_{j=1}^{n} P_y(x_j)\frac{\partial f_w(x_j)}{\partial w} + \frac{1}{\sum_{j=1}^{n}\exp(f_w(x_j))}\sum_{j=1}^{n}\exp(f_w(x_j))\frac{\partial f_w(x_j)}{\partial w} \quad (8)$$

During training, w is updated in a gradient descent manner: $w=w-\eta\Delta w$ and η is the learning rate. For details, refer to (Cao et al., 2007).

4 ILP-based Selection Framework

After we have a way of ranking sentences or concepts, we face a sentence selection problem: selecting an optimal subset of sentences as the final summary. To integrate sentence/concept ranking, we adopted an integer linear programming (ILP) framework to find the optimal sentence subset (Filatova and Hatzivassiloglou, 2004; McDonald, 2007; Gillick and Favre, 2009; Takamura and Okumura, 2009). ILP is a global optimization problem whose objective and constraints are linear in a set of integer variables.

Formally, we define the problem of sentence selection as follows:

$$\text{maximize: } \left\{\sum_i f(x_i) * z_i^x\right\} \quad (9)$$

$$s.t. \quad \sum_j z_j^u * |u_j| \le Lim$$

$$\sum_j z_j^u * I(i,j) \ge z_i^x, \quad \forall i$$

$$(z_i^x + z_j^x) * sim(x_i, x_j) < \delta \quad \forall i, j$$

$$z_i^x, z_j^u \in \{0,1\}, \quad \forall i, j$$

where:

$\boldsymbol{x_i}$ – the representation unit, such as a sentence or a concept. We term it representation unit because the summary quality is represented by the set of included x_i;

$\boldsymbol{f(x_i)}$ - the ranking function given by the learning-to-rank algorithms;

$\boldsymbol{u_j}$ - the selection unit, for instance, a sentence in this paper. $|u_j|$ is the number of words in u_j;

$\boldsymbol{z_i^x}$ - the indicator variable which denotes the presence or absence of x_i in the summary;

$\boldsymbol{z_j^u}$ - the indicator variable which denotes inclusion or exclusion of u_j;

$\boldsymbol{I(i, j)}$ - a binary constant indicating that whether x_i appears in u_j. It is either 1 or 0;

Lim - the length limit;

$\boldsymbol{sim(x_i, x_j)}$ - a similarity measure for considering the redundancy;

$\boldsymbol{\delta}$ - the redundancy threshold.

The first constraint indicates the length limit. The second constraint asserts that if a representation unit x_i is included in a summary, at least one selection unit that contains x_i must be selected. The third constraint considers redundancy. If the representation unit is sentence, the similarity measure is defined as *tf*idf* similarity, and $\delta/2$ is the similarity threshold, which was set to be 1 here. For concepts, the similarity measure can be defined as

$$sim(x_i, x_j) = \begin{cases} 1, & x_i = x_j \\ 0, & \text{otherwise} \end{cases}$$

However, other definition is also feasible, depending on what has been selected as representation unit.

Note that this framework is very general. If the representation unit x_i is a sentence, the ranking function is defined on sentence. Thus the ILP framework will find a set of sentences that can optimize the total scores of selected sentences, subject to several constraints. If the representation unit is a concept, the ranking function measures the importance of a concept to be included in a summary. Thus the goal of ILP is to find a set of sentences by maximizing the scores of concepts covered by those selected sentences.

D_q	relevant document collection in response to query q
d	one single document
w_i	unigram
w_iw_{i+1}	bigram
S	sentence
$tf_d(w_i)$	the frequency of w_i occurring in d
$df_D(w_i)$	the number of documents containing w_i in collection D

Table 1. Notations for features.

5 Features

To facilitate the following description, some notations are defined in Table 1. In our dataset, each query has a title and narrative to precisely define an information need. The following is a query example from the TAC 2008 test dataset:

```
<topic id = "D0801A">
  <title> Airbus A380 </title>
  <narrative>
      Describe developments in the production and
      launch of the Airbus A380.
  </narrative>
</topic>
```

Features for sentence ranking and concept ranking are listed in the following. We use word bigrams as concept here.

Sentence Features

(1) Cluster frequency: $\sum_{w_i \in S} tf_{D_q}(w_i)$

(2) Title frequency: $\sum_{w_i \in S} tf_d(w_i)$ where d is a new document that consists of all the titles of documents in D_q.

(3) Query frequency: $\sum_{w_i \in S} tf_d(w_i)$ where d is a document consisting of the title and narrative fields of the current topic.

(4) Theme frequency: $\sum_{w_i \in S \wedge w_i \in T} tf_{D_q}(w_i)$ where T is the top 10% frequent unigram words in D_q.

(5) Document frequency of bigrams in the sentence: $\sum_{w_iw_{i+1} \in S} df_D(w_iw_{i+1})$.

(6) PageRank score: as described in (Mihalcea and Tarau, 2004), each sentence in D_q is a node in the graph and the cosine similarity between a pair of sentences is used as edge weight.

Concept Features

(1) Cluster frequency: $tf_{D_q}(w_iw_{i+1})$, the frequency of w_iw_{i+1} occurring in D_q.

(2) Title frequency: $tf_d(w_iw_{i+1})$, where d is a document consisting of all the titles of documents in D_q.

(3) Query Frequency: the frequency of the bigram occurring in the topic title and narrative.

(4) Average term frequency: $\sum_{d \in D_q} tf_d(w_iw_{i+1}) / |D_q|$. $|D_q|$ is the number of documents in the set.

(5) Document frequency: the document frequency of this bigram.

(6) Minimal position: the minimal position of this bigram relative to the document length.

(7) Average position: the average position of this bigram in collection D_q.

6 Experimental Results

6.1 Data Preprocessing

We conducted experiments on the TAC 2008 and TAC 2009 datasets. The task requires producing a 100-word summary for each query (also termed topic sometimes). There are 48 queries in TAC 2008 and 44 queries in TAC 2009. A query example has been given in Section 5. Relevant documents for these queries have been specified. And four human-written summaries were supplied as reference summaries for each query.

We segmented the relevant documents into sentences using the LingPipe toolkit [1] and stemmed words using the Porter Stemmer. Word bigrams are used as concepts in this paper. If the two words in a bigram are both stopwords, the bigram will be discarded. The sen-

[1] http://alias-i.com/lingpipe/index.html

tence features and bigram features are then calculated. As our focus is on comparing different ranking strategies and selection strategies, we did not apply any sophisticated linguistic or semantic processing techniques (as pre- or post-processing). Thus we did not compare our results to those submitted to the TAC conferences.

We train the learning algorithms on one dataset and then evaluate the algorithms on the other. The generated summaries are evaluated using the ROUGE toolkit (Lin and Hovy, 2003).

6.2 Preparing Training Samples

As our work includes both sentence ranking and concept ranking, we need to establish two types of training data. Fortunately, we are able to do this based on the reference summaries and annotation results provided by the TAC conferences.

For the sentence ranking problem, we compute the average ROUGE-1 score for each sentence by comparing it to the four reference summaries for each query. This score is treated as the gold-standard score. In ListNet, these scores are directly used (see formula (5)). While in RankNet, the sentences for a query are grouped into 10 bins according to their ROUGE-1 scores, and then we extract sentences from different bins respectively to form a pair. We assume that a sentence in a higher scored bin should rank ahead of those sentences in lower scored bins.

As for the concept ranking problem, gold-standard scores are obtained from the human annotated Pyramid data. The weight of each semantic content unit (SCU) is the number of reference summaries in which the SCU appears. So straightforwardly, the gold-standard score of a bigram is the largest weight of all SCUs that contain the bigram. And if a bigram does not occur in any SCU, its score will be 0. Thus the bigram scores belong to the set {0,1,2,3,4} as there are four human-written summaries for each query. These scores are directly used in ListNet (see formula (5)). And in RankNet, bigram pairs are constructed according to the gold-standard scores.

6.3 Learning Parameters

For SVR, the radial basis kernel function is employed and the optimal values for parameters *C*, *v* and *g* (for the kernel) are found using the *gridregression.py* tool provided by LibSVM (Chang and Lin, 2001) with a 5-fold cross validation on the training set.

RankNet applies a three-layer (one hidden layer) neural network with only one node in the output layer, as described in (Burges et al., 2005). The number of hidden neurons was empirically set to be 10. The learning rate was set to 0.001 for sentence ranking and 0.01 for bigram ranking.

As for ListNet, the learning rate for sentence ranking and concept ranking are both set to be 0.1 empirically.

6.4 Comparing Ranking Strategies

In this section, we compared different ranking strategies for both sentence ranking and concept ranking. The sentence selection strategies were fixed to the ILP selection framework as shown in Section 4. We chose ILP as the selection strategy because we want to compare our system with the following two methods (as baselines):

(1) ***SENT_ILP***: A sentence-level method proposed by McDonald (2007) with ILP formulation. We implemented the query-focused version of the formulae as TAC 2008 and 2009 required query-focused summarization.

(2) ***DF_ILP***: A concept-level ILP method using document frequency to score word bigrams (Gillick and Favre, 2009), without any learning process.

The differences between our framework and SENT_ILP are: a) SENT_ILP used a redundancy factor in the objective function whereas we modeled redundancy as constraints; b) SENT_ILP used *tf***idf* similarity to compute relevance scores whereas we used learning algorithms.

The ROUGE-1 and ROUGE-2 measures for each method are presented in Table 2 and Table 3. Note that the performance on the TAC 2008 dataset was obtained from the models that were trained on the TAC 2009 dataset. Then, the datasets were interchanged for training and testing, respectively. Different learning-to-rank strategies (SVR, RankNet, ListNet) do not show significant differences between one and another, but they all outperform *SENT_ILP* substantially (p-value < 0.0001). And for concept ranking, RankNet and ListNet both achieve significantly better ROUGE-2 results (p-value < 0.005) than

DF_ILP. This infers that considering more features will have better results than using document frequency to score concepts. The Wilcoxon signed-rank test (Wilcoxon, 1945) is used for significance tests in our experiment. A good ranking strategy for modeling relevance is important for extractive summarization. RankNet which used a three-layer network (non-linear function) as the ranking function performs slightly better than ListNet which is based on a linear ranking function.

Dataset	Method	ROUGE-1	ROUGE-2
TAC 2008	SVR	0.35086	0.08447
	RankNet	**0.36025**	**0.09291**
	ListNet	0.35365	0.09129
	SENT_ILP	0.31546	0.06500
TAC 2009	SVR	0.36125	0.09659
	RankNet	**0.36216**	**0.09778**
	ListNet	0.35480	0.09126
	SENT_ILP	0.31962	0.07034

Table 2. Results of sentence ranking strategies.

Dataset	Method	ROUGE-1	ROUGE-2
TAC 2008	SVR	0.36555	0.10291
	RankNet	**0.37564**	**0.11213**
	ListNet	0.36863	0.10660
	DF_ILP	0.36922	0.10373
TAC 2009	SVR	0.37126	0.10698
	RankNet	**0.37513**	**0.11364**
	ListNet	0.37499	0.11313
	DF_ILP	0.36347	0.10156

Table 3. Results of concept ranking strategies.

It is worth noting that Pyramid annotations may not cover all important bigrams, partly because SCUs in reference summaries have been rephrased by human annotators. Note that we simply extract original sentences to form a summary, thus it is possible that a bigram which is important in the original sentences does not appear in any rephrased SCUs at all. Such bigrams will have a gold-standard score of 0, which is erroneous supervision. For example, the bigrams *hurricane katrina* in topic D0804A about *Katrina pet rescue* and *life support* in D0806A about *Terri Schiavo case* are not annotated in any SCUs, but these bigrams are both key terms for the topics.

6.5 Comparing Selection Strategies

In order to study the influence of different selection strategies, we compare the ILP selection strategy (as introduced in Section 4) with other popular selection strategies, based on the same sentence ranking algorithm (we chose sentence-level RankNet). The baselines to be compared are as follows:

(1) ***MMR***: As shown in (Carbonell and Goldstein, 1998), the formula of MMR is:

$$MMR = \arg\max_{s_i \in R-S} \left\{ \lambda D_1(q, s_i) - (1-\lambda) \max_{s_j \in S} D_2(s_i, s_j) \right\}$$

where q is the given query; R is the set of all sentences; S is the set of already included sentences; D_1 is the normalized ranking score $f(x_i)$ of s_i, and D_2 is the cosine similarity of the feature vectors for s_i and s_j. Our implementation was similar to the MMR strategy in the MEAD[2]summarizer.

(2) ***DiP***: Diversity penalty which penalizes the score of candidate sentences according to the already selected ones (Wan, 2007).

Dataset	Method	ROUGE-1	ROUGE-2
TAC 2008	ILP	**0.36025**	**0.09291**
	MMR	0.35459	0.09086
	DiP	0.35263	0.08689
TAC 2009	ILP	**0.36216**	**0.09778**
	MMR	0.35148	0.08881
	DiP	0.34714	0.08672

Table 4. Comparing selection strategies.

The corresponding ROUGE scores are presented in Table 4. ILP outperforms other selection strategies significantly on the TAC 2009 dataset (both ILP vs. MMR and ILP vs. DiP). Although improvements are observed with ILP on the TAC 2008 dataset, the difference is not significant (using ILP vs. using MMR). MMR is comparable to DiP as they are both based on greedy search in nature.

To investigate the difference between these strategies, we present in-depth analysis here. First, the average length of summaries generated by ILP is 97.1, while that by MMR and DiP are 95.5 and 92.7, respectively. Note that the required summary length is 100 and that more words can potentially cover more information. Thus, ILP can generate summaries with more information. This is because ILP is a global optimization algorithm, subject to the length constraint. Second, the average rank of sentences selected by ILP is 12.6, while that by MMR and

[2] http://www.summarization.com/mead/

DiP is about 5, which is substantially different. ILP can search down the ranked list while the other two methods tend to only select the very top sentences. Third, there are 4.1 sentences on average in each ILP-generated summary, while the number for MMR and DiP generated summaries are 2.7 and 2.5, respectively. Thus ILP tend to select shorter sentences than MMR and DiP. This may help reduce redundancy as longer sentences may contain more topic irrelevant clauses or phrases.

6.6 Discussions

Interestingly, although the learning-to-rank algorithms combined with the ILP selection strategy perform well in summarization, the performance is still far from that of manual summarization. In this study, we investigate the upper bound performance. We used the presented ILP framework to generate summaries based on the gold-standard scores, rather than the scores given by the learning algorithms. In other words, $f(x_i)$ in formula (9) is replaced by the gold-standard scores. The ROUGE results are shown in Table 5. We also listed the best/worst/average ROUGE scores of human summaries in TAC by comparing one human summary (as generated summary) to the other three human summaries (as reference summaries). These results are substantially better than those by the learning algorithms. Sentence- and concept- level ranking produces very close results to best human summaries. Some ROUGE-2 scores are even higher than those of human summaries. This is reasonable as human annotators may have difficulty in organizing content when there are many documents and sentences. The results reflect that there is a remarkable gap between the gold-standard scores and the learned scores.

Dataset	Method	ROUGE-1	ROUGE-2
TAC 2008	Sentence-level	0.44216	0.14842
	Concept-level	0.42222	**0.16018**
	Human Best	**0.44220**	0.13079
	Human Average	0.41417	0.11606
	Human Worst	0.38005	0.10736
TAC 2009	Sentence-level	0.45500	0.15565
	Concept-level	0.43526	**0.17118**
	Human Best	**0.45663**	0.14864
	Human Average	0.44443	0.12680
	Human Worst	0.39652	0.11109

Table 5. Upper bound performance.

7 Conclusion and Future Work

We presented systematic and extensive analysis on studying two key problems in extractive summarization: the ranking problem and the selection problem. We compared three genres of learning-to-rank algorithms for the ranking problem, and investigated ILP, MMR, and Diversity Penalty strategies for the selection problem. To the best of our knowledge, this is the first work of presenting systematic comparison and analysis on studying these problems. We also at the first time proposed to use learning-to-rank algorithms to perform concept ranking for extractive summarization.

Our future work will focus on: (1) exploiting more features that can reflect summary quality; (2) optimizing summarization evaluation metrics directly with new learning algorithms.

Abstract

We present a method for producing a bird's-eye view of statements that are expressed on Web pages on a given topic. This method aggregates statements that are relevant to the topic, and shows contradictory and contrastive relations among them. This view of contradictions and contrasts helps users acquire a top-down understanding of the topic. To realize this, we extract such statements and relations, including cross-document implicit contrastive relations between statements, in an unsupervised manner. Our experimental results indicate the effectiveness of our approach.

1 Introduction

The quantity of information on the Web is increasing explosively. Online information includes news reports, arguments, opinions, and other coverage of innumerable topics. To find useful information from such a mass of information, people generally use conventional search engines such as Yahoo! and Google. They input keywords to a search engine as a query and obtain a list of Web pages that are relevant to the keywords. They then use the list to check several dozen top-ranked Web pages one by one.

This method of information access does not provide a bird's-eye view of the queried topic; therefore it can be highly time-consuming and difficult for a user to gain an overall understanding of what is written on the topic. Also, browsing only top-ranked Web pages may provide the user with biased information. For example, when a user searches for information on "agaricus," claimed to be a health food, using a conventional search engine, many commercial pages touting its health benefits appear at the top of the ranks, while other pages remain low-ranked. The user may miss an existing Web page that indicates its unsubstantiated health benefits, and could be unintentionally satisfied by biased or one-sided information.

direct contrastive statement	"A is more P than B"
contrastive keyword pair	(A, B)
contradictory relation	"A is P" $\Leftrightarrow$ "A is not P"
contrastive relation	"A is P" $\leftrightarrow$ "B is P (not P)"

Table 1: Overview of direct contrastive statements, contrastive keyword pairs and contradictory/contrastive relations. Note that "P" is a predicate.

This paper proposes a method for producing a bird's-eye view of statements that are expressed on Web pages on a given query (topic). In particular, we focus on presenting contradictory/contrastive relations and statements on the topic. This presentation enables users to grasp what arguing points exist and furthermore to see contradictory/contrastive relations between them at a glance. Presenting these relations and statements is thought to facilitate users' understanding of the topic. This is because people typically think about contradictory and contrastive entities and issues for decision-making in their daily lives.

Our system presents statements and relations that are important and relevant to a given topic, including the statements and relations listed in Table 1. *Direct contrastive statements* compare two entities or issues in a single sentence. The contrasted entities or issues are also extracted as *contrastive keyword pairs*. In addition to them, our

Coling 2008: Poster Volume, pages 534–542,
Beijing, August 2010

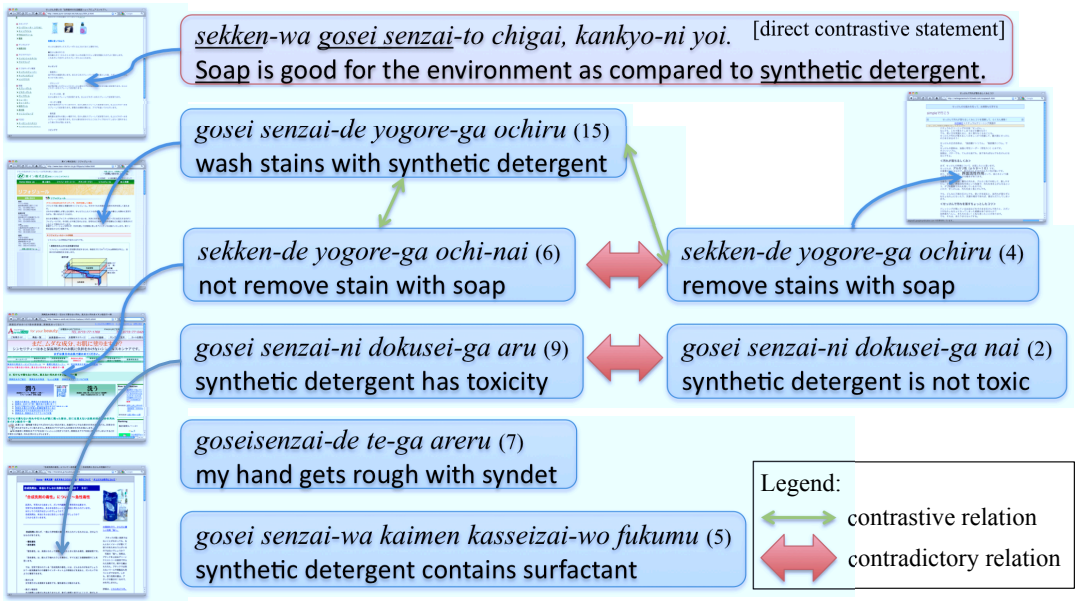

Figure 1: Examples of statements on "*gosei senzai*" (synthetic detergent), which are represented by rounded rectangles. Each statement is linked with the pages from which it is extracted. The number in a parenthesis represents the number of pages.

system shows *contradictory and contrastive relations* between statements. Contradictory relations are the relations between statements that are contradictory about an entity or issue. Contrastive relations are the relations between statements in which two entities or issues are contrasted.

In particular, we have the following two novel contributions.

- We identify contrastive relations between statements, which consist of in-document and cross-document implicit relations. These relations complement direct contrastive statements, which are explicitly mentioned in a single sentence.
- We precisely extract direct contrastive statements and contrastive keyword pairs in an unsupervised manner, whereas most previous studies used supervised methods (Jindal and Liu, 2006b; Yang and Ko, 2009).

Our system focuses on the Japanese language. For example, Figure 1 shows examples of extracted statements on the topic "*gosei senzai*" (synthetic detergent). Rounded rectangles represent statements relevant to this topic. The first statement is a direct contrastive statement, which refers to a contrastive keyword pair, "*gosei senzai*" (synthetic detergent) and "*sekken*" (soap). The pairs of statements connected with a broad arrow have contradictory relations. The pairs of statements connected with a thin arrow have contrastive relations. Users not only can see what is written on this topic at a glance, but also can check out the details of a statement by following its links to the original pages.

2 Related Work

Studies have been conducted on automatic extraction of direct contrastive sentences (comparative sentences) for English (Jindal and Liu, 2006b) and for Korean (Yang and Ko, 2009). They prepared a set of keywords that serve as clues to direct contrastive sentences and proposed supervised techniques on the basis of tagged corpora. We propose an unsupervised method for extracting direct contrastive sentences without constructing tagged corpora.

From direct contrastive sentences, Jindal and Liu (2006a) and Satou and Okumura (2007) proposed methods for extracting quadruples of (target, basis, attribute, evaluation). Jindal and Liu (2006a) extracted these quadruples and obtained an F-measure of 70%-80% for the extraction of "target" and "basis." Since this extraction was

not their main target, they did not perform error analysis on the extracted results. Satou and Okumura (2007) extracted quadruples from blog posts. They provided a pair of named entities for "target" and "basis," whereas we automatically identify such pairs. Ganapathibhotla and Liu (2008) proposed a method for detecting which entities ("target" and "basis") in a direct contrastive statement are preferred by its author.

There is also related work that focuses on non-contrastive sentences. Ohshima et al. (2006) extracted coordinated terms, which are semantically broader than our contrastive keyword pairs, using hit counts from a search engine. They made use of syntactic parallelism among coordinated terms. Their task was to input one of coordinated terms as a query, which is different from ours. Somasundaran and Wiebe (2009) presented a method for recognizing a stance in online debates. They formulated this task as debate-side classification and solved it by using automatically learned probabilities of polarity.

To aggregate statements and detect relations between them, one of important modules is recognition of synonymous, entailed, contradictory and contrastive statements. Studies on rhetorical structure theory (Mann and Thompson, 1988) and recognizing textual entailment (RTE) deal with these relations. In particular, evaluative workshops on RTE have been held and this kind of research has been actively studied (Bentivogli et al., 2009). The recent workshops of this series set up a task that recognizes contradictions. Harabagiu et al. (2006), de Marneffe et al. (2008), Voorhees (2008), and Ritter et al. (2008) focused on recognizing contradictions. For example, Harabagiu et al. (2006) used negative expressions, antonyms and contrast discourse relations to recognize contradictions. These methods only detect relations between given sentences, and do not create a bird's-eye view.

To create a kind of bird's-eye view, Kawahara et al. (2008), Statement Map (Murakami et al., 2009) and Dispute Finder (Ennals et al., 2010) identified various relations between statements including contradictory relations, but do not handle contrastive relations, which are one of the important relations for taking a bird's-eye view on a topic. Lerman and McDonald (2009) proposed a method for generating contrastive summaries about given two entities on the basis of KL-divergence. This study is related to ours in the aspect of extracting implicit contrasts, but contrastive summaries are different from contrastive relations between statements in our study.

3 Our Method

We propose a method for grasping overall information on the Web on a given query (topic). This method extracts and presents statements that are relevant to a given topic, including direct contrastive statements and contradictory/contrastive relations between these statements.

As a unit for statements, we use a predicate-argument structure (also known as a case structure and logical form). A predicate-argument structure represents a "who does what" event. Processes such as clustering, summarization, comparison with other knowledge and logical consistency verification, which are required for this study and further analysis, are accurately performed on the basis of predicate-argument structures. The extraction of our target relations and statements is performed via identification and aggregation of synonymous, contrastive, and contradictory relations between predicate-argument structures.

As stated in section 1, we extract direct contrastive statements, contrastive keyword pairs, relevant statements, contrastive relations and contradictory relations. We do this with the following steps:

1. Extraction and aggregation of predicate-argument structures
2. Extraction of contrastive keyword pairs and direct contrastive statements
3. Identification of contradictory relations
4. Identification of contrastive relations

Below, we first describe our method of extracting and aggregating predicate-argument structures. Then, we explain our method of extracting direct contrastive statements with contrastive keyword pairs, and identifying contradictory and contrastive relations in detail.

3.1 Extraction and Aggregation of Predicate-argument Structures

A predicate-argument structure consists of a predicate and one or more arguments that have a dependency relation to the predicate.

We extract predicate-argument structures from automatic parses of Web pages on a given topic by using the method of Kawahara et al. (2008). We apply the following procedure to Web pages that are retrieved from the TSUBAKI (Shinzato et al., 2008) open search engine infrastructure, by inputting the topic as a query.

1. Extract important sentences from each Web page. Important sentences are defined as sentences neighboring the topic word(s).
2. Obtain results of morphological analysis (JUMAN[1]) and dependency parsing (KNP[2]) of the important sentences, and extract predicate-argument structures from them.
3. Filter out functional and meaningless predicate-argument structures, which are not relevant to the topic. Pointwise mutual information between the entire Web and the target Web pages for a topic is used.

Note that the analyses in step 2 are performed beforehand and stored in an XML format (Shinzato et al., 2008).

Acquired predicate-argument structures vary widely in their representations of predicates and arguments. In particular, many separate predicate-argument structures have the same meaning due to spelling variations, transliterations, synonymous expressions and so forth. To cope with this problem, we apply "keyword distillation" (Shibata et al., 2009), which is a process of absorbing spelling variations, synonymous expressions and keywords with part-of relations on a set of Web pages about a given topic. As a knowledge source to merge these expressions, this process uses a knowledge base that is automatically extracted from an ordinary dictionary and the Web. For instance, the following predicate-argument structures are judged to be synonymous[3].

(1) a. *sekken-wo tsukau*
soap-ACC use

b. *sopu-wo tsukau*
soap-ACC use

c. *sekken-wo shiyou-suru*
soap-ACC utilize

We call the predicate-argument structures that are obtained as the result of the above procedure **statement candidates**. The final output of our system consists of direct contrastive statements (with contrastive keyword pairs), top-N statements (**major statements**) in order of frequency of statement candidates, and statements with contradictory/contrastive relations. Contradictory/contrastive relations are identified against major statements by searching statement candidates.

Another outcome of keyword distillation is a resultant set of keywords that are important and relevant to the topic. We call this set of keywords **relevant keywords**, which also include words or phrases in the query. Relevant keywords are used to extract contrastive keyword pairs.

3.2 Extraction of Contrastive Keyword Pairs and Direct Contrastive Statements

We extract contrastive keyword pairs from contrastive constructs, which are manually specified as patterns of predicate-argument structures. Statements that contain contrastive constructs are defined as direct contrastive statements.

For example, the following sentence is a typical direct contrastive statement, which contains a contrastive verb "*chigau*" (differ).

(2) *sekken-wa gosei senzai-to chigai, · · ·*
soap-TOP synthetic detergent-ABL differ

(soap differs from synthetic detergent, · · ·)

From this sentence, a contrastive keyword pair, "*sekken*" (soap) and "*gosei senzai*" (synthetic detergent), is extracted. The above sentence is extracted as a direct contrastive statement.

We preliminarily evaluated this simple pattern-based method and found that it has the following three problems.

[1] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/juman-e.html

[2] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/knp-e.html

[3] In this paper, we use the following abbreviations: NOM (nominative), ACC (accusative), DAT (dative), ABL (ablative), CMI (comitative), GEN (genitive) and TOP (topic marker).

- Keyword pairs that are mentioned in a contrastive construct are occasionally not relevant to the given topic.
- Non-contrastive keyword pairs are erroneously extracted due to omissions of attributes and targets of comparisons.
- Non-contrastive keyword pairs that have an is-a relation are erroneously extracted.

To deal with the first problem, we filter out keyword pairs that are contrastive but that are not relevant to the topic. For this purpose, we apply filtering by using relevant keywords, which are described in section 3.1.

As an example of non-contrastive keyword pairs (the second problem), from the following sentence, a keyword pair, "*tokkyo seido*" (patent system) and "*nihon*" (Japan), is incorrectly extracted by the pattern-based method.

(3) *amerika-no tokkyo seido-wa nihon-to*
America-GEN patent system-TOP Japan-ABL
kotonari, $\cdots$
different
(patent system of America is different from ϕ of Japan $\cdots$)

In this sentence, "*nihon*" (Japan) has a meaning of "*nihon-no tokkyo seido*" (patent system of Japan). That is to say, "*tokkyo seido*" (patent system), which is the attribute of comparison, is omitted.

In this study, in addition to patterns of contrastive constructs, we use checking and filtering on the basis of similarity. The use of similarity is inspired by the semantic parallelism between contrasted keywords. As this similarity, we employ distributional similarity (Lin, 1998), which is calculated using automatic dependency parses of 100 million Japanese Web pages. By searching similar keywords from the above sentence, we successfully extract a contrastive keyword pair, "*amerika*" (America) and "*nihon*" (Japan), and the above sentence as a direct contrastive statement.

Similarly, a target of comparison can be omitted as in the following sentence.

(4) *nedan-wa gosei senzai-yori takaidesu*
price-TOP synthetic detergent-ABL high
(price of ϕ is higher than synthetic detergent)

In this example, the similarity between "*nedan*" (price) and "*gosei senzai*" (synthetic detergent) is lower than a threshold, and this sentence and the extracts from it are filtered out.

As for the third problem, we may extract non-contrastive keyword pairs that have an is-a relation. From the following sentence, we incorrectly extract a contrastive keyword pair, "*konbini*" (convenience store) and "*7-Eleven*," which cannot be filtered out due to its high similarity.

(5) *7-Eleven-wa hokano konbini-to*
7-Eleven-TOP other convenience store-ABL
kurabete, $\cdots$
compare
(7-Eleven is $\cdots$ compared to other convenience stores)

To deal with this problem, we use a filter on the basis of a set of words that indicate the existence of hypernyms, such as "*hokano*" (other) and *ippanno* (general). We prepare six words for this purpose.

To sum up, we use the following procedure to identify contrast keyword pairs.

1. Extract predicate-argument structures that do not match the above is-a patterns and match one of the following patterns. They are extracted from the statement candidates.
   - X-*wa* Y-*to* {*chigau* | *kotonaru* | *kuraberu*}
     (X {differ | vary | compare} from/with Y)
   - X-*wa* Y-*yori* [adjective]
     (X is more $\cdots$ than Y)

   Note that each of X and Y is a noun phrase in the argument position.
2. Extract (x, y) that satisfies both the following conditions as a contrastive keyword pair. Note that (x, y) is part of a word sequence in (X, Y), respectively.
   - Both x and y are included in a set of relevant keywords.
   - (x, y) has the highest similarity among any other candidates of (x, y), and this similarity is higher than a threshold.

Note that the threshold is determined based on a preliminary experiment using a set of synonyms (Aizawa, 2007). We extract the sentence that contains the predicate-argument structure used in step 1 as a direct contrastive statement.

3.3 Identification of Contradictory Relations

We identify contradictory relations between statement candidates. In this paper, contradictory relations are defined as the following two types (Kawahara et al., 2008).

negation of predicate

If the predicate of a candidate statement is negated, its contradiction has the same or synonymous predicate without negation. If not, its contradiction has the same or synonymous predicate with negation.

(6) a. *sekken-ga kankyou-ni yoi*
soap-NOM environment-DAT good

b. *sekken-ga kankyou-ni yoku-nai*
soap-NOM environment-DAT not good

antonym of predicate

The predicate of a contradiction is an antonym of that of a candidate statement. To judge antonymous relations, we use an antonym lexicon extracted from a Japanese dictionary (Shibata et al., 2008). This lexicon consists of approximately 2,000 entries.

(7) a. *gosei senzai-ga anzen-da*
synthetic detergent-NOM safe

b. *gosei senzai-ga kiken-da*
synthetic detergent-NOM dangerous

To identify contradictory relations between statements in practice, we search statement candidates that satisfy one of the above conditions against major statements.

3.4 Identification of Contrastive Relations

We identify contrastive relations between statement candidates. In this paper, we define a contrastive relation as being between a pair of statement candidates whose arguments are contrastive keyword pairs and whose predicates have synonymous or contradictory relations. Contradictory relations of predicates are defined in the same way as section 3.3.

In the following example, (a, b) and (a, c) have a contrastive relation. Also, (b, c) has a contradictory relation.

(8) a. *gosei senzai-de yogore-ga ochiru*
synthetic detergent-CMI stain-NOM wash

Topic: bio-ethanol
(bio-ethanol fuel, gasoline)
(bio-ethanol car, electric car)
Topic: citizen judgment system
(citizen judgment system, jury system)
(citizen judgment system, lay judge system)
Topic: patent system
(patent system, utility model system)
(large enterprise, small enterprise)
Topic: Windows Vista
(Vista, XP)

Table 2: Examples of extracted contrastive keyword pairs (translated into English).

b. *sekken-de yogore-ga ochiru*
soap-CMI stain-NOM wash

c. *sekken-de yogore-ga ochi-nai*
soap-CMI stain-NOM not wash

The process of identifying contrastive relations between statements is performed in the same way as the identification of contradictory relations. That is to say, we search statement candidates that satisfy the definition of contrastive relations against major statements.

4 Experiments

We conducted experiments for extracting contrastive keyword pairs, direct contrastive statements and contradictory/contrastive relations on 50 topics, such as age of adulthood, anticancer drug, bio-ethanol, citizen judgment system, patent system and Windows Vista.

We retrieve at most 1,000 Web pages for a topic from the search engine infrastructure, TSUBAKI. As major statements, we extract 10 statement candidates in order of frequency.

Below, we first evaluate the extracted contrastive keyword pairs and direct contrastive statements, and then evaluate the identified contradictory and contrastive relations between statements.

4.1 Evaluation of Contrastive Keyword Pairs and Direct Contrastive Statements

Contrastive keyword pairs and direct contrastive statements were extracted on 30 of 50 topics. 99 direct contrastive statements and 73 unique contrastive keyword pairs were obtained on 30 topics. The average number of obtained contrastive keyword pairs for a topic was approximately 2.4. Ta-

Topic: "*tyosakuken hou*" (copyright law)		
"*syouhyouken-wa tyosakuken-yori zaisantekina kachi-wo motsu.*"		
The trademark right has more financial value than the copyright.		
"*tyosakuken hou-de hogo-sareru*" protected by the copyright law	⇔	"*tyosakuken hou-de hogo-sare-nai*" not protected by the copyright law
"*tyosakuken-wo shingai-suru*" infringe the copyright	⇔	"*tyosakuken-wo shingai-shi-nai*" not infringe the copyright
	↖↘	"*syouhyouken-wo shingai-shi-nai*" not infringe the trademark right
Topic: "*genshiryoku hatsuden syo*" (nuclear power plant)		
"*genshiryoku hatsuden syo-wa karyoku hatsuden syo-to chigau.*"		
Nuclear power plants are different from thermoelectric power plants.		
"*CO2-wo hassei-shi-nai*" not emit carbon dioxide	⇔	"*CO2-wo hassei-suru*" emit carbon dioxide
"*genpatsu-wo tsukuru*" construct a nuclear power plant	⇔	"*genshiryoku hatsuden syo-wo tsukura-nai*" not construct a nuclear power plant
	↖↘	"*karyoku hatsuden syo-wo tsukuru*" construct a thermoelectric power plant

Table 3: Examples of identified direct contrastive statements, contradictory relations and contrastive relations. The sentences with two underlined parts are direct contrastive statements. The arrows "⇔" and "↔" represent a contradictory relation and a contrastive relation, respectively.

ble 2 lists examples of obtained contrastive keyword pairs. We successfully extracted not only contrastive keyword pairs including topic words, but also those without them.

Our manual evaluation of the extracted contrastive keyword pairs found that 89% (65/73) of the contrastive keyword pairs are actually contrasted in direct contrastive statements. Correct contrastive keyword pairs were extracted on 28 of 30 topics. We also evaluated the contrastive keyword pairs extracted without similarity filtering. In this case, 190 contrastive keyword pairs on 41 topics were extracted and 44% (84/190) of them were correct. Correct contrastive keyword pairs were extracted on 31 of 41 topics. Therefore, similarity filtering did not largely decrease the recall, but significantly increased the precision.

We have eight contrastive keyword pairs that were incorrectly extracted by our proposed method. These contrastive keyword pairs accidentally have similarity that is higher than the threshold. Major errors were caused by the ambiguity of Japanese ablative keyword "*yori*."

(9) *heisya-wa* *bitWallet sya-yori*
our company-TOP bitWallet, Inc.-ABL

Edy gifuto-no gyomu itaku-wo ukete-imasu
Edy gift-GEN entrustment-ACC have

(Our company is entrusted with Edy gift by bitWallet, Inc.)

In this example, "*yori*" means not the basis of contrast but the source of action. The similarity filtering usually prevents incorrect extraction from such a non-contrastive sentence. However, in this case, the pair of "*heisya*" (our company) and "*bitWallet sya*" (bitWallet, Inc.) was not filtered due to the high similarity between them. To cope with this problem, it is necessary to use linguistic knowledge such as case frames.

4.2 Evaluation of Contradictory and Contrastive Relations

Contradictory relations were identified on 49 of 50 topics. For 49 topics, 268 contradictory relations were identified. The average number of identified contradictory relations for a topic was 5.5. Contrastive relations were identified on 18 of 30 topics, on which contrastive keyword pairs were extracted. For the 18 topics, 60 contrastive relations were identified. The average number of identified contrastive relations for a topic was 3.3.

Table 3 lists examples of the identified contradictory and contrastive relations as well as direct contrastive statements. We manually evaluated the identified contradictory relations and the contrastive relations that were identified for correct contrastive keyword pairs. As a result, we concluded that they completely obey our definitions.

We also classified each of the obtained contradictory and contrastive relations into two classes: "cross-document" and "in-document." "Cross-

Topic: age of adulthood
lower the age of adulthood to 18
↔ lower the voting age to 18
Topic: anticancer drug
anticancer drugs have side effects
↔ anticancer drugs have effects

Table 4: Examples of unidentified contrastive relations (translated into English).

document" means that a contradictory/contrastive relation is obtained not from a single page but across multiple pages. If a relation can be obtained from both, we classified it into "in-document." As a result, 67% (179/268) of contradictory relations and 70% (42/60) of contrastive relations were "cross-document." We can see that many cross-document implicit relations that cannot be retrieved from a single page were successfully identified.

4.3 Discussions

We successfully identified contradictory relations on almost all the topics. However, out of 50 topics, we extracted contrastive keyword pairs on 30 topics and contrastive relations on 18 topics. To investigate the resultant contrastive relations from the viewpoint of recall, we manually checked whether there were unidentified contrastive relations among 100 statement candidates for each topic. We actually checked 20 topics and found six unidentified contrastive relations in total. Table 4 lists examples of the unidentified contrastive relations. Out of 20 topics, in total, 44 contrastive relations are manually discovered on 13 topics, but out of 13 topics, 38 contrastive relations are identified on eight topics by our method. Therefore, we achieved a recall of 86% (38/44) at relation level and 62% (8/13) at topic level. We can see that our method was able to cover a relatively wide range of contrastive relations on the topics on which our method successfully extracted contrastive keyword pairs.

To detect such unidentified contrastive relations, it is necessary to robustly extract contrastive keyword pairs. In the future, we will employ a bootstrapping approach to identify patterns of direct contrastive statements and contrastive keyword pairs. We will also use patterns of contrastive discourse structures as well as those of predicate-argument structures.

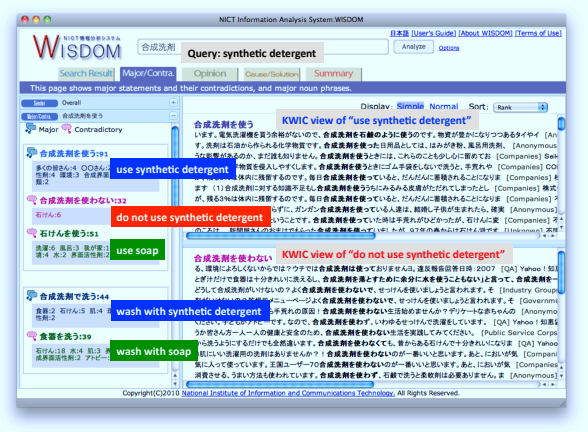

Figure 2: A view of major, contradictory and contrastive statements in WISDOM.

5 Conclusion

This paper has described a method for producing a bird's-eye view of statements that are expressed in Web pages on a given topic. This method aggregates statements relevant to the topic and shows the contradictory/contrastive relations and statements among them.

In particular, we successfully extracted direct contrastive statements in an unsupervised manner. We specified only several words for the extraction patterns and the filtering. Therefore, our method for Japanese is thought to be easily adapted to other languages. We also proposed a novel method for identifying contrastive relations between statements, which included cross-document implicit relations. These relations complemented direct contrastive statements.

We have incorporated our proposed method into an information analysis system, WISDOM[4] (Akamine et al., 2009), which can show multi-faceted information on a given topic. Now, this system can show contradictory/contrastive relations and statements as well as their contexts as a view of KWIC (keyword in context) (Figure 2). This kind of presentation facilitates users' understanding of an input topic.

mooney@cs.utexas.edu

Abstract

We present a probabilistic generative model for learning semantic parsers from ambiguous supervision. Our approach learns from natural language sentences paired with world states consisting of multiple potential logical meaning representations. It disambiguates the meaning of each sentence while simultaneously learning a semantic parser that maps sentences into logical form. Compared to a previous generative model for semantic alignment, it also supports full semantic parsing. Experimental results on the Robocup sportscasting corpora in both English and Korean indicate that our approach produces more accurate semantic alignments than existing methods and also produces competitive semantic parsers and improved language generators.

1 Introduction

Most approaches to learning semantic parsers that map sentences into complete logical forms (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Kate and Mooney, 2006; Wong and Mooney, 2007b; Lu et al., 2008) require fully-supervised corpora that provide full formal logical representations for each sentence. Such corpora are expensive and difficult to construct. Several recent projects on "grounded" language learning (Kate and Mooney, 2007; Chen and Mooney, 2008; Chen et al., 2010; Liang et al., 2009) exploit more easily and naturally available training data consisting of sentences paired with world states consisting of multiple potential semantic representations. This setting is partially motivated by a desire to model how children naturally learn language in the context of a rich, ambiguous perceptual environment.

In particular, Chen and Mooney (2008) introduced the problem of learning to sportscast by simply observing natural language commentary on simulated Robocup robot soccer games. The training data consists of natural language (NL) sentences ambiguously paired with logical meaning representations (MRs) describing recent events in the game extracted from the simulator. Most sentences describe one of the extracted recent events; however, the specific event to which it refers is unknown. Therefore, the learner has to figure out the correct matching (*alignment*) between NL and MR before inducing a semantic parser or language generator. Based on an approach introduced by Kate and Mooney (2007), Chen and Mooney (2008) repeatedly retrain both a supervised semantic parser and language generator using an iterative algorithm analogous to Expectation Maximization (EM). However, this approach is somewhat ad hoc and does not exploit a well-defined probabilistic generative model or real EM training.

On the other hand, Liang et al. (2009) introduced a probabilistic generative model for learning semantic correspondences in ambiguous training data consisting of sentences paired with observed world states. Compared to Chen and Mooney (2008), they demonstrated improved alignment results on Robocup sportscasting data. However, their model only produces an NL–MR alignment and does *not* learn either an effective

Coling 2008: Poster Volume, pages 543–551,
Beijing, August 2010

semantic parser or language generator. In addition, they use a combination of a simple Markov model and a bag-of-words model when generating natural language for MRs, therefore, they do not model context-free linguistic syntax.

Motivated by the limitations of these previous methods, we propose a new generative alignment model that includes a full semantic parsing model proposed by Lu et al. (2008). Our approach is capable of disambiguating the mapping between language and meanings while also learning a complete semantic parser for mapping sentences to logical form. Experimental results on Robocup sportscasting show that our approach outperforms all previous results on the NL–MR matching (alignment) task and also produces competitive performance on semantic parsing and improved language generation.

2 Related Work

The conventional approach to learning semantic parsers (Zelle and Mooney, 1996; Ge and Mooney, 2005; Kate and Mooney, 2006; Zettlemoyer and Collins, 2007; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007b; Lu et al., 2008) requires detailed supervision unambiguously pairing each sentence with its logical form. However, developing training corpora for these methods requires expensive expert human labor.

Chen and Mooney (2008) presented methods for grounded language learning from ambiguous supervision that address three related tasks: NL–MR alignment, semantic parsing, and natural language generation. They solved the problem of aligning sentences and meanings by iteratively retraining an existing supervised semantic parser, WASP (Wong and Mooney, 2007b) or KRISP (Kate and Mooney, 2006), or an existing supervised natural-language generator, WASP^{-1} (Wong and Mooney, 2007a). During each iteration, the currently trained parser (generator) is used to produce an improved NL–MR alignment that is used to retrain the parser (generator) in the next iteration. However, this approach does not use the power of a probabilistic correspondence between an NL and MRs during training.

On the other hand, Liang et al. (2009) proposed a probabilistic generative approach to produce a Viterbi alignment between NL and MRs. They use a hierarchical semi-Markov generative model that first determines which facts to discuss and then generates words from the predicates and arguments of the chosen facts. They report improved matching accuracy in the Robocup sportscasting domain. However, they only addressed the alignment problem and are unable to parse new sentences into meaning representations or generate natural language from logical forms. In addition, the model uses a weak bag-of-words assumption when estimating links between NL segments and MR facts. Although it does use a simple Markov model to order the generation of the different fields of an MR record, it does not utilize the full syntax of the NL or MR or their relationship.

Chen et al. (2010) recently reported results on utilizing the improved alignment produced by Liang et al. (2009)'s model to initialize their own iterative retraining method. By combining the approaches, they produced more accurate NL–MR alignments and improved semantic parsers.

Motivated by this prior research, our approach combines the generative alignment model of Liang et al. (2009) with the generative semantic parsing model of Lu et al. (2008) in order to fully exploit the NL syntax and its relationship to the MR semantics. Therefore, unlike Liang et al.'s simple Markov + bag-of-words model for generating language, it uses a tree-based model to generate grammatical NL from structured MR facts.

3 Background

This section describes existing models and algorithms employed in the current research. Our model is built on top of the generative semantic parsing model developed by Lu et al. (2008). After learning a probabilistic alignment and parsing model, we also used the WASP and WASP^{-1} systems to produce additional parsing and generation results. In particular, since our current system is incapable of effectively generating NL sentences from MR logical forms, in order to demonstrate how our matching results can aid NL generation, we use WASP^{-1} to learn a generator. This follows the experimental scheme of Chen et al. (2010), which demonstrated that an improved NL–MR

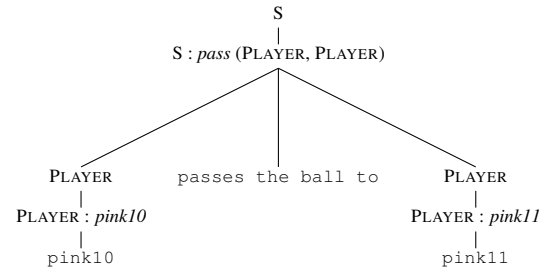

Figure 1: Sample hybrid tree from English sportscasting dataset where $(\mathbf{w}, \mathbf{m})$ = (pink10 passes the ball to pink11, *pass*(*pink10*, *pink11*))

matching from Liang et al. (2009) results in better overall parsing and generation. Finally, our overall generative model uses the IGSL (Iterative Generation Strategy Learning) method of Chen and Mooney (2008) to initially estimate the prior probability of each event-type generating a natural-language comment.

3.1 Generative Semantic Parsing

Lu et al. (2008) introduced a generative semantic parsing model using a hybrid-tree framework. A *hybrid tree* is defined over a pair, $(\mathbf{w}, \mathbf{m})$, of a natural-language sentence and its logical meaning representation. The tree expresses a correspondence between word segments in the NL and the grammatical structure of the MR. In a hybrid tree, MR production rules constitute the internal nodes, while NL words (or phrases) constitute the leaves. A sample hybrid tree from the English Robocup data is given in Figure 1.

A generative model based on hybrid trees is defined as follows: starting from a root semantic category, the model generates a production of the MR grammar, and then subsequently generates a mixed hybrid pattern of NL words and child semantic categories. This process is repeated until all leaves in the hybrid tree are NL words (or phrases). Each generation step is only dependent on the parent step, thus, generation is assumed to be a Markov process.

Lu et al. (2008)'s generative parsing model estimates the joint probability $P(\mathcal{T}, \mathbf{w}, \mathbf{m})$, which represents the probability of generating a hybrid tree $\mathcal{T}$ with NL $\mathbf{w}$, and MR $\mathbf{m}$. This probability is computed as the product of the probabilities of the steps in the generative process. Since there are multiple ways to construct a hybrid tree given a pair of NL and MR, the data likelihood of the pair $(\mathbf{w}, \mathbf{m})$ given by the learned model is calculated by summing $P(\mathcal{T}, \mathbf{w}, \mathbf{m})$ over all the possible hybrid trees for NL $\mathbf{w}$ and MR $\mathbf{m}$.

The model is normally trained in a fully supervised setting using NL–MR pairs. In order to learn from ambiguous supervision, we extend this model to include an additional generative process for selecting the subset of available MRs used to generate NL sentences.

3.2 WASP and WASP^{-1}

WASP (Word-Alignment-based Semantic Parsing) is a semantic parsing system that uses syntax-based statistical machine translation techniques. It induces a probabilistic synchronous context-free grammar (PSCFG) for generating corresponding NL–MR pairs. Since a PSCFG is symmetric with respect to the two languages it generates, the same learned model can be used for both semantic parsing (mapping NL to MR) and natural language generation (mapping MR to NL), Since there is no prespecified formal grammar for the NL, the WASP^{-1} system learns an n-gram language model for the NL side and uses it to choose the most probable NL translation for a given MR using a noisy-channel model.

3.3 IGSL

Chen and Mooney (2008) introduced the IGSL method for determining which event types a human commentator is more likely to describe in natural language. This is sometimes called *strategic generation* or *content selection*, the process of choosing *what to say*; as opposed to *tactical generation*, which determines *how to say it*. IGSL uses a method analogous to EM to train on ambiguously supervised data and iteratively improve probability estimates for each event type, specifying how likely each MR predicate is to elicit a comment. The algorithm alternates between two processes: calculating the expected probability of an NL–MR matching based on the currently learned estimates, and updating the probability of each event type based on the expected match counts. IGSL was shown to be quite effective at predicting which events in a Robocup game

	English	Korean
# of NL comments	2036	1999
# of extracted MR events	10452	10668
# of NLs w/ matching MRs	1868	1913
# of MRs w/ matching NLs	4670	4610
Avg. # of MRs per NL	2.50	2.41

Table 1: Stats for Robocup sportscasting data

a human would comment upon. In our proposed model, we use IGSL probability scores as initial priors for our event selection model.

4 Evaluation Dataset

In our experiments, we use the Robocup sportscasting data produced by Chen et al. (2010), which includes both English and Korean commentaries. The data was collected by having both English and Korean speakers commentate the final games from the RoboCup simulation soccer league for each year from 2001 through 2004. Table 1 presents some statistics on this sportscasting data. To construct the ambiguous training data, each NL commentary sentence is paired with MRs for all extracted simulation events that occurred in the previous 5 seconds (an average of 2.5 events).

Figure 2 shows a sample trace from the Robocup English data. Each NL commentary sentence normally has several possible MR matches that occurred within the 5-second window, indicated by edges between the NL and MR. Bold edges represent gold standard matches constructed solely for evaluation purposes. Note that not every NL has a gold matching MR. This occurs because the sentence refers to unrecognized or undetected events or situations or because the matching MR lies outside the 5-second window.

5 Generative Model

Like Liang et al. (2009)'s generative alignment model, our model is designed to estimate $P(\mathbf{w}|\mathbf{s})$, where $\mathbf{w}$ is an NL sentence and $\mathbf{s}$ is a world state containing a set of possible MR logical forms that can be matched to $\mathbf{w}$. However, our approach is intended to support both determining the most likely match between an NL and its MR in its world state, **and** semantic parsing, i.e. finding the

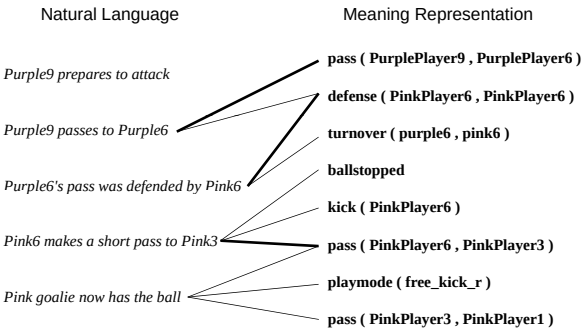

Figure 2: Sample trace from Robocup English data.

most probable mapping from a given NL sentence to an MR logical form.

Our generative model consists of two stages:

- Event selection: $P(\mathbf{e}|\mathbf{s})$, chooses the event $\mathbf{e}$ in the world state $\mathbf{s}$ to be described.
- Natural language generation: $P(\mathbf{w}|\mathbf{e})$, models the probability of generating natural-language sentence $\mathbf{w}$ from the MR specified by event $\mathbf{e}$.

5.1 Event selection model

The event selection model specifies the probability distribution for picking an event that is likely to be commented upon amongst the multiple MR logical forms in the world state $\mathbf{s}$. The probability of picking an event is assumed to depend only on its event type as given by the predicate of its MR. For example, the MR $pass(pink10, pink11)$ has event type $pass$ and arguments $pink10$ and $pink11$.

Our model is similar to Liang et al. (2009)'s *record choice* model, but we only model their notion of *salience*, denoting that some event types are more likely to be described than others. We do not model their notion of *coherence*, which models the order of event types in the commentary. We found that for sportscasting the order of described events depends only on the sequence of events in the game and does not exhibit any additional detectable pattern due to linguistic preferences.

The probability of picking an event e of type t_e is denoted by $p(t_e)$. If there are multiple events of type t in a world state $\mathbf{s}$, then an event of type t is selected uniformly from the set $\mathbf{s}(t)$ of events

of type t in state $\mathbf{s}$. Therefore, the probability of picking an event is given by:

$$P(\mathbf{e}|\mathbf{s}) = p(t_e)\frac{1}{|\mathbf{s}(t_e)|} \quad (1)$$

5.2 Natural language generation model

The natural-language generation model defines the probability distribution of NL sentences given an MR specified by the previously selected event. We use Lu et al. (2008)'s generative model for this step, in which:

$$P(\mathbf{w}|\mathbf{e}) = \sum_{\forall \mathcal{T}\ over\ (\mathbf{w},\mathbf{m})} P(\mathcal{T}, \mathbf{w}|\mathbf{m}) \quad (2)$$

where $\mathbf{m}$ is the MR logical form defined by event $\mathbf{e}$ and $\mathcal{T}$ is a hybrid tree defined over the NL–MR pair $(\mathbf{w}, \mathbf{m})$.

The probability $P(\mathcal{T}, \mathbf{w}|\mathbf{m})$ is calculated using the generative semantic parsing model of Lu et al. (2008) using the joint probability of the NL–MR pair $(\mathbf{w}, \mathbf{m})$, i.e. the inside probability of generating $(\mathbf{w}, \mathbf{m})$. The likelihood of a sentence $\mathbf{w}$ is then the sum over all possible hybrid trees defined by the NL–MR pair $(\mathbf{w}, \mathbf{m})$. [1]

The natural language generation model covers the roles of both the *field choice* model and *word choice* models of Liang et al. (2009). Since our event selection model only chooses an event based on its type, the order of its arguments still needs to be addressed. However, Lu et al.'s generative model includes ordering the MR arguments (as specified by MR production rules) as well as the generation of NL words and phrases to express these arguments. Thus, it is unnecessary to separately model argument ordering in our approach.[2]

[1] Lu et al. (2008) propose 3 models for generative semantic parsing: unigram, bigram, and mixgram (interpolation between the two). We used the bigram model, where the generation of a hybrid-tree component (NL word or semantic category) depends on the previously generated component as well as the parent MR production. The bigram model always performed the best on all tasks in our experimental evaluation.

[2] We also tried using a Markov model to order arguments like Liang et al. (2009), but preliminary experimental results showed that this additional component actually decreased performance rather than improving it.

6 Learning and Inference

This composite generative model is trained using conventional EM methods. The process is similar to Lu et al. (2008)'s, an inside-outside style algorithm using dynamic programming to generate a hybrid tree from the NL–MR pair $(\mathbf{w}, \mathbf{m})$, except our model's estimation process additionally deals with calculating expected counts under the posterior $P(\mathbf{e}|\mathbf{w}, \mathbf{s}; \theta)$ in the E-step and normalizing the counts to optimize parameters. The whole process is quite efficient; training time takes about 30 minutes to run on sportscasts of three games in either English or Korean.

Unfortunately, we found that EM tended to get stuck at local maxima with respect to learning the event-type selection probabilities, $p(t)$. Therefore, we also tried initializing these parameters with the corresponding strategic generation values learned by the IGSL method of Chen and Mooney (2008). Since IGSL was shown to be quite effective at predicting which event types were likely to be described, the use of IGSL priors provides a good starting point for our event selection model.

Our model is built on top of Lu et al. (2008)'s generative semantic parsing model, which is also trained in several steps in its best-performing version.[3] Thus, the overall model is vulnerable to getting stuck in local optima when running EM across these multiple steps. We also tried using random restarts with different initialization of parameters, but initializing with IGSL priors performed the best in our experimental evaluation.

7 Experimental Evaluation

We evaluated our proposed model on the Robocup sportscasting data described in Section 4. Our experimental results cover 3 tasks: NL–MR matching, semantic parsing, and tactical generation. Following Chen and Mooney (2008), the experiments were conducted using 4-fold (leave one game out) cross validation. Since the corpus contains data for four separate games, each fold uses 3 games for training and the remaining game for

[3] The bigram model of Lu et al. (2008), which is the one used in this paper, must be trained using parameters previously learned for the IBM Model 1 and unigram model in order to exhibit the best performance. We followed the same training scheme in our version.

testing for semantic parsing and tactical generation. Matching performance is measured in training data, since the goal is to disambiguate this data. All results are averaged across these 4 folds.

We also use the same performance metrics as Chen and Mooney (2008). The accuracy of matching and semantic parsing are measured using F-measure, the harmonic mean of precision and recall, where precision is the fraction of the system's annotations that are correct, and recall is the fraction of the annotations from the gold-standard that the system correctly produces. Generation is evaluated using BLEU score (Papineni et al., 2002) between generated sentences and reference NL sentences in the test set. We compare our results to previous results from Chen and Mooney (2008) and Chen et al. (2010) and to matching results on Robocup data from Liang et al. (2009).

7.1 NL–MR Matching

The goal of matching is to find the most probable NL–MR alignment for ambiguous examples consisting of an NL sentence and multiple potential MR logical forms. In Robocup sportscasting, the MRs for a given sentence correspond to all game events that occur within a 5-second window prior to the NL comment. Not all NL sentences have a matching MR in this window, but most do. During testing, an NL $\mathbf{w}$ is matched to an MR $\mathbf{m}$ if and only if the learned semantic parser produces $\mathbf{m}$ as the most probable parse of $\mathbf{w}$. Thus, our model does not force every NL to match an MR. If the most probable semantic parse of a sentence does not match *any* of the possible recent events, it is simply left unmatched. Matching is evaluated against the gold-standard matches supplied with the data, which are used for evaluation purposes only. The gold matching data is never used during training.

Table 2 shows the detailed results for both English and Korean data.[4] Our best approach outperforms all previous methods for both English and Korean by quite large margins. Note that initializing our EM training with IGSL's estimates improves performance significantly, and this approach outperforms Chen et al. (2010)'s best method, which also uses IGSL.

In particular, our proposed model outperforms the generative alignment model of Liang et al. (2009), indicating that the extra linguistic information and MR grammatical structure used by Lu et al. (2008)'s generative language model make our overall model more effective than a simple Markov + bag-of-words model for language generation.

Chen et al. (2010)	0.803	**0.812**
Our learned parser	0.742	0.764
Lu et al. + our matching	**0.810**	0.794
WASP + our matching	0.786	0.808
Lu et al. + Liang et al.	0.790	0.690
WASP + Liang et al.	0.803	0.740

Table 3: Semantic Parsing Results (F-measure). Results are the highest reported in the cited work.

7.2 Semantic Parsing

Semantic parsing is evaluated by determining how accurately NL sentences in the test set are correctly mapped to their meaning representations. Results are presented in Table 3.[5] [6] For our model, we report results using the parser learned directly from the ambiguous supervision, as well

[4] Since the Korean data was not yet available for use by either Chen and Mooney (2008) or Liang et al. (2009), we present the results reported by Chen et al. (2010) for these methods.

[5] The best result of Chen and Mooney (2008) is for WASPER-GEN, and that of Chen et al. (2010) is for WASPER with Liang et al.'s matching initialization for English and for WASER-GEN-IGSL-METEOR with Liang et al.'s initialization for Korean.

[6] Our semantic parsing results are based on our best matching results with IGSL initialization.

as results for training a supervised parser (both WASP and Lu et al. (2009)'s) on the NL–MR matching produced by our model. We also present results for training Lu et al.'s parser and WASP on Liang et al.'s NL–MR matchings.

Our initial learned semantic parser does not perform better than the best results reported by Chen et al. (2010), but it is clearly better than the initial results of Chen and Mooney (2008). Training WASP and Lu et al.'s supervised parser on our method's highly accurate set of disambiguated NL–MR pairs improved the results. Retraining Lu et al.'s parser gave the best overall results for English, and retraining WASP gave the second highest results for Korean, only failing to beat the very best results of Chen et al. (2010). It is somewhat surprising that simply retraining on the hardened set of most probable NL–MR matches gives better results than the parser trained using EM, which actually exploits the uncertainty in the underlying matches. Further investigations of this phenomenon are indicated.

Comparing with the corresponding results for training WASP and Lu et al.'s supervised parser on the NL–MR matchings produced by Liang et al.'s alignment method, it is clear that our matchings produce more accurate semantic parsers except when training WASP on English.

7.3 Tactical Generation

Tactical generation is evaluated based on how well the learned model generates accurate NL sentences from MR logical forms. Without integrating a language model for the NL, the existing generative model is not very effective for tactical generation. Lu et al. (2009) introduced an effective language generator for the hybrid tree framework using a Tree-CRF model; however, we did not have access to this system. Therefore, for tactical generation, we used the publicly available WASP^{-1} system (Wong and Mooney, 2007a) trained on disambiguated NL–MR matches. This approach also allows direct comparison with the results of Chen and Mooney (2008) and Chen et al. (2010), who also used WASP^{-1} for tactical generation. Our objective is to show that the more accurate matchings produced by our generative model can improve tactical generation.

	English	Korean
Chen and Mooney (2008)	0.4560	0.5575
Chen et al. (2010)	0.4599	0.6796
WASP^{-1} + Liang et al.	0.4580	0.5828
WASP^{-1} + our matching	**0.4727**	**0.7148**

Table 4: Tactical Generation Results (BLEU score). Results are the highest reported in the cited work.

The results are shown in Table 4.[7] [8] Overall, WASP^{-1} trained on the NL–MR matching from our alignment model performs better than all previous methods. In particular, using the matchings from our method to train WASP^{-1} produces better tactical generators than using matchings from Liang et al.'s approach.

7.4 Discussion

Overall, our model performs particularly well at matching NL and MRs under ambiguous supervision, and the difference is larger for English than Korean. However, improved matching results do not necessarily translate into significantly better semantic parsers. For English, the improvement in matching is almost 10 percentage points in F-measure, but the semantic parsing result trained with this more accurate matching shows only 1 point improvement.

Compared to Liang et al. (2009), our more accurate (i.e. higher F-measure) matchings provide a clear improvement in both semantic parsing and tactical generation. The only exception is English parsing using WASP, which seems to be due to some misleading noise in our alignments. WASP seems to be affected more than Lu et al.'s system by such extraneous noise. However, in tactical generation, this extraneous noise does not seem to lead to worse performance, and our approach always gives the best results. As discussed by Chen and Mooney (2008) and Chen et al. (2010), tactical generation is somewhat easier than semantic parsing in that semantic parsing needs to learn

[7] The best result of Chen and Mooney (2008) is for WASPER-GEN, and that of Chen et al. (2010) is for WASPER with Liang et al.'s matching initialization for English and for WASER-GEN with Liang et al. initialization for Korean.

[8] Our generation results are based on our best matching results with IGSL initialization.

to map a variety of synonymous natural-language expressions to the same meaning representation, while tactical generation only needs to learn one way to produce a correct natural language description of an event. This difference in the nature of semantic parsing and tactical generation may be the cause of the different trends in the results.

8 Conclusions and Future Work

We have presented a novel generative model capable of probabilistically aligning natural-language sentences to their correct meaning representations given the ambiguous supervision provided by a grounded language acquisition scenario. Our model is also capable of simultaneously learning to semantically parse NL sentences into their corresponding meaning representations. Experimental results in Robocup sportscasting show that the NL–MR matchings inferred by our model are significantly more accurate than those produced by all previous methods. Our approach also learns competitive semantic parsers and improved language generators compared to previous methods. In particular, we showed that our alignments provide a better foundation for learning accurate semantic parsers and tactical generators compared to those of Liang et al. (2009), whose generative model is limited by a simple bag-of-words assumption.

In the future, we plan to test our model on more complicated data with higher degrees of ambiguity as well as more complex meaning representations. One immediate direction is evaluating our approach on the datasets of weather forecasts and NFL football articles used by Liang et al. (2009). However, our current model does not support matching multiple meaning representations to the same natural-language sentence, and needs to be extended to allow multiple MRs to generate a single NL sentence.

Acknowledgements

We thank Wei Lu and Wee Sun Lee for sharing their software and giving helpful comments for the paper. We also thank Percy Liang for sharing his code and experimental results with us. Additionally, we thank David Chen in UTCS ML group for his comments and advice. Finally, we thank the anonymous reviewers for their comments. This work was funded by the NSF grant IIS. 0712907X. The experiments were executed and run on the Mastodon Cluster, provided by NSF Grant EIA-0303609.

Local Space-Time Smoothing for Version Controlled Documents

Seungyeon Kim
Georgia Institute of Technology

Guy Lebanon
Georgia Institute of Technology

Abstract

Unlike static documents, version controlled documents are continuously edited by one or more authors. Such collaborative revision process makes traditional modeling and visualization techniques inappropriate. In this paper we propose a new representation based on local space-time smoothing that captures important revision patterns. We demonstrate the applicability of our framework using experiments on synthetic and real-world data.

1 Introduction

Most computational linguistics studies concentrate on modeling or analyzing documents as sequences of words. In this paper we consider modeling and visualizing version controlled documents which is the authoring process leading to the final word sequence. In particular, we focus on documents whose authoring process naturally segments into consecutive versions. The revisions, as the differences between consecutive versions are often called, may be authored by a single author or by multiple authors working collaboratively.

One popular way to keep track of version controlled documents is using a version control system such as CVS or Subversion (SVN). This is often the case with books or with large computer code projects. In other cases, more specialized computational infrastructure may be available, as is the case with the authoring API of Wikipedia.org, Slashdot.com, and Google Wave. Accessing such API provides information about what each revision contains, when was it submitted, and who edited it. In any case, we formally consider a version controlled document as a sequence of documents $d_1, \ldots, d_l$ indexed by their revision number where d_i typically contains some locally concentrated additions or deletions, as compared to d_{i-1}.

In this paper we develop a continuous representation of version controlled documents that generalizes the locally weighted bag of words representation (Lebanon et al., 2007). The representation smooths the sequence of version controlled documents across two axes-time t and space s. The time axis t represents the revision and the space axis s represents document position. The smoothing results in a continuous map from a space-time domain to the simplex of term frequency vectors

$$\gamma : \Omega \to \mathbb{P}_V \quad \text{where} \quad \Omega \subset \mathbb{R}^2, \quad \text{and} \quad (1)$$

$$\mathbb{P}_V = \left\{ w \in \mathbb{R}^{|V|} : w_i \geq 0, \ \sum_{i=1}^{|V|} w_i = 1 \right\}.$$

The mapping above (V is the vocabulary) captures the variation in the local distribution of word content across time and space. Thus $[\gamma(s,t)]_w$ is the (smoothed) probability of observing word w in space s (document position) and time t (version). Geometrically, γ realizes a divergence-free vector field (since $\sum_w [\gamma(s,t)]_w = 1$, γ has zero divergence) over the space-time domain Ω.

We consider the following four version controlled document analysis tasks. The first task is visualizing word-content changes with respect to space (how quickly the document changes its content), time (how much does the current version differs from the previous one), or mixed space-time. The second task is detecting sharp transitions or edges in word content. The third task is concerned with segmenting the space-time domain into a finite partition reflecting word content. The fourth task is predicting future revisions. Our main tool in addressing tasks 1-4 above is to analyze the values of the vector field γ and its first

Coling 2008: Poster Volume, pages 552–560,
Beijing, August 2010

order derivatives fields

$$\nabla\gamma = (\dot{\gamma}_s, \dot{\gamma}_t)\,. \tag{2}$$

2 Space-Time Smoothing for Version Controlled Documents

With no loss of generality we identify the vocabulary V with positive integers $\{1,\ldots,V\}$ and represent a word $w \in V$ by a unit vector[1] (all zero except for 1 at the w-component)

$$e(w) = (0,\ldots,0,1,0,\ldots,0)^\top \quad w \in V. \tag{3}$$

We extend this definition to word sequences thus representing documents $\langle w_1,\ldots,w_N\rangle$ ($w_i \in V$) as sequences of V-dimensional vectors $\langle e(w_1),\ldots,e(w_N)\rangle$. Similarly, a version controlled document is sequence of documents $d^{(1)},\ldots,d^{(l)}$ of potentially different lengths $d^{(j)} = \langle w_1^{(j)},\ldots,w_{N(j)}^{(j)}\rangle$. Using (3) we represent a version controlled document as the array

$$\begin{array}{ccc} e(w_1^{(1)}), & \ldots, & e(w_{N(1)}^{(1)}) \\ \vdots & \ddots & \vdots \\ e(w_1^{(l)}), & \ldots, & e(w_{N(l)}^{(l)}) \end{array} \tag{4}$$

where columns and rows correspond to space (document position) and time (versions).

The array (4) of high dimensional vectors represents the version controlled document without any loss of information. Nevertheless the high dimensionality of V suggests we smooth the vectors in (4) with neighboring vectors in order to better capture the local word content. Specifically we convolve each component of (4) with a 2-D smoothing kernel K_h to obtain a smooth vector field γ over space-time (Wand and Jones, 1995) e.g.,

$$\gamma(s,t) = \sum_{s'}\sum_{t'} K_h(s-s',t-t')e(w_{s'}^{(t')})$$
$$K_h(x,y) \propto \exp\left(-(x^2+y^2)/(2h^2)\right). \tag{5}$$

Thus as (s,t) vary over a continuous domain $\Omega \subset \mathbb{R}^2$, $\gamma(s,t)$, which is a weighted combination of neighboring unit vectors, traces a continuous surface in $\mathbb{P}_V \subset \mathbb{R}^V$. Assuming that the kernel K_h is a normalized density it can be shown that $\gamma(s,t)$ is a non-negative normalized vector i.e., $\gamma(s,t) \in \mathbb{P}_V$ (see (1) for a definition of $\mathbb{P}_V$) measuring the local distribution of words around the space-time location (s,t). It thus extends the concept of lowbow (locally weighted bag of words) introduced in (Lebanon et al., 2007) from single documents to version controlled documents.

One difficulty with the above scheme is that the document versions $d_1,\ldots,d_l$ may be of different lengths. We consider two ways to resolve this issue. The first pads shorter document versions with zero vectors as needed. We refer to the resulting representation γ as the non-normalized representation. The second approach normalizes all document versions to a common length, say $\prod_{j=1}^{l} N(j)$. That is each word in the first document is expanded into $\prod_{j\neq 1} N(j)$ words, each word in the second document is expanded into $\prod_{j\neq 2} N(j)$ words etc. We refer to the resulting representation γ as the normalized representation.

The non-normalized representation has the advantage of conveying absolute lengths. For example, it makes it possible to track how different portions of the document grow or shrink (in terms of number of words) with the version number. The normalized representation has the advantage of conveying lengths relative to the document length. For example, it makes it possible to track how different portions of the document grow or shrink with the version number relative to the total document length. In either case, the space-time domain Ω on which γ is defined (5) is a two dimensional rectangular domain $\Omega = [0,I]\times[0,J]$.

Before proceeding to examine how γ may be used in the four tasks described in Section 1 we demonstrate our framework with a simple low dimensional example. Assuming a vocabulary of two words $V = \{1,2\}$ we can visualize γ by displaying its first component as a grayscale image (since $[\gamma(s,t)]_2 = 1 - [\gamma(s,t)]_1$ the second component is redundant). Specifically, we created a version controlled document with three contiguous segments whose $\{1,2\}$ words were sampled from Bernoulli distributions with parameters 0.3 (first segment), 0.7 (second segment), and 0.5 (third segment). That is, the probability of getting 1 is highest for the second segment, equal for the third and lowest for the first segment. The initial lengths of the segments were

[1] Note the slight abuse of notation as V represents both a set of words and an integer $V = \{1,\ldots,V\}$ with $V = |V|$.

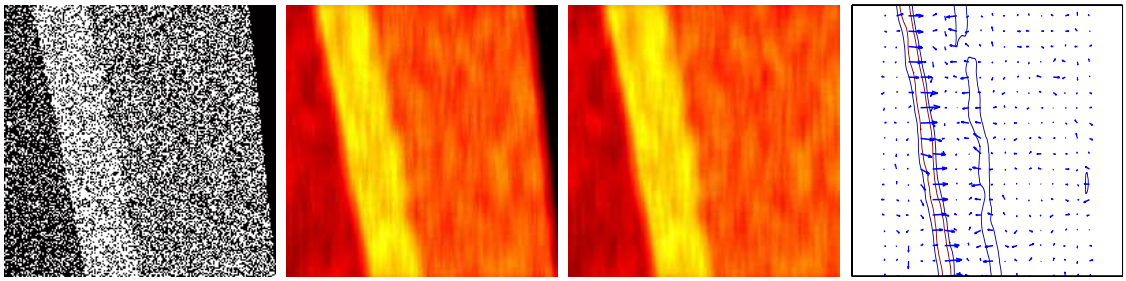

Figure 1: Four space-time representations of a simple synthetic version controlled document over $V = \{1, 2\}$ (see text for more details). The left panel displays the first component of (4) (non-smoothed array of unit vectors corresponding to words). The second and third panels display $[\gamma(s,t)]_1$ for the non-normalized and normalized representations respectively. The fourth panel displays the gradient vector field $(\dot{\gamma}_s(s,t), \dot{\gamma}_t(s,t))$ (contour levels represent the gradient magnitude). The black portions of the first two panels correspond to zero padding due to unequal lengths of the different versions.

30, 40 and 120 words with the first segment increasing and the third segment decreasing at half the rate of the first segment with each revision. The length of the second segment was constant across the different versions. Figure 1 displays the nonsmoothed ragged array (4) (left), the non-normalized $[\gamma(s,t)]_1$ (middle left) and the normalized $[\gamma(s,t)]_1$ (middle right).

While the left panel doesn't distinguish much between the second and third segment the two smoothed representations display a nice segmentation of the space-time domain into three segments, each with roughly uniform values. The non-normalized representation (middle left) makes it easy to see that the total length of the version controlled document is increasing but it is not easy to judge what happens to the relative sizes of the three segments. The normalized representation (middle right) makes it easy to see that the first segment increases in size, the second is constant, and the third decreases in size. It is also possible to notice that the growth rate of the first segment is higher than the decay rate of the third.

3 Visualizing Change in Space-Time

We apply the space-time representation to four tasks. The first task, visualizing change, is described in this section. The remaining three tasks are described in the next three section.

The space-time domain Ω represents the union of all document versions and all document positions. Some parts of Ω are more homogeneous and some are less in terms of their local word distribution. Locations in Ω where the local word distribution substantially diverges from its neighbors correspond to sharp content transitions. On the other hand, locations whose word distribution is more or less constant correspond to slow content variation.

We distinguish between three different types of changes. The first occurs when the word content changes substantially between neighboring document positions within a certain document version. As an example consider a document location whose content shifts from high level introductory motivation to a detailed technical description. Such change is represented by

$$\|\dot{\gamma}_s(s,t)\|^2 = \sum_{w=1}^{V} \left(\frac{\partial [\gamma(s,t)]_w}{\partial s} \right)^2 . \qquad (6)$$

A second type of change occurs when a certain document position undergoes substantial change in local word distribution across neighboring versions. An example is erroneous content in one version being heavily revised in the next version. Such change along the time axis corresponds to the magnitude of

$$\|\dot{\gamma}_t(s,t)\|^2 = \sum_{w=1}^{V} \left(\frac{\partial [\gamma(s,t)]_w}{\partial t} \right)^2 . \qquad (7)$$

Expression (6) may be used to measure the instantaneous rate of change in the local word distribution. Alternatively, integrating (6) provides a global measure of change

$$h(s) = \int \|\dot{\gamma}_s(s,t)\|^2 \, dt, \quad g(t) = \int \|\dot{\gamma}_t(s,t)\|^2 \, ds$$

with $h(s)$ describing the total amount of spatial change across all revisions and $g(t)$ describing

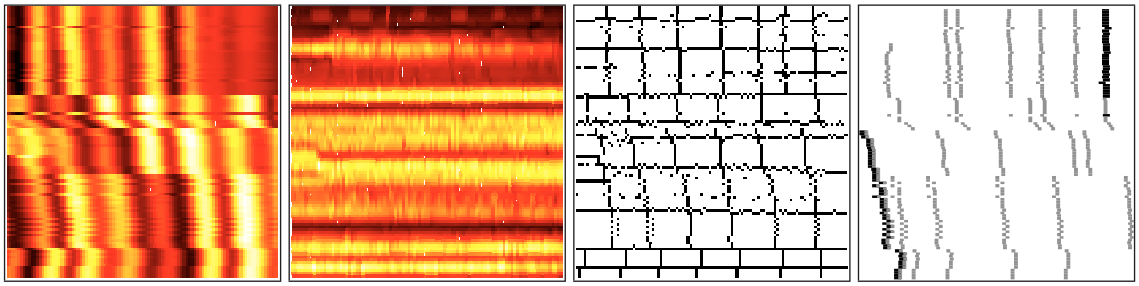

Figure 2: Gradient and edges for a portion of the version controlled Wikipedia Religion article. The left panel displays $\|\dot{\gamma}_s(s,t)\|^2$ (amount of change across document locations for different versions). The second panel displays $\|\dot{\gamma}_t(s,t)\|^2$ (amount of change across versions for different document positions). The third panel displays the local maxima of $\|\dot{\gamma}_s(s,t)\|^2 + \|\dot{\gamma}_t(s,t)\|^2$ which correspond to potential edges, either vertical lines (section and subsection boundaries) or horizontal lines (between substantial revisions). The fourth panel displays boundaries of sections and subsections as black and gray lines respectively.

the total amount of version change across different document positions. $h(s)$ may be used to detect document regions undergoing repeated substantial content revisions and $g(t)$ may be used to detect revisions in which substantial content has been modified across the entire document.

We conclude with the integrated directional derivative

$$\int_0^1 \|\dot{\alpha}_s(r)\dot{\gamma}_s(\alpha(r)) + \dot{\alpha}_t(r)\dot{\gamma}_t(\alpha(r))\|^2 \, dr \quad (8)$$

where $\alpha : [0,1] \to \Omega$ is a parameterized curve in the space-time and $\dot{\alpha}$ its tangent vector. Expression (8) may be used to measure change along a dynamically moving document anchor such as the boundary between two book chapters. The space coordinate of such anchor shifts with the version number (due to the addition and removal of content across versions) and so integrating the gradient across one of the two axis as in (7) is not appropriate. Defining $\alpha(r)$ to be a parameterized curve in space-time realizing the anchor positions $(s,t) \in \Omega$ across multiple revisions, (8) measures the amount of change at the anchor point.

3.1 Experiments

The right panel of Figure 1 shows the gradient vector field corresponding to the synthetic version controlled document described in the previous section. As expected, it tends to be orthogonal to the segment boundaries. Its magnitude is displayed by the contour lines which show highest magnitudes around segment boundaries.

Figure 2 shows the norm $\|\dot{\gamma}_s(s,t)\|^2$ (left), $\|\dot{\gamma}_t(s,t)\|^2$ (middle left) and the local maxima of $\|\dot{\gamma}_s(s,t)\|^2 + \|\dot{\gamma}_t(s,t)\|^2$ (middle right) for a portion of the version controlled Wikipedia Religion article. The first panel shows the amount of change in local word distribution within documents. High values correspond to boundaries between sections, topics or other document segments. The second panel shows the amount of change as one version is replaced with another. It shows which revisions change the word distributions substantially and which result in a relatively minor change. The third panel shows only the local maxima which correspond to edges between topics or segments (vertical lines) or revisions (horizontal lines).

4 Edge Detection

In many cases documents may be divided to semantically coherent segments. Examples of text segments include individual news stories in streaming broadcast news transcription, sections in article or books, and individual messages in a discussion board or an email trail. For non-version controlled documents finding the text segments is equivalent to finding the boundaries or edges between consecutive segments. See (Hearst, 1997; Beeferman et al., 1999; McCallum et al., 2000) for several recent studies in this area.

Things get a bit more complicated in the case of version controlled documents. Segments, and their boundaries exist in each version. As in case of image processing, we may view segment boundaries as edges in the space-time domain Ω. These boundaries separate the segments from each other, much like borders separate countries

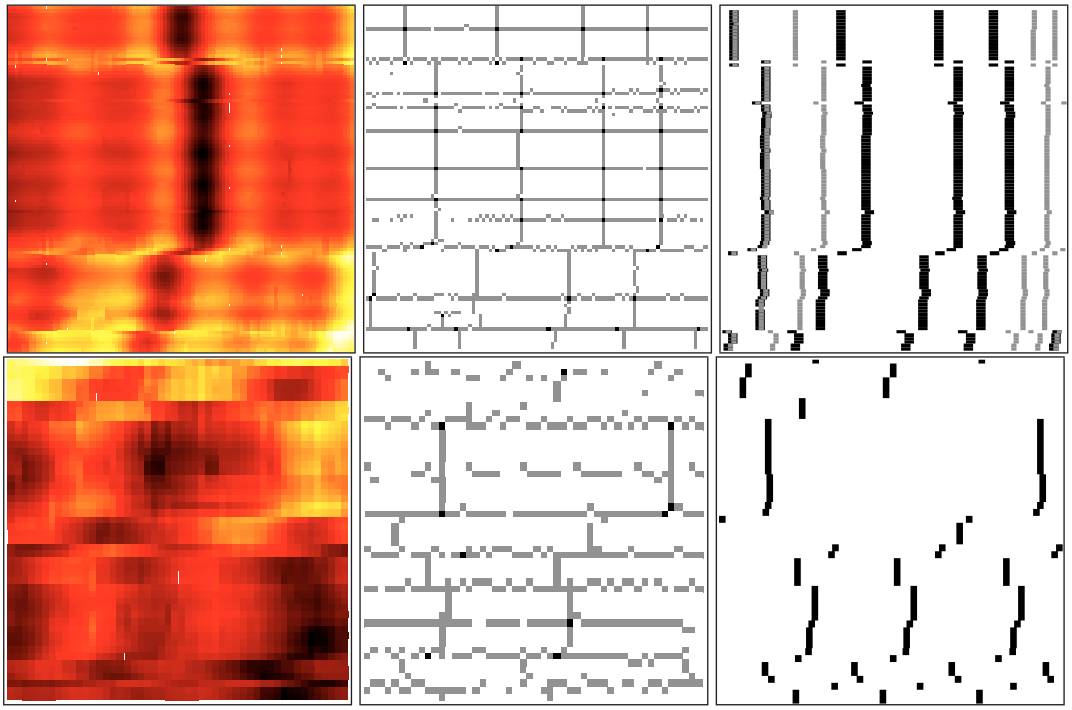

Figure 3: Gradient and edges of a portion of the version controlled Atlanta Wikipedia article (top row) and the Google Wave Amazon Kindle FAQ (bottom row). The left column displays the magnitude of the gradient in both space and time $\|\dot{\gamma}_s(s,t)\|^2 + \|\dot{\gamma}_t(s,t)\|$. The middle column displays the local maxima of the gradient magnitude (left column). The right column displays the actual segment boundaries as vertical lines (section headings for Wikipedia and author change in Google Wave). The gradient maxima corresponding to vertical lines in the middle column matches nicely the Wikipedia section boundaries. The gradient maxima corresponding to horizontal lines in the middle column correspond nicely to major revisions indicated by a discontinuities in the location of the section boundaries.

in a two dimensional geographical map.

Assuming all edges are correctly identified, we can easily identify the segments as the interior points of the closed boundaries. In general, however, attempts to identify segment boundaries or edges will only be partially successful. As a result predicted edges in practice are not closed and do not lead to interior segments. We consider now the task of predicting segment boundaries or edges in Ω and postpone the task of predicting a segmentation to the next section.

Edges, or transitions between segments, correspond to abrupt changes in the local word distribution. We thus characterize them as points in Ω having high gradient value. In particular, we distinguish between vertical edges (transitions across document positions), horizontal edges (transitions across versions), and diagonal edges (transitions across both document position and version). These three types of edges may be diagnosed based on the magnitudes of $\dot{\gamma}_s$, $\dot{\gamma}_t$, and $\dot{\alpha}_1\gamma_s + \dot{\alpha}_2\gamma_t$ respectively.

4.1 Experiments

Besides the synthetic data results in Figure 2, we conducted edge detection experiments on six different real world datasets. Five datasets are Wikipedia.com articles: Atlanta, Religion, Language, European Union, and Beijing. Religion and European Union are version controlled documents with relatively frequent updates, while Atlanta, language, and Beijing have less frequent changes. The sixth dataset is the Google Wave Amazon Kindle FAQ which is a less structured version controlled document.

Preprocessing included removing html tags and pictures, word stemming, stop-word removal, and removing any non alphabetic characters (numbers and punctuations). The section heading information of Wikipedia and the information of author of each posting in Google Wave is used as ground truth for segment boundaries. This information was separated from the dataset and was used for training and evaluation (on testing set).

Figure 3 displays a gradient information, local maxima, and ground truth segment boundaries for

Figure 4: Test set error rate and F1 measure for edge prediction (section boundaries in Wikipedia articles and author change in Google Wave). The space-time domain Ω was divided to a grid with each cell labeled edge ($y = 1$) or no edge ($y = 0$) depending on whether it contained any edges. Method a corresponds to a predictor that always selects the majority class. Method b corresponds to the TextTiling test segmentation algorithm (Hearst, 1997) without paragraph boundaries information. Method c corresponds to a logistic regression classifier whose feature set is composed of statistical summaries (mean, median, max, min) of $\dot{\gamma}_s(s,t)$ within the grid cell in question as well as neighboring cells.

the version controlled Wikipedia articles Religion and Atlanta. The local gradient maxima nicely match the segment boundaries which lead us to consider training a logistic regression classifier on a feature set composed of gradient value statistics (min, max, mean, median of $\|\dot{\gamma}_s(s,t)\|$ in the appropriate location as well as its neighbors (the space-time domain Ω was divided into a finite grid where each cell either contained an edge ($y = 1$) or did not ($y = 0$)). The table in Figure 4 displays the test set accuracy and F1 measure of three predictors: our logistic regression (method c) as well as two baselines: predicting edge/no-edge based on the marginal $p(y)$ distribution (method a) and TextTiling (method b) (Hearst, 1997) which is a popular text segmentation algorithm. Since we do not assume paragraph information in our experiment we ignored this component and considered the document as a sequence with $w = 20$ and 29 minimum depth gaps parameters (see (Hearst, 1997)). We conclude from the figure that the gradient information leads to better prediction than TextTiling (on both accuracy and F1 measure).

5 Segmentation

As mentioned in the previous section, predicting edges may not result in closed boundaries. It is possible to analyze the location and direction of the predicted edges and aggregate them into a sequence of closed boundaries surrounding the segments. We take a different approach and partition points in Ω to k distinct values or segments based on local word content and space-time proximity.

For two points $(s_1, t_2), (s_2, t_2) \in \Omega$ to be in the same segment we expect $\gamma(s_1, t_1)$ to be similar to $\gamma(s_2, t_2)$ and for (s_1, t_1) to be close to (s_2, t_2). The first condition asserts that the two locations discuss the same topic. The second condition asserts that the two locations are not too far from each other in the space time domain. More specifically, we propose to segment Ω by clustering its points based on the following geometry

$$d((s_1,t_1),(s_2,t_2)) = d_H(\gamma(s_1,t_1),\gamma(s_2,t_2)) + \sqrt{c_1(s_1-s_2)^2 + c_2(t_1-t_2)^2} \quad (9)$$

where $d_H : \mathbb{P}_V \times \mathbb{P}_V \to \mathbb{R}$ is Hellinger distance

$$d_H^2(u,v) = \sum_{i=1}^{V} (\sqrt{u_i} - \sqrt{v_i})^2. \quad (10)$$

The weights c_1, c_2 are used to balance the contributions of word content similarity with the similarity in time and space.

5.1 Experiments

Figure 5 displays the ground truth segment boundaries and the segmentation results obtained by applying k-means clustering ($k = 11$) to the metric (9). The figure shows that the predicted segments largely match actual edges in the documents even though no edge or gradient information was used in the segmentation process.

6 Predicting Future Operations

The fourth and final task is predicting a future revision d_{l+1} based on the smoothed representation of the present and past versions $d_1, \ldots, d_l$. In

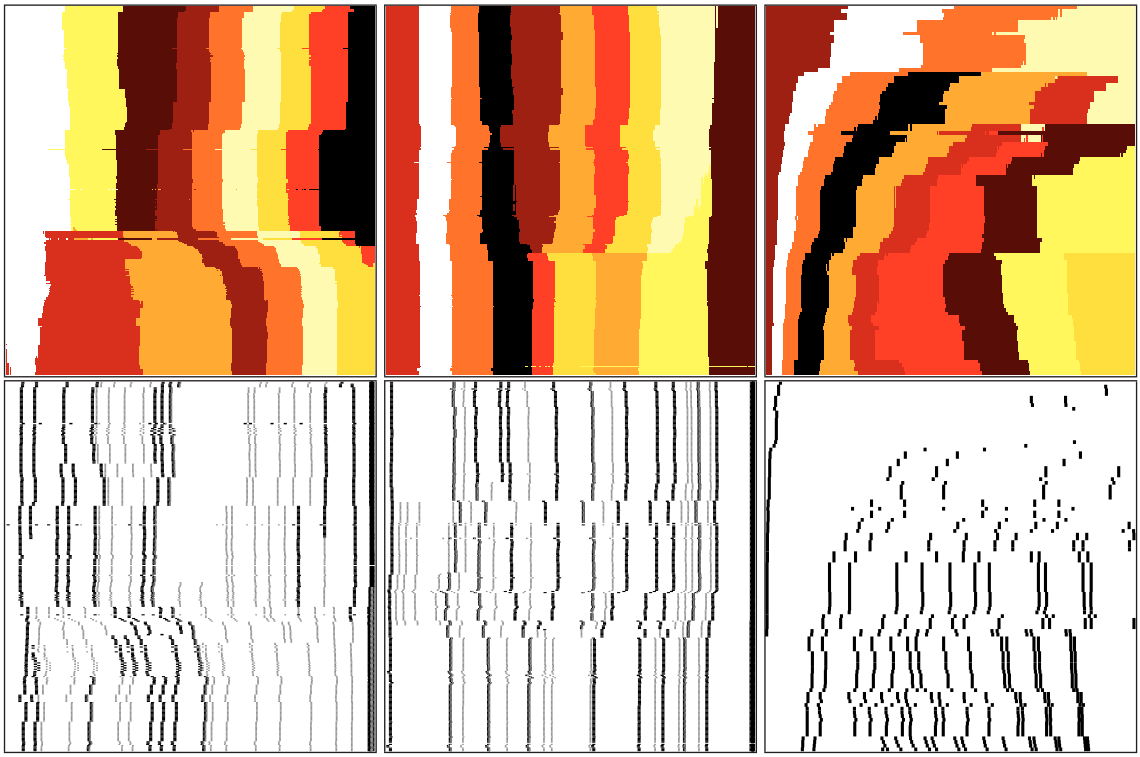

Figure 5: Predicted segmentation (top) and ground truth segment boundaries (bottom) of portions of the version controlled Wikipedia articles Religion (left), Atlanta (middle) and the Google Wave Amazon Kindle FAQ(right). The predicted segments match the ground truth segment boundaries. Note that the first 100 revisions are used in Google Wave result. The proportion of the segments that appeared in the beginning is keep decreasing while the revisions increases and new segments appears.

terms of Ω, this means predicting features associated with $\gamma(s,t), t \geq t'$ based on $\gamma(s,t), t < t'$.

6.1 Experiments

We concentrate on predicting whether Wikipedia edits are reversed in the next revision. This action, marked by a label UNDO or REVERT in the Wikipedia API, is important for preventing content abuse or removing immature content (by predicting ahead of time suspicious revisions).

We predict whether a version will undergo UNDO in the next version using a support vector machine based on statistical summaries (mean, median, min, max) of the following feature set $\|\dot{\gamma}_s(s,t)\|$, $\|\ddot{\gamma}_s(s,t)\|$, $\|\dot{\gamma}_t(s,t)\|$), $\|\dot{\gamma}_t(s,t)\|$, $g(h)$, and $h(s)$. Figure 6 shows the test set error and F1 measure for the logistic regression based on the smoothed space-time representation (method c), as well as two baselines. The first baseline (method a) predicts the majority class and the second baseline (method b) is a logistic regression based on the term frequency content of the current test version. Using the derivatives of γ, we obtain a prediction that is better than choosing majority class or logistic regression based on word content. We thus conclude that the derivatives above provide more useful information (resulting in lower error and higher F1) for predicting future operations than word content features.

7 Related Work

While document analysis is a very active research area, there has been relatively little work on examining version controlled documents. Our approach is the first to consider version controlled documents as continuous mappings from a space-time domain to the space of local word distributions. It extends the ideas in (Lebanon et al., 2007) of using kernel smoothing to create a continuous representation of documents. In fact, our framework generalizes (Lebanon et al., 2007) as it reverts to it in the case of a single revision.

Other approaches to sequential analysis of documents concentrate on discrete spaces and discrete models, with the possible extension of (Wang et al., 2009). Related papers on segmentation and sequential document analysis are (Hearst,

1997; Beeferman et al., 1999; McCallum et al., 2000) with (Hearst, 1997) being the closest in spirit to our approach. An influential model for topic modeling within and across documents is latent Dirichlet allocation (Blei et al., 2003; Blei and Lafferty, 2006). Our approach differs in being fully non-parametric and in that it does not require iterative parametric estimation or integration. The interpretation of local word smoothing as a non-parametric statistical estimator (Lebanon et al., 2007) may be extended to our paper in a straightforward manner.

Several attempts have been made to visualize themes and topics in documents, either by keeping track of the word distribution or by dimensionality reduction techniques e.g., (Fortuna et al., 2005; Havre et al., 2002; Spoerri, 1993; Thomas and Cook, 2005). Such studies tend to visualize a corpus of unrelated documents as opposed to ordered collections of revisions which we explore.

8 Summary and Discussion

The task of analyzing and visualizing version controlled document is an important one. It allows external control and monitoring of collaboratively authored resources such as Wikipedia, Google Wave, and CVS or SVN documents. Our framework is the first to develop analysis and visualization tools in this setting. It presents a new representation for version controlled documents that uses local smoothing to map a space-time domain Ω to the simplex of tf vectors $\mathbb{P}_V$. We demonstrate the applicability of the representation for four tasks: visualizing change, predicting edges, segmentation, and predicting future revision operations.

Visualizing changes may highlight significant structural changes for the benefit of users and help the collaborative authoring process. Improved edge prediction and text segmentation may assist in discovering structural or semantic changes and their evolution with the authoring process. Predicting future operation may assist authors as well as prevent abuse in coauthoring projects such as Wikipedia.

The experiments described in this paper were conducted on synthetic, Wikipedia and Google Wave articles. They show that the proposed formalism achieves good performance both qualitatively and quantitatively as compared to standard baseline algorithms.

It is intriguing to consider the similarity between our representation and image processing. Predicting segment boundaries are similar to edge detection in images. Segmenting version controlled documents may be reduced to image segmentation. Predicting future operations is similar to completing image parts based on the remaining pixels and a statistical model. Due to its long and successful history, image processing is a good candidate for providing useful tools for version controlled document analysis. Our framework facilitates this analogy and we believe is likely to result in novel models and analysis tools inspired by current image processing paradigms. A few potential examples are wavelet filtering, image compression, and statistical models such as Markov random fields.

A Logistic Regression Model of Determiner Omission in PPs

{tibor, kesselmeier, mueller, roch, stadtfeld, strunk}@linguistics.rub.de

Abstract

The realization of singular count nouns without an accompanying determiner inside a PP (determinerless PP, bare PP, Preposition-Noun Combination) has recently attracted some interest in computational linguistics. Yet, the relevant factors for determiner omission remain unclear, and conditions for determiner omission vary from language to language. We present a logistic regression model of determiner omission in German based on data obtained by applying annotation mining to a large, automatically and manually annotated corpus.

1 The problem and how to deal with it

Preposition-Noun Combinations (PNCs, sometimes called determinerless PPs or bare PPs) minimally consist of a preposition and a count noun in the singular that – despite requirements formulated elsewhere in the grammar of the respective language – appears without a determiner. The noun in a PNC can be extended through prenominal modification (1) and postnominal complementation (2). Still, a determiner is missing. The following examples are given from German.

(1) *auf parlamentarische Anfrage* ('after being asked in parliament'), *mit beladenem Rucksack* ('with loaded backpack'), *unter sanfter Androhung* ('under gentle threat')

(2) *Er wehrt sich gegen die Forderung nach* he defies REFL against the demand for *Stilllegung einer Verbrennungsanlage*. closedown an incineration plant
'He defies the demand for closing an incineration plant.'

PNCs occur in a wide range of languages (Himmelmann, 1998); the conditions for determiner omission, however, have not been detected yet, and conditions applying to one language do not carry over to other languages. In addition, speakers only reluctantly judge the acceptability of newly coined PNCs, so that reliance to introspective judgments cannot be assumed.

For English, Stvan (1998) and Baldwin et al. (2006) have claimed that either the semantics of the preposition or of the noun play a major role in determining whether a singular count noun may appear without a determiner in a PNC. Stvan (1998) assumes that nouns determine the well-formedness of PNCs (3) if the denotation of the noun occurs in a particular semantic field, while Baldwin et al. (2006) assume that certain prepositions impose selection restrictions on their nominal complements that allow for determiner omission (4).

(3) *from school, at school, in jail, from jail, …*

(4) *by train, by plane, by bus, by pogo stick, by hydro-foil …*

Interestingly, Le Bruyn et al. (2009) have observed that basic assumptions of Stvan's analysis do not apply to Dutch, French, or Norwegian. With regard to German, we observe that neither the pattern in (3) nor in (4) is productive. Constructions like (4) cannot be realized as PNCs in German, but require full PPs.

In the following, we propose an analysis of PNCs that combines corpus annotation, annotation mining (Chiarcos et al., 2008), and logistic regression modeling (Harrell, 2001). Annotation mining assumes that linguistically relevant generalizations can be derived in a bottom-up fashion from a suitably annotated corpus. Relevant hits in the corpus are mapped into a feature vector that serves as input for logistic regression classification. In the present case, the input con-

Coling 2008: Poster Volume, pages 561–569,
Beijing, August 2010

sists of sentences containing either PNCs or PPs. Binary logistic regression suggests itself as a classification method since the problem of PNCs can be rephrased as the following question: Under which conditions can an otherwise obligatory determiner be omitted?

The majority of required annotations can be derived automatically, but there are no available systems for the automatic determination of preposition senses in German, so preposition sense annotation has to be carried out manually and requires a language-specific tagset for preposition senses.

While our initial analysis is based on German data, the general methodology can be applied to other languages, provided that corpora receive proper annotation.

2 Corpus annotation

2.1 General characteristics

The present analysis is based on a newspaper corpus of the Swiss-German newspaper *Neue Zürcher Zeitung* from 1993 to 1999, comprising approx. 230 million words. The annotation is based on an XML-stand-off format. MMAX2 (Müller and Strube, 2006) is used for manual annotation. Annotations are carried out both for PNCs and for full-fledged PPs. For each preposition, the following data is considered: PNCs, where N is a count noun; corresponding PPs with the same count noun; and PPs containing count nouns not appearing inside PNCs.

The following annotations are provided for each dataset in the corpus:

Lexical level: part-of-speech, inflectional morphology, derivational morphology of nouns, count/mass distinction of nouns, interpretation of nouns, interpretation of prepositions, noun compounding.

Syntactic level: mode of embedding of the phrase (adjunct or complement), syntactic dependents of the noun, modification of the noun.

Global level: Is the phrase contained in a headline, title, or quotation? Is the phrase idiomatic? Headlines, titles, and quotations are particularly prone to text truncation and PNCs occurring here might not be the result of syntactic operations. Similarly, idiomatic PNCs *and* PPs might follow combination rules that differ from the general modes of combination. Hence, the annotations may serve to exclude these cases from general classification.

2.2 Automatic annotation

The following tools are employed for automatic annotation: Regression Forest Tagger (Schmid and Laws, 2008) for POS tagging and morphological analysis (the tagger contains the SMOR component for morphological analysis, cf. Schmid, 2004), and Tree Tagger (Schmid, 1995) for chunk parsing.

To determine noun meanings, we make use of two resources. The first resource is GermaNet (Kunze and Lemnitzer, 2002), the German version of WordNet. We employ 23 top-level categories, and each noun is annotated with every top-level category it belongs to.[1] Secondly, we use the computer lexicon HaGenLex (Hartrumpf et al., 2003), which offers specific sortal information derived from a formal ontology for each noun. Finally, we employ a classifier for the count/mass distinction. The classifier combines lexical statistics, expressed in terms of a decision tree classifier, with contextual information, which is handled by Naïve Bayes classification (cf. Stadtfeld 2010). The classification is based on the fine-grained distinctions first introduced in Allan (1980), but we employ a reduced set of five instead of eight classes. The classifier is type-based as it makes use of the relation between singular and plural realizations of noun lemmas, but takes the immediate context of the lemma into account.

Nouns are only assigned to a particular class if both classifiers come to the same result w.r.t. this class assignment. While this leads to some nouns being excluded from the count/mass distinction, the resulting classes show a high degree of precision.

2.3 Manual annotation of preposition senses

Prepositions are highly polysemous. What is more, the relation between a preposition and its senses has to be determined in a language-

[1] Nouns that are assigned to more than one top-level category are presumably homonymous or polysemous. We do not disambiguate the nouns. The reason is that individual features will be evaluated for their effect in a logistic model, and an ambiguous noun will receive a value in each feature. Hence, we can be sure that a significant semantic feature will be included in the classification.

specific manner. While the *Preposition Project* forms a basis for preposition sense annotation in English (cf. Litkowski and Hargraves 2005, 2007), little attention has been paid to specialized annotation schemata for preposition senses in German, which form the first prerequisite for a classification of preposition senses.

Based on four usage-based grammars and dictionaries of German (Duden 2002, Helbig and Buscha 2001, Durrell and Brée 1993, Schröder 1986), we have developed an annotation schema with a hierarchical structure, allowing for subtrees of preposition senses that require a fine-grained classification (such as TEMPORAL, SPATIAL, CAUSAL, and PRESENCE). For temporal and spatial interpretations, the annotation is further facilitated by the use of decision trees.[2]

Altogether, the annotation schema includes the following list of top-level categories: MODAL, CAUSAL, PRESENCE, SPATIAL, TEMPORAL, STATE, COMITATIVE, AGENT, REDUCTION/EXTENSION, PARTICIPATION, SUBORDINATION, RECIPIENT, AFFILIATION, CORRELATION/INTERACTION, TRANSGRESSION, ORDER, THEME, SUBSTITUTE, EXCHANGE, COMPARISON, RESTRICTIVE, COPULATIVE, ADVERSATIVE, DISTRIBUTIVE, STATEMENT/OPINION, CENTRE OF REFERENCE, and REALISATION.

Based on an extension of the weighted kappa statistic we have reached an overall kappa value (κ_w) of 0.657 and values between 0.551 and 0.860 for individual features (cf. Müller et al. 2010a). Two properties of the annotation schema prohibit the application of a standard kappa statistic: First, the schema allows subsorts, and secondly, a preposition may receive more than one annotation if its sense cannot be fully disambiguated. The values reported in Müller et al. (2010) for maximal subtypes such as SPATIAL (κ_w = 0.709) and TEMPORAL (κ_w = 0.860) can be equated to aggregate values in standard kappa statistics.

In the models presented below, we employ top-level categories only and have aggregated more specific sense annotations.

[2] The schema does not directly distinguish between local and directional senses, but makes use of cross-classification to deal with the distinction. Cf. Müller et al. (2010b).

3 Preparing logistic regression models for *ohne* ('without') and *unter* ('under', 'below')

The problem of PNCs, i.e. why a determiner is omitted in a construction which otherwise requires the realization of the determiner, can be rephrased as a problem for binary logistic regression and classification.

While binary logistic regression does not prohibit monocausal explanations, typical models for binary logistic regression employ more than one factor, and the value of the coefficients models the relative influence of the individual factors. Logistic regression thus does not only help to identify factors for determiner omission, but also reveals the interplay of multiple licensing conditions – thus possibly accounting for the relative difficulty to distinguish acceptable from inacceptable PNCs.

We are aiming at a description of PNCs in German for the 22 prepositions listed in (5).

(5) *an, auf, bei, dank, durch, für, gegen, gemäß, hinter, in, mit, mittels, nach, neben, ohne, seit, über, um, unter, vor, während, wegen*

These prepositions have been chosen on the basis of the following two assumptions: a) they appear in PNCs and PPs, and b) their 'typical' object is an NP.

We present logistic regression models of determiner realization for two prepositions: *ohne* ('without') and *unter* ('under', 'below'). The first preposition, *ohne,* is the only preposition that appears more often in PNCs than in PPs. The second preposition, *unter,* belongs to the class of highly polysemous prepositions. In fact, it is the preposition with the second largest number of senses (10 senses), only surpassed by *mit* ('with') (11 senses), which however appears much more often than *unter* in the corpus and thus requires further annotation. The following table summarizes the distribution of PNCs and PPs for both prepositions, after tokens that had been annotated as belonging to *headlines, quotations, telegram style sentences,* or as being idiomatic were excluded from the data. With regard to the first group (headlines etc.), the elimination mostly applies to PNCs, but among the PPs we found many idiomatic expressions and fixed phrases, which have also been excluded from modeling.

Preposition	Σ	PP	PNC
ohne	3,750	591	3,159
unter	5,181	4,334	857

Table 1. Data Distribution of PNCs and PPs

The analysis has been carried out in R (R Development Core Team, 2010) and makes extensive use of Harrell's DESIGN package (Harrell, 2001).

The feature vector consists of the dependent variable – the factor DET with its levels *no* and *yes* – and of relevant classificatory features representing the interpretation of the preposition (in terms of the features presented in section 2), the internal syntactic structure of the nominal projection (prenominal modification of N, syntactic arguments of N, internal structure of N as a compound, derivational status of N), the external syntactic embedding of the PNC or PP, and the interpretation of the noun.

Features starting with DEP signify syntactic arguments of the noun (DEP-S a sentential complement, DEP-NP an NP complement, etc.); the feature ADJA signifies the presence of one or more modifying adjectives; the feature COMPOUND indicates whether the noun in question is a compound. The feature GOVERNED indicates whether a noun or a verb governs the phrase. The feature NOMINALIZATION provides information about the derivational structure of the noun, in particular it indicates whether a noun is derived from a verb by use of the suffix *–ung*.

Features starting with GN are GermaNet top-level categories, features starting with HL are HaGenLex ontological sorts; both describe the interpretation of the noun.

The statistical modeling started with the assumption that each feature is relevant, so that an initial feature set of 92 features was considered. Feature elimination took place through *fast backwards elimination* (Lawless and Singhal, 1978) and manual inspection. The results of fast backwards elimination were not followed blindly. Following Harrell's (2001:56) suggestion, we have kept factors despite their low significance levels. In most cases, however, manual inspection and fast backwards elimination suggested the same results. The resulting models were subjected to *bootstrap validation* to identify possible overfitting (cf. section 5.1).

The value DET = *no* is taken to be the default value in the following models. As a consequence, negative values for coefficients indicate rising probability for an omission of a determiner, while positive coefficients shift odds in favor of a realization of the determiner.

4 Logistic models for the omission of a determiner with *ohne* and *unter*

The logistic regression models developed for the prepositions *ohne* and *unter* make use of 13 and 22 features, respectively. In each case, we have started with a full model fit (Harrell, 2001:58f.), evaluated the full model and eliminated factors through manual inspection and fast backwards elimination. The coefficients for the models for *ohne* and *unter* are reported in tables 2 and 3.

Table 3. Coefficients for a logistic model of determiner omission with *unter.*

General measures of the two models are reported in table 4. Somers' D_{xy} describes the proportion of observations, for which the model provides an appropriate class probability. D_{xy} can be derived from C, the corresponding receiver operating characteristic curve area, since $D_{xy} = 2 \times (C–0.5)$. Model L.R. (likelihood ratio) indicates the improvement reached by including the predictors. Degrees of freedom (d.f.) have been omitted from table 4, as they correspond to the number of predictors, i.e. 12 in the case of *ohne* and 23 in the case of *unter*. The high figures for Somers' D_{xy} are reassuring.

	Model L.R.	p	C	D_{xy}
ohne	1,063.5	0	0.876	0.753
unter	2,245.6	0	0.937	0.874

Table 4. Model Quality.

4.1 The model for *ohne*

Starting with the model in table 2, we can identify several groups of factors:

The first group comprises the interpretation of the preposition. The group discriminates between determiner omission and realization. The semantic features CAUSAL, COMITATIVE, and PARTICIPATION show positive coefficients, suggesting that prepositions receiving the aforementioned interpretations tend to favor an 'ordinary' NP including a determiner. The interpretation PRESENCE, on the other hand, shows a negative coefficient and thus suggests the omission of a determiner. There are further senses of *ohne,* which do not have a significant effect on determiner omission/realization.

Turning to the representation of syntactic argument structure of the noun, we find that the coefficients of DEP-S, DEP-NP, and DEP-PP receive positive values throughout. The presence of syntactic complements thus shifts odds in favor of determiner realization. There is a strong preference against determiner omission with DEP-S, and somewhat weaker values for Dep-NP and Dep-PP, respectively. A comparison of interpretation and complement realization offers a general assessment of PNCs. As *ohne* and *unter* share only a few senses, we do not necessarily expect that the discerning senses relevant for a realization of a PNC with *ohne* carry over to *unter;* but we do expect that features pertaining to the syntactic structure of the nominal complement play a role not only for *ohne,* but for *unter* (or for prepositions admitting PNCs in general) as well. And this prediction is actually borne out in the model for *unter.* The model thus already offers interesting insights not only w.r.t. the realization conditions of PNCs and PPs headed by *ohne,* but for broader analyses of PNCs as well.

We will return to the role and value of the features ADJA and NOMINALIZATION in section 4.3.

The last group comprises the semantic characteristics of nouns derived from GermaNet. If a noun is classified as belonging to the relevant GermaNet top-level categories, determiner omission is favored.

4.2 The model for *unter*

A first glance at the model for *unter* shows that it requires a larger set of predictors than the model for *ohne.* In part, this is due to the higher degree of polysemy of *unter:* with more senses, we expect more semantic predictors to enter the discrimination. In addition, a wider range of senses

also allows for a wider range of selection restrictions, and hence for a larger number of different sortal specifications for selected nouns. The higher complexity of the model, however, should not conceal a peculiarity of this model that casts serious doubt on the idea that PNCs are monocausally licensed by particular senses of a preposition: the model selects five senses from the ten top level interpretations of *unter,* but the coefficients are unsigned. Thus, the model indicates that the senses SPATIAL, CAUSAL, SUBORDINATION, ORDER, and TRANSGRESSION *block* the omission of a determiner. What we do not find are senses that favor the omission of a determiner.

The features DEP-S, DEP-NP, and DEP-PP again favor the realization of a determiner. A comparison of the coefficient of DEP-S to the coefficients of DEP-NP and DEP-PP shows, however, that the presence of a sentential complement has a strong influence on determiner realization, while NP- and PP-complements may still occur in PNCs, as their coefficients are relatively low (also in comparison to the coefficients of these values for *ohne).*[4]

In more general terms, we suspect a general mechanism relating sentential complementation to the realization of the determiner, a topic to be addressed in future research.

It should also be noted that the external syntactic realization of the phrase plays a role for *unter.* The feature GOVERNED did not play a role for *ohne,* but suggests the realization of a determiner for *unter.* The reason might be that few verbs or nouns govern the preposition *ohne*. Prepositional objects headed by *unter,* however, are more common. Prepositional objects headed by *ohne* make up only 1.2 % of the occurrences of *ohne* in the present corpus, while the share of prepositional objects headed by *unter* is three times larger: 3.6 %.

Finally, we note that a variety of sortal classifications for nouns suggest either an omission or realization of the determiner, supporting the assumption that in addition to the preposition's meaning, the meaning of the noun plays a role. GermaNet top-level categories were already discriminating in the model for *ohne;* but the model for *unter* also makes use of HaGenLex sortal categories (HL-AD and HL-AS). The predictors stand for dynamic and static concepts that both receive an abstract interpretation. Their inclusion is particularly interesting, as it is sometimes claimed (e.g. Bale and Barner, 2009) that 'abstract' nouns are never to be classified as count nouns.

4.3 General assessment of the models

Both models show that the realization of syntactic complements, of sentential complements in particular, seems to impede determiner omission. That syntactic complexity does not seem to play a role per se, can be deduced from the coefficients for the factor ADJA: While ADJA favors determiner realization with *ohne,* it prohibits determiner realization with *unter.*

The role of morphological derivation through *–ung,* as represented by the factor NOMINALIZATION, is the same in both models: derived nominals shift odds in favor of determiner omission. While the derivational structure might be considered a formal property of the construction, it might also reflect an underlying denotational distinction between events and objects, which has to be clarified in future work.

It is a striking feature of the model for *unter that* we do not find interpretational features of the preposition *unter* that favor determiner omission. Taken together with the other factors in the two models presented, the analysis suggests a picture rather different from the (more or less) monocausal analyses of Stvan (1998) and Baldwin et al. (2006). With regard to *unter* a model in the sense of Baldwin et al. (2006) could only provide negative rules of the form *"if P does not mean this, its nominal complement may be realized without a determiner",* but such a model would lead to less precision than the multicausal model presented here.

5 Validation of the models

5.1 Bootstrap validation

Logistic regression models may suffer from overfitting the data. We have thus carried out a

[4] One could argue against the inclusion of the coefficient for DEP-PP altogether, as it does not seem to be significant ($p > 0.05$) in the first place. However, we have followed Harrell's (2001) advice that blind exclusion of seemingly insignificant factors may not lead to model improvement. In fact, models for *unter* including Dep-PP outperform models excluding this feature.

bootstrap validation of both models and applied penalized maximum likelihood estimation (Harrell, 2001) to the models. The results of the initial (non-penalized) models are reported in Table 5 and Table 6, where we report values for D_{xy} and the average maximal error of the model. Bootstrap validation makes use of sampling with replacement. The training samples for evaluation thus may contain certain instances many times, but some original data will never be sampled and can thus be used for testing the models. Bootstrap validation is carried out 200 times, the results being averaged. The overfitting of the models is determined by the optimism derived from the bootstrap evaluation.

	D_{xy}	E_{max}
Original Index	0.7525	0.0000
Training	0.7578	0.0000
Test	0.7497	0.0123
Optimism	0.0080	0.0123
Corrected Index	0.7445	0.0123

Table 5. Bootstrap validation of model for *ohne.*[5]

5.2 Representing the influence of factors in a nomogram

The respective influence of individual factors can be read of a nomogram (Banks, 1985) derived from the models presented above (we make use of a tabular presentation for reasons of legibility). The nomogram for *ohne* consists of the tables 9 and 10. Table 9 lists the individual scores for the factors in the model for *ohne,* were 0 indicates that the pertinent property is not present and 1 indicates that the property is present. Table 10 maps the sum to probability of determiner omission.

Predictor	**0**	**1**
NOMINALIZATION	27	0
ADJA	0	22
CAUSAL	0	24
COMITATIVE	0	45
PARTICIPATION	0	67
PRESENCE	15	0
DEP-S	0	100
DEP-NP	0	59
DEP-PP	0	43
GN-RELATION	20	0
GN-ATTRIBUTE	27	0
GN-EVENT	17	0
GN-ARTEFACT	8	0

Table 9. Nomogram: individual scores of predictors for *ohne.*

Total Points	**Pr("Omission of Det")**
118	0.9
134	0.8
144	0.7
153	0.6

161	0.5
169	0.4
178	0.3
188	0.2
204	0.1

Table 10. Nomogram: mapping from total points to probability of determiner omission.

As an illustration, consider pairs of *ohne* and a noun with the values in (6) and (7).

(6) NOMINALIZATION = 1, ADJA = 1, COMITATIVE = 1, all other senses including PRESENCE = 0, all GN features = 0, DEP features = 0.

(7) NOMINALIZATION = 0, ADJA = 1, PRESENCE = 1, all other senses = 0, GN-ATTRIBUTE = 1, all other GN features = 0, DEP features = 0.

Given the individual scores for the factors in table 9, the total number of points for the combination in (6) is 144, leading to a probability of 0.7 that a determiner will be omitted in the construction. In other words, a determiner omission is likely with the feature set given in (6). In (7), we reach a total of 92 only, so that the likelihood of determiner omission rises above 0.9.

6 Summary and prospects

The models presented support the general assumption that the realization or omission of a determiner in a prepositional phrase should be analyzed as a multicausal phenomenon. The logistic regression analysis presents evidence for the assumption that the senses of the preposition and the interpretation of the noun (possibly governed by selection restrictions of the preposition) as well as the syntactic complexity of the embedded nominal projection are major factors in determining whether an article can be dropped or not.

With regard to the complexity of the nominal projection, the two models presented here indicate that it is not complexity per se, but that the realization of a complement of the noun, in particular of a sentential complement, clearly raises the probability of article realization. While this is a speculation, based on the models presented here, it might very well be that this dependency reflects a deeper referential requirement.

In developing further models for prepositions, we expect that the realization of a complement of the noun will establish itself as a common factor, but this has to await further research and model development.

Using Syntactic and Semantic based Relations for Dialogue Act Recognition

Tina Klüwer, Hans Uszkoreit, Feiyu Xu
Deutsches Forschungszentrum für Künstliche Intelligenz (DFKI)
Projektbüro Berlin
{tina.kluewer,uszkoreit,feiyu}@dfki.de

Abstract

This paper presents a novel approach to dialogue act recognition employing multi-level information features. In addition to features such as context information and words in the utterances, the recognition task utilizes syntactic and semantic relations acquired by information extraction methods. These features are utilized by a Bayesian network classifier for our dialogue act recognition. The evaluation results show a clear improvement from the accuracy of the baseline (only with word features) with 61.9% to an accuracy of 67.4% achieved by the extended feature set.

1 Introduction

Dialogue act recognition is an essential task for dialogue systems. Automatic dialogue act classification has received much attention in the past years either as an independent task or as an embedded component in dialogue systems. Various methods have been tested on different corpora using several dialogue act classes and information coming from the user input.

The work presented in this paper is part of a dialogue system called *KomParse* (Klüwer et al., 2010), which is an application of a NL dialogue system combined with various question answering technologies in a three-dimensional virtual world named *Twinity*, a web-based online product of the Berlin startup company *Metaversum*[1]. The KomParse NPCs provide various services through conversation with game users such as selling pieces of furniture to users via text based conversation.

The main task of the input interpretation component of the agent is the detection of the dialogue acts contained in the user utterances. This classification is done via a cue-based method with various features from multi-level knowledge sources extracted from the incoming utterance considering a small context of the previous dialogue.

In contrast to existing systems using mainly lexical features, i.e. words, single markers such as punctuation (Verbree et al.,) or combinations of various features (Stolcke et al., 2000) for the dialogue act classification, the results of the interpretation component presented in this paper are based on syntactic and semantic relations. The system first gathers linguistic information coming from different levels of deep linguistic processing similar to (Allen et al., 2007). The retrieved information is used as input for an information extraction component that delivers the relations embedded in the actual utterance (Xu et al., 2007). These relations combined with additional features (a small dialogue context and mood of the sentence) are then utilized as features for the machine-learning based recognition.

The classifier is trained on a corpus originating from a Wizard-of-Oz experiment which was semi-automatically annotated. It contains automatically annotated syntactic relations namely, predicate argument structures, which were checked and corrected manually afterwards. Furthermore these relations are enriched by manual annotation with semantic frame information from VerbNet to gain an additional level of semantic richness. These two representations of relations, the syntax-based re-

[1] http://www.metaversum.com/

Coling 2008: Poster Volume, pages 570–578,
Beijing, August 2010

lations and the VerbNet semantic relations, were used in separate training steps to detect how much the classifier can benefit from either notations.

A systematic analysis of the data has been conducted. It turns out that a comparatively small set of syntactic relations cover most utterances, which can moreover be expressed by an even smaller set of semantic relations. Because of this observation as well as the overall performance of the classifier the interpretation is extended with an additional rule based approach to ensure the robustness of the system.

The paper is organized as follows: Section 2 provides an overview about existing dialogue act recognition systems and the features they use for classification.
Section 3 introduces the original data used as basis for the annotation and the classification task.
In Section 4 the annotation that provides the necessary information for the dialogue act classification and involves the relation extraction is described in detail. The annotation is split into three main steps: The annotation of dialogue information (section 4.1), the integration of syntactic information (section 4.2) and finally the manual annotation of VerbNet predicate and role information in section 4.3.
Section 5 presents the results of the actual classification task using different feature sets and in Section 6 the results and methods are summarized.
Finally, Section 7 provides a brief description of the rule-based interpretation and presents an outlook on future work.

2 Related Work

Dialogue Acts (DAs) represent the functional level of a speaker's utterance, such as a greeting, a request or a statement. Dialogue acts are verbal or nonverbal actions that incorporate participant's intentions originating from the theory of Speech Acts by Searle and Austin (Searle, 1969). They provide an abstraction from the original input by detecting the intended action of an utterance, which is not necessarily inferable from the surface input (see the two requests in the following example).

Can you show me a red car please?

Please show me a red car!

To detect the action included in an utterance, different approaches have been suggested in recent years which can be clustered into two main classes: The first class uses AI planning methods to detect the intention of the utterance based on belief states of the communicating agents and the world knowledge. These systems are often part of an entire dialogue system e.g. in a conversational agent which provides the necessary information about current beliefs and goals of the conversation participants at runtime. One example is the TRIPS system (Allen et al., 1996). Because of the huge amount of reasoning, systems in this class generally gather as much linguistic information as possible.

The second class uses cues derived from the actual utterance to detect the right dialogue act, mostly using machine learning methods. This class gained much attention due to less computational costs. The probabilistic classifications are carried out via training on labeled examples of dialogue acts described by different feature sets. Frequently used cues for dialogue acts are lexical features such as the words of the utterance or ngrams of words for example in (Verbree et al.,), (Zimmermann et al., 2005) or (Webb and Liu, 2008). Although the performance of the classification task is difficult to compare, because of the variety of different corpora, dialogue act sets and algorithms used, these approaches do provide considerably good results. For example (Verbree et al.,) achieve accuracy values of 89% on the ICSI Meeting Corpus containing 80.000 utterances with a dialogue act set of 5 distinct dialogue act classes and amongst others the features "ngrams of words" and "ngrams of POS information".

Another group of systems utilizes acoustic features derived from Automatic Speech Recognition for automatic dialogue act tagging (Surendran and Levow, 2006), context features like the preceding dialogue act or ngrams of previous dialogue acts (Keizer and Akker, 2006).

However grammatical and semantic information is not that often incorporated into feature sets, with the exception of single features such as the

Dialogue Act	Meaning	Frequency
REQUEST	The utterance contains a wish or demand	449
REQUEST_INFO	The utterance contains a wish or demand regarding information	154
PROPOSE	The utterance serves as suggestion or showing of an object	216
ACCEPT	The utterance contains an affirmation	167
REJECT	The utterance contains a rejection	88
PROVIDE_INFO	The utterance provides an information	156
ACKNOWLEDGE	The utterance is a backchannelling	9

Table 1: The used Dialogue Act Set

type of verbs or arguments or the presence or absence of special operators e.g. wh-phrases (Andernach, 1996). (Keizer et al., 2002) use among others linguistic features like sentence type for classification with Bayesian networks. Although (Jurafsky et al., 1998) already noticed a strong correlation between selected dialogue acts and special grammatical structures, approaches using grammatical structure were not very succesful.

While grammatical and semantic features are not often incorporated into dialogue act recognition, they are a commonly used in related fields like automatic classification of rhetorical relations. For example (Sporleder and Lascarides, 2008) and (Lapata and Lascarides, 2004) extract verbs as well as their temporal features derived from parsing to infer sentence internal temporal and rhetorical relations. Their best model for analysing temporal relations between two clauses achieves 70.7% accuracy. (Subba and Eugenio, 2009) also show a significant improvement of a discourse relation classifier incorporating compositional semantics compared to a model without semantic features. Their VerbNet based frame semantics yield in a better result of 4.5%.

3 The Data

The data serving as the basis for the relation identification as well as the training corpus for the dialogue act classifier is taken from a Wizard-of-Oz experiment (Bertomeu and Benz, 2009) in which 18 users furnish a virtual living room with the help of a furniture sales agent. Users buy pieces of furniture and room decoration from the agent by describing their demands and preferences in a text chat. During the dialogue with the agent, the preferred objects are then selected and directly put to the right location in the apartment. In the experiments, users spent one hour each on furnishing the living room by talking to a human wizard controlling the virtual sales agent. The final corpus consists of 18 dialogues containing 3,171 turns with 4,313 utterances and 23,015 alpha-numerical strings (words). The following example shows a typical part of such a conversation:

USR.1: And do we have a little side table for the TV?
NPC.1: I could offer you another small table or a sideboard.
USR.2: Then I'll take a sideboard that is similar to my shelf.
NPC.2: Let me check if we have something like that.

Table 2: Example Conversation from the Wizard-of-Oz Experiment

4 Annotation

The annotation of the corpus is carried out in several steps.

4.1 Pragmatic Annotation

The first annotation step consists of annotating discourse and pragmatic information including dialogue acts, projects according to (Clark, 1996), sentence mood, the topic of the conversation and an automatically retrieved information state for every turn of the conversations. From the annotated information the following elements were selected as features in the final recognition system:

- The dialogue acts which carry the intentions of the actual utterance as well as the last preceding dialogue act. The set used for annotation is a domain specific set containing the dialogue acts shown in table 1.
- The sentence mood. Sentence mood was annotated with one of the following values: declarative, imperative, interrogative.

- The topic of the utterance. The topic value is coreferent with the currently discussed object. Topic can consist of an object class (e.g. sofa) or an special object instance (sofa_1836). The topic of the directly preceding utterance was chosen as a feature too.

4.2 Annotation with Predicate Argument Structure

The second annotation step, applied to the utterance level of the input, automatically enriches the annotation with predicate argument structures. Each utterance is parsed with a predicate argument parser and annotated with syntactic relations organized according to PropBank (Palmer et al., 2005) containing the following features: Predicate, Subject, Objects, Negation, Modifiers, Copula Complements.

A single relation mainly consists of a predicate and the belonging arguments. Verb modifiers like attached PPs are classified as "argM" together with negation ("argM_neg") and modal verbs ("argM_modal"). Arguments are labeled with numbers according to the found information for the actual structure. PropBank is organized in two layers, the first one being an underspecified representation of a sentence with numbered arguments, the second one containing fine-grained information about the semantic frames for the predicate comparable to FrameNet (Baker et al., 1998). While the information in the second layer is stable for each verb, the values of the numbered arguments can change from verb to verb. While for one verb the "arg0" may refer to the subject of the verb, another verb may encapsulate a direct object behind the same notation "arg0". This is very complicated to handle in a computational setup, which needs continuous labeling for the successive components. Therefore the arguments were in general named as in PropBank but consistently numbered by syntactic structure. This means for example that the subject is always labeled as "arg1".

Consider the example "Can you put posters or pictures on the wall?". The syntactic relation will yield in the following representation:

```
<predicate: put>
<ArgM_modal: can>
<Arg1: you>
<Arg2: posters or pictures>
<ArgM: on the wall>
```

Predicate Argument Structure Parser The syntactic predicate argument structure that constitutes the syntactic relations and serves as basis for the VerbNet annotation, is automatically retrieved by a rule-based predicate argument parser. The rules utilized by the parser describe subtrees of dependency structures in XML by means of relevant grammatical functions. For detecting verbs with two arguments in the input, for instance, a rule can be written describing the dependency structure for a verb with a subject and an object. This rule would then detect every occurrence of the structure "Verb-Subj-Obj" in a dependency tree. This sample rule would express the following constraints: The matrix unit should be of the part of speech "Verb" , The structure belonging to this verb must contain a "nsubj" dependency and an "obj" dependency.

The rules deliver raw predicate argument structures, in which the detected arguments and the verb serve as hooks for further information lookup in the input. If a verb fulfills all requirements described by the rule, in a second step all modificational arguments existing in the structure are recursively acquired. The same is done for modal arguments as well as modifiers of the arguments such as determiners, adjectives or embedded prepositions. After the generation of the main predicate argument structure from the grammatical functions, the last step inserts the content values present in the actual input into the structure to get the syntactic relations for the utterance.

Before the input can be parsed with the predicate argument parser, some preprocessing steps of the corpus are needed. These include:

Input Cleaning The input data coming from the users contain many errors. Some string substitutions as well as the external Google spellchecker were applied to the input before any further processing.

Segmentation For clausal separation we apply a simple segmentation via heuristics based on punctuation.

POS Tagging Then the input is processed by

the external part-of-speech tagger TreeTagger (Schmid, 1994).

The embedded dependency parser is the Stanford Dependency Parser (de Marneffe and Manning, 2008), but other dependency parsers could be employed instead. The predicate argument parser is an standalone software and can be used either as a system component or for batch processing of a text corpus.

4.3 VerbNet Frame Annotation

The last step of annotation consists of the manual annotation of semantic predicate classes and semantic roles. Moreover, the automatically determined syntactic relations are checked and corrected if possible. VerbNet (Schuler, 2005) is utilized as a source for semantic information. The VerbNet role set consists of 21 general roles used in all VerbNet classes. Examples of roles in this general role set are “agent”, “patient” and “theme”.

For the manual addition of the semantic frame information a web-based annotation tool has been developed. The annotation tool shows the utterance which should be annotated in the context of the dialogue including the information from the preceding annotation steps. All VerbNet classes containing the current predicate are listed as possibilities for the predicate classification together with their syntactic frames. The annotators can select the appropriate predicate class and frame according to the arguments found in the utterance. If an argument is missing in the input that is required in the selected frame a null argument is added to the structure. If the right predicate class is existing, but the predicate is not yet a member of the class, it is added to the VerbNet files. In case the right predicate class is found but the fitting frame is missing, the frame is added to the VerbNet files. Thus during annotation 35 new members have been added to the existing VerbNet classes, 4 Frames and 4 new subclasses. Via these modifications, a version of VerbNet has been developed that can be regarded as a domain-specific VerbNet for the sales domain.

During the predicate classification, the annotators also assign the appropriate semantic roles to the arguments belonging to the selected predicate. The semantic roles are taken from the selected VerbNet frame.

From the annotated semantic structure, semantic relations are inferred such as the one in the following example:

```
<predicate: put-3.1>
<agent: you>
<theme: posters or pictures>
<destination: on the wall>
```

5 Dialogue Act Recognition

Two datasets are derived from the corpus: The dataset containing the utterances of the users (CST) and one dataset containing the utterances of the wizard (NPC), whereas the NPC corpus is cleaned from the “protocol sentences”. Protocol sentences are canned sentences the wizard used in every conversation, for example to initialize the dialogue. For the experiments, the two single datasets “NPC” and “CST” as well as a combined dataset called “ALL” are used. Unfortunately from the original 4,313 utterances in total, many utterances could not be used for the final experiments. First, fragments are removed and only the utterances found by the parser to contain a valid predicate argument structure are used. After protocol sentences are taken out too, a dataset of 1702 valid utterances remains. Moreover, 292 utterances are annotated to contain no valid dialogue act and are therefore not suitable for the recognition task. Of the remaining utterances, 171 predicate argument structures were annotated as wrong because of completely ungrammatical input. In this way we arrive at a dataset of 804 instances for the users and 435 for the wizard, summing up to 1239 instances in total.

The features used for dialogue act recognition exploit the information extracted from the different annotation steps:

- Context features: The last preceding dialogue act, equality between the last preceding topic and the actual topic, sentence mood
- Syntactic relation features: Syntactic predicate class, arguments, negation
- VerbNet semantic relation features: VerbNet predicate class, VerbNet frame arguments, negation

- Utterance features: The original utterances without any modifications

Different sets of features for training and evaluation are generated from these:

DATASET_Syn: All utterances of the specified dataset described via syntactic relation and context features.

DATASET_VNSem: All utterances of the specified dataset described via VerbNet semantic relations and context features.

DATASET_Syn_Only: All utterances of the specified dataset only described via the syntactic relations.

DATASET_VNSem_Only: All utterances of the specified dataset only described via the VerbNet semantic relations.

DATASET_Context_Only: All utterances of the specified dataset described via the context features and negation without any information regarding relations.

DATASET_Utterances_Context: The utterances of the specified dataset as strings combined with the whole set of context features without further relation extraction results.

DATASET_Utterances: Only the utterances of the specified dataset as strings. This and the last "Utterances"-set serve as baselines.

Dialogue Act Recognition is carried out via the Bayesian network classifier AOEDsr from the WEKA toolkit. AODEsr augments AODE, an algorithm averaging over all of a small space of alternative naive-Bayes-like models that have weaker independence assumptions than naive Bayes, with Subsumption Resolution (Zheng and Webb, 2006). Evaluation is performed using crossfolded evaluation.

All results of the experiments are given in terms of accuracy.

Results for the dataset "All" comparing the syntactic relations with VerbNet relations as well as the pure utterances and context are shown in table 4.

Dataset	Accuracy
All_Syn	67.4%
All_VNSem	66.8%
All_Utterances_Context	61.9%
All_Utterances	48.1%

Table 4: Dialogue Act Classification Results for the "ALL" Datasets

The best result is achieved with the syntactic information, although the VerbNet information provides an abstraction over the predicate classification. Both the set containing the VerbNet relations as well as the syntactic relations are much better than the set containing only the context and the original utterances. The dataset containing only the utterances could not reach 50%.

Although the experiments show much better results using the relations instead of the original utterance, the overall accuracy is not very satisfying. Several reasons for this phenomenon come into consideration. While it can to a certain extend be the fault of the classifying algorithm (see table 8 for some tests with a ROCCHIO based classifier), the main reason might as well lie in the imprecise boundaries of the dialogue act classes: Several categories are hard to distinguish even for a human annotator as you can see from the wrongly classified examples in table 3. Another possibility can be the comparatively small number of total training instances.

For the NPC dataset the results are slightly better and much better still for the set CST, which is due to a smaller number (6) of dialogue acts: The dialogue act "PROPOSE", which is the act for showing an object or proposing a possibility, was not used by any user, but only by the wizard.

Dataset	Accuracy
CST_Syn	73.1%
NPC_Syn	68.5%

Table 5: Dialogue Act Classification Results for Datasets "CST" and "NPC"

To find out if one sort of features is especially important for the classification we reorga-

Utterance	Right Classification	Classified As

Let see what you have and where we can put it	request_info	request

Table 3: Wrongly classified instances

nize the training sets to contain only the context features without the relations (All_Context_Only) on the one hand and only the relational information without the context features on the other hand (All_Syn_Only and All_VNSem_Only). Results are shown in table 6.

Dataset	Accuracy
All_Context_Only	56.6%
All_VNSem_Only	53.5%
All_Syn_Only	50.8%

Table 6: Dialogue Act Classification Results for Context and Relation sets

Table 6 shows that the results are considerably worse if only parts of the features are used. The set with context feature performs 3,1% better than the best set with the relations only. Furthermore the VerbNet semantic relation set leads to nearly 3% better accuracy, which may mean that the abstraction of semantic predicates provides a better mapping to dialogue acts after all if used without further features which may be ranked more important by the classifier.

Besides the experiments with the Bayesian networks, additional experiments are performed using a modified ROCCHIO algorithm similar to the one in (Neumann and Schmeier, 2002). Three different datasets were tested (see table 7).

Dataset	Accuracy
All_Utterances	70.1%
All_Utterances_Context	73.2%
All_Syn	74.4%

Table 8: Dialogue Act Classification Results using the ROCCHIO Algorithm

Table 8 shows that the baseline dataset containing only the utterances already provides much better results with the ROCCHIO algorithm, delivering 70.1% which is more than 10% more accuracy compared to the 48.1% of the Bayesian classifier. If tested together with the context features the accuracy of the utterance dataset raises to 73.2% and, after including the relational information, even to 74.4%. Thus, the results of this ROCCHIO experiment also prove that the employment of the relation information leads to improved accuracy of the classification.

6 Conclusion

This paper reports on a novel approach to automatic dialogue act recognition using syntactic and semantic relations as new features instead of the traditional features such as ngrams of words.

Different feature sets are constructed via an automatic annotation of syntactic predicate argument structures and a manual annotation of VerbNet frame information. On the basis of this information, both the syntactic relations as well as the semantic VerbNet-based relations included in the utterances can be extracted and added to the feature sets for the recognition task. Besides the relation information the employed features include information from the dialogue context (e.g. the last preceding dialogue act) and other features like sentence mood.

The feature sets have been evaluated with a Bayesian network classifier as well as a ROCCHIO algorithm. Both classifiers demonstrate the benefits gained from the relations by exploiting the additionally provided information. While the difference between the best baseline feature set and the best relation feature set in the Bayesian network classifier yields a 5,5% boost in accuracy (61.9% to 67.4%), the ROCCHIO setup exceeds the boosted accuracy by another 1,5% , starting from a higher baseline of 73.2%. Based on the observed complexity of the classification task we expect that the benefit of the relational informa-

Predicate	Instances	Example
see-30.1	59	I would like to see a table in front of the sofa
put-9.1	74	Can you put it in the corner?
reflexive_appearance-48.1.2	80	Show me the red one
own-100	137	Do you have wooden chairs?
want-32.1	153	I would like some plants over here

Table 7: The Main Semantic Relations Found in the Data Sorted by Predicate

tion may turn out to be even more significant on larger learning data.

7 Future Work

The results in section 5 show that the pure classification cannot be used as interpretation component in isolation, but additional methods have to be incorporated. In a preceding analysis of the data it was found that certain predicates are very frequently uttered by the users. In the syntactic predicate scenario the total number of different predicates is 80, whereas the semantic predicates build up a total number of 66. The class containing the predicates with one to ten occurrences constitutes 137 of 1239 instances. The remaining 1101 instances are covered by only 21 different predicate classes. These predicates together with their arguments constitute a set of common domain relations for the sales domain. The main domain relations found are shown in table 7.

The figures suggest that the interpretation at least for the domain relations can be established in a robust manner, wherefore the agent's interpretation component was extended to a hybrid module including a robust rule based method. To derive the necessary rules a rule generator was developed and the rules covering the used feature set (including the context features, sentence mood and the syntactic relations) were automatically generated from the given data.

Future work will focus on the evaluation of these automatically derived rules on a recently collected but not yet annotated dataset from a second Wizard-of-Oz experiment, carried out in the same furniture sales setting.

Additional experiments are planned for evaluating the relation-based features in dialogue act recognition on other corpora tagged with different dialogue acts in order to test the overall performance of our classification approach on more transparent dialogue act sets.

Abstract

The optimal choice of speech understanding method depends on the amount of training data available in rapid prototyping. A statistical method is ultimately chosen, but it is not clear at which point in the increase in training data a statistical method become effective. Our framework combines multiple automatic speech recognition (ASR) and language understanding (LU) modules to provide a set of speech understanding results and selects the best result among them. The issue is how to allocate training data to statistical modules and the selection module in order to avoid overfitting in training and obtain better performance. This paper presents an automatic training data allocation method that is based on the change in the coefficients of the logistic regression functions used in the selection module. Experimental evaluation showed that our allocation method outperformed baseline methods that use a single ASR module and a single LU module at every point while training data increase.

1 Introduction

Speech understanding in spoken dialogue systems is the process of extracting a semantic representation from a user's speech. That is, it consists of automatic speech recognition (ASR) and language understanding (LU). Because vocabularies and language expressions depend on individual systems, it needs to be constructed for each system, and accordingly, training data are required for each. To collect more real training data, which will lead to higher performance, it is more desirable to use a prototype system than that based on the Wizard-of-Oz (WoZ) method where real ASR errors cannot be observed, and to use a more accurate speech understanding module. That is, in the bootstrapping phase, spoken dialogue systems need to operate before sufficient real data have been collected.

We have been addressing the issue of rapid prototyping on the basis of the "Multiple Language model for ASR and Multiple language Understanding (MLMU)" framework (Katsumaru et al., 2009). In MLMU, the most reliable speech understanding result is selected from candidates produced by various combinations of multiple ASR and LU modules using hand-crafted grammar and statistical models. A grammar-based method is still effective at an early stage of system development because it does not require training data; Schapire et al. (2005) also incorporated human-crafted prior knowledge into their boosting algorithm. By combining multiple understanding modules, complementary results can be obtained by different kinds of ASR and LU modules.

We propose a novel method to allocate available training data to statistical modules when the amount of training data increases. The training data need to be allocated adaptively because there are several modules to be trained, and they would cause overfitting without data allocation. There are speech understanding modules that have language models (LMs) for ASR and LU models

Coling 2008: Poster Volume, pages 579–587,
Beijing, August 2010

(LUMs), and a selection module that selects the most reliable speech understanding result from multiple candidates in the MLMU framework. When the amount of available training data is small, and an LUM and the selection module are trained on the same data set, they are trained under a closed-set condition, and thus the training data for the selection module include too many correct understanding results. In such cases, the data need to be divided into subdata sets to avoid overfitting. On the other hand, when the amount of available training data is large, so that overfitting does not occur, all available data should be used to train each statistical module to prepare as much training data as possible.

We therefore develop a method for switching data allocation policies. More specifically, two points are automatically determined at which statistical modules with more parameters start to be trained. As a result, better overall performance is achieved at every point while the amount of training data increases, compared with all combinations of a single ASR module and a single LU module.

2 Related Work

It is important to consider the amount of available training data when designing a speech understanding module. Many statistical LU methods have been studied, e.g., (Wang and Acero, 2006; Jeong and Lee, 2006; Raymond and Riccardi, 2007; Hahn et al., 2008; Dinarelli et al., 2009). They generally outperform grammar-based LU methods when a sufficient amount of training data is available; but sufficient training data are not necessarily available during rapid prototyping. Several LU methods were constructed using a small amount of training data (Fukubayashi et al., 2008; Dinarelli et al., 2009). Fukubayashi et al. (2008) constructed an LU method based on the weighted finite state transducer (WFST), in which filler transitions accepting arbitrary inputs and transition weights were added to a hand-crafted FST. This method is placed between a grammar-based method and a statistical method because a statistically selected weighting scheme is applied to a hand-crafted grammar model. Therefore, the amount of training data can be smaller compared with general statistical LU methods, but this method does not outperform them when plenty of training data are available. Dinarelli et al. (2009) used a generative model for which overfitting is less prone to occur than discriminative models when the amount of training data is small, but they did not use a grammar-based model, which is expected to achieve reasonable performance even when the amount of training data is very small.

Raymond et al. (2007) compared the performances of statistical LU methods for various amounts of training data. They used a statistical finite-state transducer (SFST) as a generative model and a support vector machine (SVM) and conditional random fields (CRF) as discriminative models. The generative model was more effective when the amount of data was small, and the discriminative models were more effective when it was large. This shows that the performance of an LU method depends on the amount of training data available, and therefore, LU methods need to be switched automatically. Wang et al. (2002) developed a two-stage speech understanding method by applying statistical methods first and then grammatical rules. They also examined the performance of the statistical methods at their first stage for various amounts of training data and confirmed that the performance is not very high when a small amount of data is used.

Schapire et al. (2005) showed that accuracy of call classification in spoken dialogue systems improved by incorporating hand-crafted prior knowledge into their boosting algorithm. Their idea is the same as ours in that they improve the system's performance by using hand-crafted human knowledge while only a small amount of training data is available. We furthermore solve the data allocation problem because there are multiple statistical models to be trained in speech understanding, while their call classification has only one statistical model.

3 MLMU Framework

MLMU is the framework for selecting the most reliable speech understanding result from multiple speech understanding modules (Katsumaru et al., 2009). In this paper, we furthermore adapt the selection module to the amount of available train-

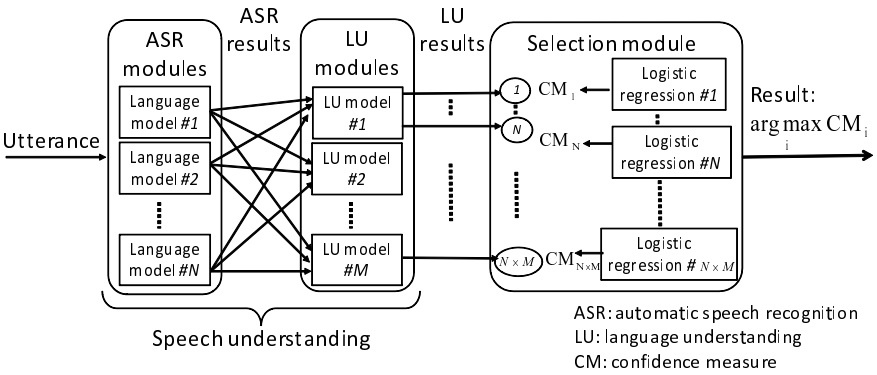

Figure 1: Overview of speech understanding framework MLMU

ing data. More specifically, the allocation policy of training data is changed and thus appropriate LMs and LUMs are selected as its result.

An overview of MLMU is shown in Figure 1. MLMU uses multiple LMs for ASR and multiple LUMs and selects the most reliable speech understanding result from all combinations of them. We denote a speech understanding module as SU_i ($i = 1, \ldots, n$). Its result is a semantic representation consisting of a set of concepts. The concept is either a semantic slot and its value or an utterance type. Note that $n = N \times M$, when N LMs and M LUMs are used. The confidence measure per utterance for a result of i-th speech understanding module SU_i is denoted as CM_i. The speech understanding result having the highest confidence measure is selected as the final result for the utterance. That is, the result is the output of SU_m where $m = \mathrm{argmax}_i\, CM_i$.

The confidence measure is calculated by logistic regression based on the features of each speech understanding result. A logistic regression function is constructed for each speech understanding module SU_i:

$$CM_i = \frac{1}{1 + e^{-(a_{i1}F_{i1} + \ldots + a_{i7}F_{i7} + b_i)}}. \qquad (1)$$

Parameters $a_{i1}, \ldots, a_{i7}$ and b_i are determined by using training data. In the training phase, teacher signal 1 is given when a speech understanding result is completely correct; that is, when no error is contained in the result. Otherwise, 0 is given. We use seven features, $F_{i1}, F_{i2}, \ldots, F_{i7}$, as independent variables. Each feature value is normalized so as to make its mean zero and its variance one.

Table 1: Features of speech understanding result obtained from SU_i

F_{i1}:	Acoustic score normalized by utterance length
F_{i2}:	Difference between F_{i1} and normalized acoustic scores of verification ASR
F_{i3}:	Average concept CM in understanding result
F_{i4}:	Minimum concept CM in understanding result
F_{i5}:	Number of concepts in understanding result
F_{i6}:	Whether any understanding result is obtained
F_{i7}:	Whether understanding result is yes/no

CM: confidence measure

The features used are listed in Table 1. Compared with those used in our previous paper (Katsumaru et al., 2009), we deleted ones that were highly correlated with other features and added ones regarding content of the speech understanding results. Features F_{i1} and F_{i2} are obtained from an ASR result. Another ASR with a general large vocabulary LM is executed for verifying the i-th ASR result. F_{i2} is the difference between its score and F_{i1} (Komatani et al., 2007). These two features represent the reliability of the ASR result. F_{i3} and F_{i4} are calculated for each concept in the LU result on the basis of the posterior probability of the 10-best ASR candidates (Komatani and Kawahara, 2000). F_{i5} is the number of concepts in the LU result. This feature is effective because the LU results of lengthy utterances tend to be erroneous in a grammar-based LU. F_{i6} represents the case when an ASR result is not accepted by the subsequent LU module. In such cases, no speech understanding result is obtained, which is

U1: It is June ninth.
ASR result:
- **grammar** "It is June ninth."
- **N-gram** "It is June noon and"
LU result:
- **grammar + FST** "month:6 day:9 type:refer-time"
- **N-gram + WFST** "month:6 type:refer-time"

U2: I will borrow it on twentieth.
(Underlined part is out-of-grammar.)
ASR result:
- **grammar** "Around two pm on twentieth."
- **N-gram** "Around two at ten on twentieth."
LU result:
- **grammar + FST** "day:20 hour:14 type:refer-time"
- **N-gram + WFST** "day:20 type:refer-time"

Combination of LM and LUM is denoted as "LM+LUM".

Figure 2: Example of speech understanding results in MLMU framework

regarded as an error. F_{i7} is added because affirmative and negative responses, typically "Yes" and "No", tend to be correctly recognized and understood.

Figure 2 depicts an example when multiple ASRs based on LMs and multiple LUs are used. In short, the correct speech understanding result is obtained from a different combination of LMs and LUMs.

4 Automatic Allocation of Training Data Using Change in Coefficients

The training data need to be allocated to the speech understanding modules (i.e., statistical LM and statistical LUM) and the selection module. If more data are allocated to the ASR and LU modules, the performances of these modules are improved, but the overall performance is degraded because of the low performance of the selection module. On the other hand, even if more training data are allocated to the selection module, the performance of each ASR and LU module remains low.

4.1 Allocation Policy

We focus on the convergence of the logistic regression functions when the amount of training data increases. The convergence is defined as the change in their coefficients, which will appear later as Equation 2, and determines two points

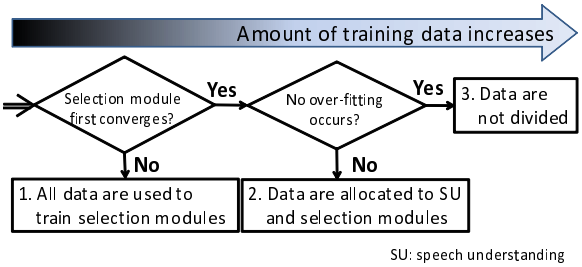

Figure 3: Flowchart of data allocation

during the increase in training data, and thus three phases are defined. The flowchart of data allocation is depicted in Figure 3. The three phases are explained below.

In the first phase, the first priority is given to the selection module. This is because the logistic regression functions used in the selection module converge with relatively less training data than those in the statistical ASR and LU modules for speech understanding; there are eight parameters for each logistic regression function as shown in Equation 1, far fewer than for other statistical models such as N-gram and CRF. The output from a speech understanding module that employs grammar-based LM and LUM would be the most reliable in many cases because its performance is better than that of other statistical modules when a very small amount of training data is available. As a result, equivalent or better performance would be achieved than methods using a single ASR module and a single LU module.

In the second phase, the training data are also allocated to the speech understanding modules after the selection module converges. This aims to improve the performance of the speech understanding modules by allocating as much training data to them as possible. The amount of training data is fixed in this phase to the amount allocated to the selection module determined in the first phase. The remaining data are used to train the speech understanding modules.

When the performances of all the speech understanding modules stabilize, the allocation phase proceeds to the third one. After this point, we hypothesize that overfitting does not occur in this phase because plenty of training data are available. All available data are used to train all mod-

ules without dividing the data in this phase.

4.2 Determining When to Switch Allocation Policies

Automatic switching from one phase to the next requires the determination of two points in the number of training utterances: when the selection module first converges ($k_{onlysel}$) and when the speech understanding modules all become stable (k_{nodiv}). These points are determined by focusing on the changes in the coefficients of the logistic regression functions when the number of utterances used as training data increases. We observe the sum of the changes in the coefficients of the functions and then identify the points at which the changes converge. The points are determined individually by the following algorithm.

Step 1 Construct two logistic regression functions for speech understanding module SU_i by using k and $(k + \delta k)$ utterances out of k_{max} utterances, where k_{max} is the amount of training data available.

Step 2 Calculate the change in coefficients from the two logistic regression functions by

$$\Delta_i(k) = \sum_j |a_{ij}(k + \delta k) - a_{ij}(k)| + |b_i(k + \delta k) - b_i(k)|, \quad (2)$$

where $a_{ij}(k)$ and $b_i(k)$ denote the parameters of the logistic regression functions, shown in Equation 1, for speech understanding module SU_i, when k utterances are used to train the functions.

Step 3 If $\Delta_i(k)$ becomes smaller than threshold θ, consider that the training of the functions has converged, and record this k as the point of convergence. If not, return to Step 1 after $k \leftarrow k + \delta k$.

The δk is the minimum unit of training data containing various utterances. We set it as the number of utterances in one dialogue session, whose average was 17. Threshold θ was set to 8, which corresponds to the number of parameters in the logistic regression functions. No experiments were conducted to determine if better performance could be achieved with other choices of θ[1].

The first point, $k_{onlysel}$, is determined using the speech understanding module that uses no training data. Specifically, we used "grammar+FST" as method SU_i. Here, "LM+LUM" denotes a combination of LM for ASR and LUM. If the function converges at k utterances, we set $k_{onlysel}$ to k and fix the k utterances as training data used by the selection module. The remaining $(k_{max} - k)$ utterances are allocated to the speech understanding modules, that is, the LMs and LUMs. Note that if k becomes equal to k_{max} before Δ_i converges, all training data are allocated to the selection module; that is, no data are allocated to the LMs and LUMs. In this case, no output is obtained from statistical speech understanding modules, and only outputs from the grammar-based modules are used.

The second point, k_{nodiv}, is determined on the basis of the speech understanding module that needs the largest amount of data for training. The amount of data needed depends on the number of parameters. Specifically, we used "N-gram+CRF" as SU_i in Equation 2. If the function converges, we hypothesize that the performance of all the speech understanding modules stabilize and thus overfitting does not occur. We then stop the division of training data, and use all available data to train the statistical modules.

5 Experimental Evaluation

5.1 Target Data and Implementation

We used a data set previously collected through actual dialogues with a rent-a-car reservation system (Nakano et al., 2007) with 39 participants. Each participant performed 8 dialogue sessions, and 5900 utterances were collected in total. Out of these utterances, we used 5240 for which the automatic voice activity detection (VAD) results agreed with manual annotation. We divided the utterances into two sets: 2121 with 16 participants as training data and 3119 with 23 participants as the test data.

[1]We do not think the value is very critical after seeing the results shown in Figure 4.

We constructed another rent-a-car reservation system to evaluate our allocation method. The system included two language models (LMs) and four language understanding models (LUMs). That is, eight speech understanding results in total were obtained. The two LMs were a grammar-based LM ("grammar", hereafter) and a domain-specific statistical LM ("N-gram"). The grammar model was described by hand to be equivalent to the FST model used in LU. The N-gram model was a class 3-gram and was trained on a transcription of the available training data. The vocabulary size was 281 for the grammar model and 420 for the N-gram model when all the training data were used. The ASR accuracies of the grammar and N-gram models were 67.8% and 90.5% for the training data and 66.3% and 85.0% for the test data when all the training data were used. We used Julius (ver. 4.1.2) as the speech recognizer and a gender-independent phonetic-tied mixture model as the acoustic model (Kawahara et al., 2004). We also used a domain-independent statistical LM with a vocabulary size of 60250, which was trained on Web documents (Kawahara et al., 2004), as the verification model.

The four LUMs were a finite-state transducer (FST) model, a weighted FST (WFST) model, a keyphrase-extractor (Extractor) model, and a conditional random fields (CRF) model. In the FST-based LUM, the FST was constructed by hand. The WFST-based LUM is based on the method developed by Fukubayashi et al. (2008). The WFSTs were constructed by using the MIT FST Toolkit (Hetherington, 2004). The weighting scheme used for the test data was selected by using training data (Fukubayashi et al., 2008). In the extractor-based LUM, as many parts as possible in the ASR result were simply transformed into concepts. As the CRF-based LUM, we used open-source software, CRF++[2], to construct the LUM. As its features, we use a word in the ASR result, its first character, its last character, and the ASR confidence of the word. Its parameters were estimated by using training data.

The metric used for speech understanding performance was concept understanding accuracy, defined as

$$1 - \frac{\text{SUB} + \text{INS} + \text{DEL}}{\text{no. of concepts in correct results}},$$

where SUB, INS, and DEL denote the numbers of substitution, insertion, and deletion errors.

Table 2: Absolute degradation in oracle accuracy when each module was removed

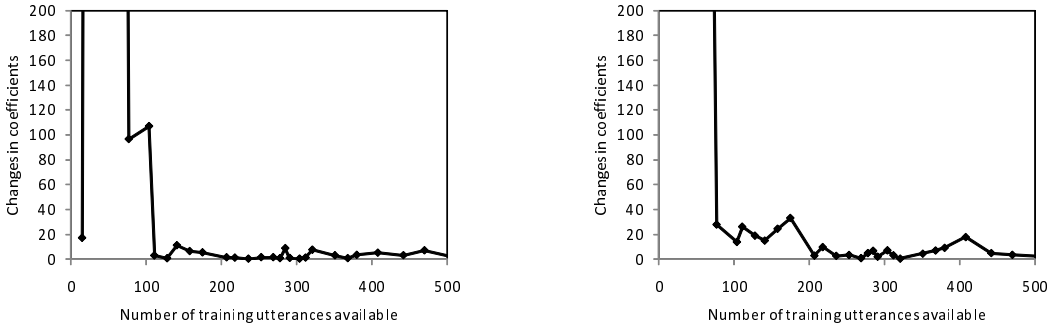
Case	(A)	(B)
With all modules (%)	86.6	90.1
w/o grammar ASR	-12.0	-1.1
w/o N-gram ASR	-6.1	-7.7
w/o FST LUM	-0.4	0.0
w/o WFST LUM	-1.2	-0.5
w/o Extractor LUM	-0.1	0.0
w/o CRF LUM	-0.6	-3.7
(w/o FST & Extractor LUMs)	-1.0	-0.1

(A): 141 utterances with 1 participant
(B): 2121 utterances with 16 participants

5.2 Effectiveness of Using Multiple LMs and LUMs

We investigated how much the performance of our framework degraded when one ASR or LU module was removed. We used the oracle accuracies, i.e., when the most appropriate result was selected by hand. The result reveals the contribution of each ASR and LU module to the performance of the framework. A module is regarded as more important when the accuracy is degraded more when it is removed than when another one is removed. Two cases (A) and (B) were defined: when the amount of available training data was (A) small and (B) large. We used 141 utterances with 1 participant for case (A) and 2121 utterances with 16 participants for case (B). The results are shown in Table 2.

When a small amount of training data was available (case (A)), the accuracy was degraded by 12.0 points when the grammar-based ASR module was removed and 6.1 points when the N-gram-based ASR module was removed. The accuracy was thus degraded substantially when either ASR module was removed. This indicates that the two ASR modules work complementarily.



(a) grammar+FST (b) N-gram+CRF

Figure 4: Change in the sum of coefficients Δ_i when amount of training data increases ("LM+LUM" denotes combination of LM and LUM)

On the other hand, when a large amount of training data was available (case (B)), the accuracy was degraded by 1.1 points when the grammar-based ASR was removed. This means that it became less important when there are plenty of training data because the coverage of the N-gram-based ASR became wider. In short, especially when the amount of training data is smaller, speech understanding modules based on a handcrafted grammar are more important because of the low performance of statistical modules.

Concerning the LUMs, the accuracy was degraded when any of the LUM modules was removed when a small amount of training data was available. When a large amount of training data was available, the module based on CRF in particular became more important.

5.3 Results and Evaluation of Automatic Allocation

Figure 4 shows the change in the sum of the coefficients, Δ_i, with the increase in the amount of training data. In Figure 4(a), the change was very large while the amount of training data was small, and decreased dramatically and converged around one hundred utterances. By applying θ (=8) to Δ_i, we set 111 utterances as the first point, $k_{onlysel}$, up to which all the training data are allocated to the selection module, as described in Section 4.1. Similarly, from the results shown in Figure 4(b), we set 207 utterances as the second point, k_{nodiv}, from which the training data are not divided.

To evaluate our method for allocating training data, we compared it with two baseline methods:

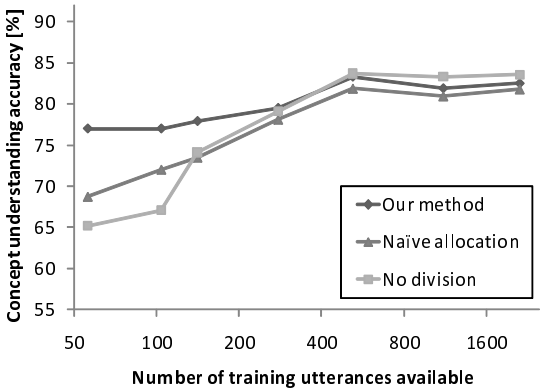


Figure 5: Results of allocation methods

- No-division method: All data available at each point were used to train both the speech understanding modules and the selection module. That is, the same data set was used to train them.
- Naive-allocation method: Training data available at each point were allocated equally to the speech understanding modules and the selection module.

As shown in Figure 5, our method had the best concept understanding accuracy when the amount of training data was small, that is, up to about 278 utterances. This indicates that our method for allocating the available training data is effective when the amount of training data is small.

This result is explained more specifically by us-

Table 3: Concept understanding accuracy for 141 utterances

	Accuracy (%)
Our method	77.9
Naive allocation	73.5
No division	74.1

ing the case in which 141 utterances were used as the training data. 111 ($= k_{onlysel}$) were secured to train the selection module and 30 utterances were allocated to train the speech understanding modules. As shown in Table 3, the accuracy with our method was 3.8 points higher than that with the no-division baseline method. This was achieved by avoiding the overfitting of the logistic regression functions; i.e., the data input to the functions became similar to the test data due to allocation, so the concept understanding accuracy for the test set was improved. The accuracy with our method was 4.4 points higher than that with the naive allocation baseline method. This was because the amount of training data allocated to the selection module was less than our method, and accordingly the selection module was not trained sufficiently.

5.4 Comparison with methods using a single ASR and a single LU

Figure 6 plots concept understanding accuracy with our method against baseline methods using a single ASR module and a single LU module for various amounts of training data. Each module for comparison was constructed by using all available training data at each point while training data increased; i.e., the same condition as our method. The accuracies of only three speech understanding modules are shown in the figure, out of the eight obtained by combining two LMs for ASR and four LUMs. These three are the ones with the highest accuracies while the amount of training data increased. Our method switched the allocation phase at 111 and 207 utterances, as described in Section 5.3.

Our method performed equivalently or better than all baseline methods even when only a small amount of training data was available. As a result, our method outperformed all the baseline methods

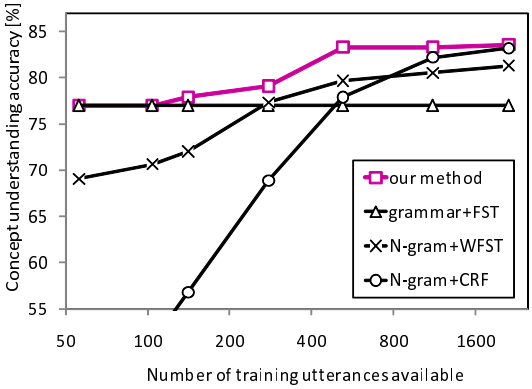

Figure 6: Comparison with baseline methods using single speech understanding

at every point while training data increase.

6 Conclusion

We developed a method to automatically allocate training data to statistical modules so as to avoid performance degradation caused by overfitting. Experimental evaluation showed that speech understanding accuracies achieved by our method were equivalent or better than the baseline methods based on all combinations of a single ASR module and a single LU module at every point while training data increase. This includes a case when a very small amount of training data is available. We also showed empirically that the training data should be allocated while an amount of training data is not sufficient. Our method allocated available training data on the basis of our allocation policy described in Section 4.1, and outperformed the two baselines where the training data were equivalently allocated and not allocated.

When plenty of training data were available, there was no difference between our method and the speech understanding method that requires the most training data, i.e., N-gram+CRF, as shown in Figure 6. It is possible that our method combining multiple speech understanding modules would outperform it as Schapire et al. (2005) reported. In their data, there were some examples that only a hand-crafted rules can parse. Including such a task as more complicated language understanding grammar is required, verification of our method in other tasks is one of the future works.

DL Meet FL: A Bidirectional Mapping between Ontologies and Linguistic Knowledge*

Hans-Ulrich Krieger and **Ulrich Schäfer**
Language Technology Lab
German Research Center for Artificial Intelligence (DFKI)
{krieger|ulrich.schaefer}@dfki.de

Abstract

We present a transformation scheme that mediates between description logics (DL) or RDF-encoded ontologies and type hierarchies in feature logics (FL). The *DL-to-FL* direction is illustrated by an implemented offline procedure that maps ontologies with large, dynamically maintained instance data to named entity (NE) and information extraction (IE) resources encoded in typed feature structures. The *FL-to-DL* translation is exemplified by a (currently manual) translation of so-called MRS (Minimal Recursion Semantics) representations into OWL instances that are based on OWL classes, generated from the the type hierarchy of a deep linguistic grammar. The paper will identify parts of knowledge which can be translated from one formalism into the other without loosing information and parts which can only be approximated. The work described here is important for the Semantic Web to become a reality, since semantic annotations of natural language documents (DL) can be automatically generated by shallow and deep natural language parsing systems (FL).

1 Introduction and motivation

Ontologies on the one hand and resources for natural language processing (lingware) on the other hand, though closely related, are often maintained independently, thus constituting a duplication of work.

In the *first* part of this paper, we describe an implemented offline procedure that can be used to map concepts and instance information from ontologies to lingware resources for named entity recognition and information extraction systems. The approach (i) improves NE/IE precision and recall in closed domains, (ii) exploits linguistic knowledge for identifying ontology instances in texts more robustly, (iii) gives full access to ontology instances and concepts in natural language processing results, and (iv) avoids duplication of work in development and maintenance of ontologies and lingware. The advantages of this approach for Semantic Web and natural language (NL) processing-based applications come from a *cross-fertilization* effect. While ontology instance data can improve precision and recall of, e.g., named entity recognition (NER) and information extraction (IE) in closed domains, linguistic knowledge contained in NER and IE components can help to recognize ontology instances (or concepts) occurring in text, e.g., by taking into account inflection, anaphora, and context. Furthermore, (Haghighi and Klein, 2009) and others have shown that incorporating finer-grained semantic information on entities occurring in text (e.g., for antecedent filtering) helps to improve performance of coreference resolution systems.

If both resources would be managed jointly at a single place (in the ontology), they could be easily kept up-to-date and in sync, and their maintenance would be less time-consuming. When ontology concepts and instances are recognized in text, their name or ID can be used by applications to support subsequent queries, navigation, or inference in the ontology using an ontology query language (e.g., SPARQL). The procedure we describe here, preserves hierarchical concept information and links to ontology concepts and instances. Applications are, e.g., hybrid deep-shallow question answering (Frank et al., 2007), automatic typed hyperlinking (Busemann et al., 2003) of instances and concepts occurring in documents, or other innovative applications that combine Semantic Web and NL processing technologies, e.g., for semantic search (Schäfer et al., 2008).

The *second* part of this paper outlines the inverse transformation from feature logics (FL) into description logics (DL). Walking along this direction has the big advantage of potentially applying subsequent description logic reasoners to the lexical semantics of natural language input text in order to infer new knowledge, e.g., in interactive natural language ques-

*The work described in this paper has been carried out in the TAKE project (Technologies for Advanced Knowledge Extraction), funded by the German Federal Ministry of Education and Research under contract number 01IW08003.

Beijing, August 2010

tion answering. As an example, we will carefully develop the (approximate) translation of so-called robust minimal recursion semantic (RMRS) structures (Copestake, 2003) into OWL descriptions (McGuinness and van Harmelen, 2004). RMRS structures are the semantic output of various NL processing engines, encoded in typed feature structures (TFS). Since NL processors (e.g., taggers, chunkers, deep parsers) only build up structure, subsequent processing steps are either not realized or implemented in ad hoc way,

- dealing with merging & normalization of RMRS,
- infering new knowledge (e.g., w.r.t. the foregoing dialog),
- taking into account extralinguistic knowledge for reasoning.

Now, by moving from a specialized "designer language" (RMRS) to OWL, we can take advantage of years of solid theoretical and practical work in logic, especially in description logics. Since OWL is an instance of the description logics family and the defacto language for the Semantic Web, we can utilize the built-in reasoning capabilities of OWL and (rule-based) description logic reasoners.

The structure of this paper is as follows. In the next section, we outline the relationship between description logics and feature logics, trying to make clear what they have in common, but at the same time explaining their differences. Section 3 describes the syntactic mapping process from the ontology to feature structure descriptions. In Section 4, we present an example where recognized named entities enriched with ontology information are used in hybrid NL processing and subsequent applications. After that, Section 5 explains the mapping of RMRS structures into OWL descriptions. Finally, Section 6 shows that a subsequent description logic reasoner can utilize these descriptions to infer new knowledge.

2 The relationship between description and feature logics

Description logics (DL) (Baader et al., 2003) and *feature logics* (FL) (Carpenter, 1992) have been pursued independently for quite a while. Their close relationship was recognized by (Nebel and Smolka, 1990). Instances of both families of knowledge representation formalisms are usually decidable two-variable fragments of first-order predicate logic. Even though DL dialects usually have an intractable worst-case complexity, average-case reasoning is usually fast, due to the availability of highly-optimized tableaux reasoners. When adding seemingly easy constructs such as "role-value maps" (the analog to reentrancies), the underlying logical calculus becomes undecidable.

From an abstract viewpoint, both DL and FL employ unary and binary predicates for which the two communities invented different names (we only list some of them):

arity	description logic	feature logic
unary	concept, class	type, category
binary	role, property	feature, attribute

Though these names are different, both representation families (usually) vary in further, not so subtle details:

description logic	feature logic
open world assumption	closed world assumption
full Boolean concept logic	only conjunctions
relational properties	functional properties
role-value maps forbidden	reentrancies allowed

Let us be more verbose here to see the descriptional consequences of both approaches in terms of a mutual translation. We note here that we take OWL (McGuinness and van Harmelen, 2004) as an instance of DL and $\mathcal{TDL}$ (type description language) (Krieger and Schäfer, 1994) as an example of FL. OWL, the outcome of the DAML+OIL standardization, is regarded to be the de-facto language for the Semantic Web. OWL still makes use of constructs from RDF and RDFS, but restricts the expressive power of RDFS, thereby ensuring decidability of the standard inference problems. Compared to RDF(S), OWL provides more fine-grained modelling constructs, such as `intersectionOf` or `unionOf`.

Within the Head-Driven Phrase Structure Grammar (HPSG) (Pollard and Sag, 1994) paradigm in modern computational linguistics (CL), $\mathcal{TDL}$ is a language that has been employed in various implemented systems, such as PAGE, LKB, PET, or *SProUT*.

Before going into the details of our approximate transformation schema, let us quickly explain how to *atomize* a typed feature structure (TFS) in terms of description logic primitives, using OWL. Consider the following TFS which is a gross simplification of the *Head-Feature Principle* in HPSG. In terms of the "one-dimensional" line-based $\mathcal{TDL}$ notation, we write

```
phrase1 := phrase &
  [HEAD #h1, HEAD-DTR|HEAD #h1],
```

or as a two-dimensional AVM (attribute-value matrix) notation, we have

$$\text{phrase1} \equiv \left[\begin{array}{l} \textit{phrase} \\ \text{HEAD } \boxed{\text{h1}} \\ \text{HEAD-DTR|HEAD } \boxed{\text{h1}} \end{array}\right]$$

Assuming that this is an individual of class *phrase*, we can obtain a meaning-preserving OWL representation (we assume that HEAD and HEAD-DTR are functional OWL object properties):

```
<owl:Thing rdf:ID="h1"/>

<rdf:Description rdf:about="hdtr1">
  <rdf:type rdf:resource="owl:Thing"/>
  <HEAD rdf:resource="h1"/>
</rdf:Description>

<rdf:Description rdf:about="phr1">
  <rdf:type rdf:resource="phrase"/>
  <HEAD rdf:resource="h1"/>
  <HEAD-DTR rdf:resource="hdtr1"/>
</rdf:Description>
```

Note that only the top-level structure is explicitly typed (*phrase*); every other substructure thus is assigned the most general type, which translates into the OWL class `owl:Thing`. Note also the sharing of information under paths `HEAD` and `HEAD-DTR|HEAD`—this is realized by refering to the the name `h1` in the above RDF/OWL description for `phr1` and `hdtr1`.

Given a set of OWL descriptions, obtaining the inverse direction from DL to FL should now be clear. It is important here to group statements that are related to a specific class, viz., inheritance information (e.g., `intersectionOf`) together with property information about roles that are "introduced" on a given class (as given by the value of `rdfs:domain`). In Section 3, we focus on this inverse direction (DL-to-FL), whereas Section 5 exemplifies the FL-to-DL direction.

Let us finally elaborate fundamental differences between the DL and FL families that can only be approximated in terms of "less expressive" constructs.

Open vs. closed world assumption. Typed feature logics usually "live" in a closed world, meaning that if two types t_1 and t_2 do not share a common subtype (having a greatest lower bound), the unification (conjuntion) is assumed to be the bottom type (OWL: `owl:Nothing`), meaning that no individual exists which is of both t_1 and t_2 at the same time. This is totally different to the DL point of view: *what can not proven to be true* (whether the conjunction of t_1 and t_2 denotes the empty set) *is not believed to be false*. Thus we either have to introduce a new type t on the FL side, abbreviating the conjunction of t_1 and t_2 ($\mathcal{TDL}$: t := t_1 & t_2.), or to close the subclass hierarchy on the DL side: $\bot \equiv t_1 \sqcap t_2$ (OWL: `disjointWith`). This decision clearly depends on the direction of the transformation.

Boolean vs. conjunctive description logic. Typed feature logics rarely provide more than *conjunctions* of feature-value constraints. This is due to the fact that disjunctive descriptions render almost linear (conjunctive) unification exponential. A full Boolean calculus, such as OWL DL, even has an NEXPTIME complexity. Thus it is clear that the direction from DL to FL can only be approximated. The inverse direction is clearly trivial with the notable exception of *reentrancies* (see below).

To flesh out our point, consider the DL axiom *human* $\equiv$ *man* $\sqcup$ *woman* that fully determines ($\equiv$) *human* in terms of the union of the concepts *man* and *woman*. Given the syntax of $\mathcal{TDL}$, we can approximate parts of the intended meaning of the description by `man :< human` and `woman :< human`, since the above DL axiom entails that *man* $\sqsubseteq$ *human* and *woman* $\sqsubseteq$ *human* is the case. This is exactly specified by the above two $\mathcal{TDL}$ type definitions. Further, not so trivial approximations can be found in (Flickinger, 2002). The idea here is that foreseeable disjunctions of DL concepts can be emulated by introducing additional FL types (in the worst case, exponentially-many new types, however). Even negated concepts can be simulated this way, since FL lives in a closed world (see above).

Relational vs. functional properties. By default, roles in DL are relational properties, meaning that for a fixed individual in the domain of a given role, the number of individuals in the range needs not to be 0 or 1. DL further allows to impose *cardinality (or number) restrictions* on roles, so that we might write ≥ 0 *livingParents* $\sqcap \leq 2$ *livingParents* which says that one can have at least 0 and at most 2 living parents. This is in sharp contrast to FL which usually assume functional roles (so-called features), making such roles essentially partial functions. A partial workaround has been proposed in CL systems by using (ordered) difference lists to collect information. Other systems, such as *SProUT* (Krieger et al., 2004), come up with bags (or multisets) that even violate the foundational axiom (a set must not contain itself) in order to achieve runtime efficiency.

Summarizing, the FL-to-DL direction of translating features into roles is easy, since features in FL can be easily defined as functional roles in DL (OWL even provides the `owl:FunctionalProperty` characteristics). The inverse direction is only a gross approximation in that cardinality constraints can not be

stated on the FL side.

Role-value maps & reentrancies. The above Head-Feature Principle example seems to indicate that role-value maps can be easily represented in DL, simply by using the name of an individual to specify identity. In fact, this is true, but only for the ABox of a knowledge base, i.e., only for the set of individuals (or instances). However, the notion of role-value maps in DL or reentrencies in FL refers to the TBox and the set of concept definitions, resp. Thus, one can not intensionally specify identity of information for a potentially infinite number of individuals via a class axiom in DL, but needs to extensionally specify identity of information for each individual in the ABox.

3 OntoNERdIE: from OWL to $\mathcal{TDL}$

In this section, we describe an instantiation of the DL-to-FL mapping. OntoNERdIE is an offline procedure that maps ontology concept and instance information to lingware resources (Schäfer, 2006). The approach has been implemented for the language technology ontology that backs up the LT World web portal (http://www.lt-world.org), but can be easily adapted to other domains and ontologies, since it is fully automated, except for the choice of relevant main concepts and properties that are going to be mapped which is a matter of configuration.

The target named entity recognition and information extraction tool we employ here is *SProUT* (Drożdżyński et al., 2004), a shallow multilingual, multi-purpose NL processor. The advantage of *SProUT* in the described approach for named entity recognition and information extraction is that it comes with (1) a type system and typed feature structures as the basic data type, (2) a powerful, declarative rule mechanism with regular expressions over typed feature structures, and (3) a highly efficient gazetteer module with fine-grained, customizable classification of recognized entities.

SProUT provides additional modules such as morphology or a reference resolver that can be exploited in the rule system, e.g., to use context or morphological variation for improved NER. Through automatically generated mappings, *SProUT* output enriched with ontology information can be used for robust, hybrid deep-shallow parsing, and semantic analysis.

In this section, we describe the offline processing steps of the OntoNERdIE approach. The online part in applications is described in Section 4. The approach heavily relies on XSLT transformations (Clark, 1999) of the XML representation formats, both in the offline mapping and in the online application.

3.1 RDF preprocessing

Input to the mapping procedure is an OWL ontology file, containing both concept and instance descriptions. The RDF file is pre-processed with a generic XSLT stylesheet sorting and merging `rdf:Description`s that are distributed over the file but which belong together. We use XSLT's `key` and `generate-id` functions. Depending on the application, the next two processing stages take a list of concepts as filter because it will typically not be desirable to extract all concepts or instances available in the ontology. In both cases, resource files are generated as output that can be used to extend existing named entity recognition resources. E.g., while general rules can recognize domain-independent named entities (e.g., any person name), the extended resource contains specific, and potentially more detailed information for domain-specific entities.

3.2 Extracting inheritance

The second stylesheet converts RDFS `subClassOf` statements from output step 1 (Section 3.1) into a set of $\mathcal{TDL}$ type definitions that can be immediately imported by the *SProUT* named entity recognition grammar. Currently 1,260 type definitions for the same number of `subClassOf` statements in the LT World ontology are generated, e.g.,

```
NL_Parsing := Written_Language &
  Language_Analysis.
```

This is of course a lossy conversion because not all relations supported in an OWL ontology (such as `unionOf`, `disjointWith`, `intersectionOf`) are mapped. However, we think that for NE classifications, the `subClassOf` taxonomy mappings will be sufficient. Other relations could be formulated as direct (though slower) ontology queries using the `OBJID` mechanism described in the next step. If the target of OntoNERdIE is a NER system different from *SProUT* and without a type hierarchy, this step can be omitted. The `subClassOf` information can always be gained by querying the ontology appropriately on the basis of the concept name.

3.3 Generating gazetteer entries

The next stylesheet selects statements about instances of relevant concepts via the `rdf:type` information and converts them to structured gazetteer source files for the *SProUT* gazetteer compiler (or into a different format in case of another NER system). In the following example, one of the approximately 20,000 converted entries for LT World is shown.

```
Bernd Kiefer | GTYPE: lt_person |
  SNAME: "Kiefer" | GNAME: "Bernd" |
  CONCEPT: Active_Person |
  OBJID: "obj_62893"
```

The attribute CONCEPT contains a $\mathcal{TDL}$ type generated in step 2 (described in Section 3.2). For convenience, several ontology concepts are mapped (defined manually as part of the configuration of the stylesheet) to only a few named entity classes (under attribute GTYPE). For the LT World ontology, these classes are person, organization, event, project, product, and technology. The advantage of this simplification is that NER context rules from existing *SProUT* named entity grammars can be re-used for improved robustness and disambiguation.

The rules, e.g., recognize name variants with title like Prof. Kiefer, Dr. Kiefer, or Mr. Kiefer with or without a first name. Moreover, context (e.g., prepositions with location names, verbs), morphology and reference resolution information can be exploited in these rules.

The following *SProUT* rule lt-event (extended $\mathcal{TDL}$ syntax) simply copies the slots of a matched gazetteer entry for events (e.g., a conference) to the output as a recognized named entity.

```
lt-event :> gazetteer &
  [GTYPE lt_event, SURFACE #name,
   CONCEPT #concept, OBJID #objid,
   GABBID #abbrev]
  ->
  ne-event & [EVENTNAME #name,
    CONCEPT #concept, OBJID #objid,
    GABBID #abbrev].
```

OBJID contains the object identifier of the instance in the ontology. It can be used as a link back to the full knowledge stored in the ontology, e.g., for subsequent queries, like *Who else participated in project* [*with OBJID obj_4789*]*?*.

In case multiple instances with same names but different object IDs occur in the ontology (which actually happens to be the case in LT World), multiple alternatives are generated as output which is probably the expected and desired behavior (e.g., for frequent names such as John Smith). On the other hand, if product or event names with an abbreviated variant exist in the ontology, they both point to the same object ID (provided they are stored appropriately in the ontology).

4 Application to hybrid deep-shallow parsing

We now describe and exemplify how the named entities enriched with ontology information are employed in a robust, hybrid deep-shallow architecture, combining domain-specific shallow named entity recognition with deep, broad-coverage, domain-independent, unification-based parsing for generating a semantic representation of the meaning of parsed sentences. An application of this scenario is deep question analysis for question answering of structured knowledge sources, encoded as an OWL ontology (Frank et al., 2007).

The output of *SProUT* for a recognized named entity is a typed feature structure in XML containing the instantiated RHS of the recognition rule as shown in step 3 (Section 3.3) with the copied structured gazetteer data, plus some additional information like character span, named entity type, etc. The mapping of recognized named entities to generic lexicon entries of the deep grammar, in this case the English Resource Grammar (Flickinger, 2002), for hybrid processing are performed through an XSLT stylesheet, automatically generated from the *SProUT* type hierarchy. Analogous mappings are supported for other grammars available in the DELPH-IN repository (see http://www.delph-in.net). The mapping basically transports the surface string, a character span, and a generic lexicon type of the deep grammar for a chart item to be generated in an XML format, readable by the deep parser. A sample output of the semantic representation generated by the deep parser is shown in Figure 1. The semantic representation format, called RMRS, is described in (Copestake, 2003) and in Section 5.3 below.

In addition to the basic named entity type mapping for default lexicon entries, the recognized concepts are also useful for constraining the semantic sort in the deep grammar in a more fine-grained way (e.g., for disambiguation). The deep parser's XML input chart format foresees "injection" of such types into deep structures. Here, OBJID and other structured information, like given name and surname, can be preserved in the representation. The advantage of the RMRS format is that it can also be combined *ex post* with analyses from other deep or shallow NLP components, e.g., with partial analyses when a full parse fails.

5 (R)MRS2OWL: from $\mathcal{TDL}$ to OWL

This section is devoted to the translation of MRSs which are encoded as TFSs into a set of OWL expressions. An example of a variant of MRS, a so-called robust MRS (RMRS) has already been depicted in Figure 1. RMRS will be explained in more detail in Section 5.3.

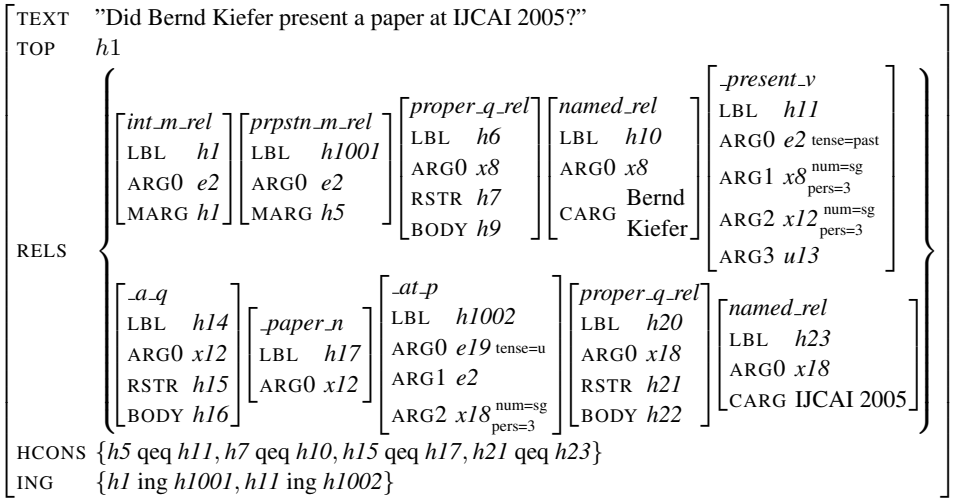

Figure 1: RMRS generated through hybrid parsing.

5.1 Some words on MRSs

There exist good linguistic reasons for assuming that the semantics of a sentence like *Kim ate a cookie* is not $past(eat(kim', cookie'))$, but instead something like $\exists e \ . \ eating(e) \wedge subject(e, kim') \wedge object(e, cookie') \wedge before(e, now)$. This approach to NL semantics is often called *Event* or *Davidsonian* semantics (named after the American philosopher Donald Davidson). HPSG has incorporated ideas from event semantics by defining so-called Minimal Recursion Semantics (MRS) structures (Copestake et al., 2005) that are constructed in parallel with the syntactic structure. MRS as such provides a flat compositional semantics and maximizes splitting using equality constraints. Structural ambiguities, as can be found in the famous sentence *Every farmer who owns a donkey beats it*, are not spelled out, but instead quantifier scope is underspecified. By imposing constraints on the scope, specific analysis trees can be reconstructed. Robust MRS (RMRS) (Copestake, 2003), derived from MRS, was designed as an abstract language that supports the integration of partial and total analysis results from deep and shallow processors and provides a good tradeoff between robustness and accuracy (see (Frank et al., 2004) for an example).

5.2 Why the translation is useful

NL processors (e.g., tokenizer, POS tagger, shallow chunk parser, deep parser, etc.) that are geared towards (R)MRSs (or another common language) have the potential of combining their output on the level of semantics. However, these engines do *not* provide any form of reasoning, i.e., they only build up structure.

Consider, for instance, a deep unification-based parser that might return analyses represented as typed feature structures, where both syntax and semantics (the MRS) has been constructed with the help of unification. Now, to bring structures together and to perform deductive and abductive forms of reasoning, subsequent computational steps are necessary, but these steps strictly go beyond the power of ordinary parsing.

In order to perform these subsequent steps, we need a concrete implemented (and hopefully standardized) representation language for which editing, displaying, and reasoning tools are available. Exactly OWL accomplishes these requirements. Hence we think that the described below translation process from (R)MRSs into OWL is worthwhile, especially when one is interested in interfacing linguistic knowledge (the (R)MRSs) with extralinguistic ontologies for specific domains.

5.3 The translation process

In order to explain the translation process, we will analyze the RMRS depicted in Figure 1. The RMRS was derived from the MRS of the deep unification-based parser. We see that an RMRS contains four distinguished attributes (the `TEXT` attribute is only added for illustration):

1. `TOP`: a handle (pointer) to the top-level structure.

2. `RELS` (relations): a set of so-called *elementary predications* (EP), encoded as TFSs, each expressing an atomic semantic unit that can not be

further decomposed; due to the lack of sets, TFS grammars use a list here.

3. HCONS (handle constraints): a set of so-called *qeq constraints* (equality modulo quantifiers); the left side of a qeq constraints (a handle h in an argument position) is always related to a label l of an EP, (i) either directly ($h = l$) or (ii) indirectly, in case h dominates a quantifier q, such that $\texttt{BODY}(q) = l$ or again another quantifier, where condition (ii) is recursively applied again.

4. ING (in group): a set of relations used to express a conjunction of EPs from the set RELS.

Giving this information, it should now be clear that the TFS from Figure 1 must be realized as an instance of the OWL class RMRS and that the features TOP and RELS must be implemented as roles in OWL, all defined on RMRS through the use of rdfs:domain:

```
<owl:Class rdf:ID="RMRS"/>
<owl:ObjectProperty rdf:ID="TOP">
  <rdf:type rdf:resource=
     "&owl;FunctionalProperty"/>
  <rdfs:domain rdf:resource="#RMRS"/>
  <rdfs:range rdf:resource=
     "#HandleVar"/>
</owl:ObjectProperty>
<owl:ObjectProperty rdf:ID="RELS">
  <rdfs:domain rdf:resource="#RMRS"/>
  <rdfs:range rdf:resource="#EP"/>
</owl:ObjectProperty>
```

TOP takes exactly one argument, hence we use OWL's FunctionalProperty characteristics mechanism here. Since RELS (as well as HCONS and ING, see below) might take more than one argument, we do not impose a property restriction here, so they are relational by default. TOP maps to a special variable class (see below), and RELS to EPs.

TOP. The TOP property always takes a handle variable; other variable classes, such as label vars are used for restricting properties:

```
<owl:Class rdf:ID="Var"/>
<owl:Class rdf:ID="HandleVar">
  <rdfs:subClassOf rdf:resource=
     "#Var"/>
</owl:Class>
<owl:Class rdf:ID="LabelVar">
  <rdfs:subClassOf rdf:resource=
     "#Var"/>
</owl:Class>
```

Actually, this modelling is mere window-dressing and clearly verbose, since an OWL instance of class RMRS is always assigned a name (<RMRS rdf:ID="...">), and in fact, this name can be taken to be the TOP handle. This means that we can in principle forbear from the TOP property. However, if we want to utilize morpho-syntactical information in subsequent inference steps, we have to enrich the above variable classes with further properties/roles, such as tense, pers, or num (see, e.g., the "structured" variables in the structure for _present_v in Figure 1).

RELS. Elements of RELS, i.e., concrete EPs are essentially "slimed" instances of feature structure types. Overall, this means that we have to represent the relevant types of the linguistic type hierarchy and their subsumption relationship as OWL classes. As shown in Section 3, this process can be automated and only some guidance from a knowledge engineer is necessary to mark the features that should *not* be taken over to the DL side.

HCONS and ING. HCONS essentially specifies a ternary relation, but since OWL (and DL in general) are restricted to unary and binary relations, one way to model a qeq constraint is to define a binary property, consisting of a left-hand and a right-hand side. From what has been said above, the left-hand side is a handle and the right-hand side a label, hence we have the following declaration for qeq:

```
<owl:ObjectProperty rdf:ID="qeq">
  <rdfs:domain rdf:resource=
     "#HandleVar"/>
  <rdfs:range rdf:resource=
     "#LabelVar"/>
</owl:ObjectProperty>
```

Given this way of modelling, it is now *impossible* to define a property HCONS (as well as ING) on class RMRS, since properties can only take instances of classes, but not instances of other *properties*. However, since we assume that our variables (instances of class Var) are always unique at runtime, it is in principle not necessary to group the qeq constraint *inside* an (R)MRS—note that there is still a connection between EPs and qeq constraints through the use of variables. However, if we want to talk about/want to access the qeq constraints of a specific (R)MRS instance directly, this kind of modelling is somewhat unhandy.

To overcome this seemingly wrong representation (we are neutral about this), we have to "reify" or "wrap" qeq property instances. This would mean that qeq would no longer be a property, but instead becomes a class, say QEQ, consisting of a right-hand and a left-hand side. With this in mind, we can easily model, e.g., the first qeq constraint qeq1 from the above figure:

```
<RMRS rdf:ID="rmrs1">
  <TOP  rdf:resource="#h1"/>
  <RELS rdf:resource="#ep1"/>
  <HCONS rdf:resource="#qeq1"/>
```

```
  ...
</RMRS>
<QEQ rdf:ID="qeq1">
  <LHS rdf:resource="#h5"/>
  <RHS rdf:resource="#h11"/>
</QEQ>
<HandleVar rdf:ID="h1"/>
<HandleVar rdf:ID="h5"/>
<LabelVar rdf:ID="h11"/>
<int_m_rel rdf:ID="ep1">
  <LBL rdf:resource="#h1"/>
  <ARG0 rdf:resource="#e2"/>
  <MARG rdf:resource="#h1"/>
</int_m_rel>
```

What we have said about qeq constraints so far do hold for in-group constraints as well.

6 DL reasoning: a small example

We have already said that the OWL representation of RMRS structures are a good starting point to implement some useful forms of reasoning. Consider the sentence *Did Bernd Kiefer present a paper at IJCAI 2005?* from Figure 1. From the resulting EPs and with the help of an in-group constraint, we can infer the fact that Bernd Kiefer was (physically) at IJCAI 2005, assuming he has presented a paper (which he did). The inference rule achieving this can be stated informally as *presenting a paper at a conference entails being at the conference*. A more formal representation in terms of feature structures is given in Figure 2.

Clearly this rule can be rewritten to operatate on OWL expressions (as is proposed in SWRL (Horrocks et al., 2004)) or on the underlying RDF triple notation (which, for instance, OWLIM (Kiryakov, 2006) assumes). Note the use of logical variables in the above rule in order to formulate the transport of information from the LHS to the RHS. The above rule abstract away from concrete persons and locations through the use of logic variables $?p$ and $?l$. Note further that the resulting RHS output structure is no longer a RMRS but a domain-specific representation (somewhat simplified in this example) that can be queried for or can be employed in subsequent reasoning tasks.

In (Frank et al., 2007), an implemented approach is described that utilizes an *additional* frame representation layer (Ruppenhofer et al., 2006) in which rules of the above kind are applied, using the term rewriting system of (Crouch, 2005).

7 Summary

Our paper returned to mind that there exists a close relationship between feature logics as used in computational linguistics and description logics employed in the Semantic Web community. This relationship can be utilized to obtain more and better semantic annotations through information extraction and deep parsing of text documents. We have indicated that specific language constructs in FL and DL can be mutally transformed without losing any meaning, whereas others can only be approximated (esp., role-value maps/reentrencies and functional features/relational roles).

We have described an implemented procedure that maps ontology instances and concepts to named entity recognition and information extraction resources. As argued in the paper, the benefits for minimized domain-specific and linguistic knowledge engineering are manifold. An application using hybrid shallow and deep NL processing on the basis of the mapped ontology data has been successfully implemented for question answering. This application (Frank et al., 2007) employs an additional frame semantics layer (cf. Section 6) on which light forms of reasoning take place. In order to make this additional layer superflous, we have described a transformation scheme that maps (R)MRS into OWL descriptions. Given these descriptions, rules of the above kind (Section 6) can directly operate on OWL, and no additional translation is necessary to query the instance data, encoded in RDF/OWL.

Generating Simulated Relevance Feedback: A Prognostic Search approach

Nithin Kumar M and **Vasudeva Varma**
Search and Information Extraction Lab,
International Institute of Information Technology Hyderabad,

Abstract

Implicit relevance feedback has proved to be a important resource in improving search accuracy and personalization. However, researchers who rely on feedback data for testing their algorithms or other personalization related problems are loomed with problems like unavailability of data, staling up of data and so on. Given these problems, we are motivated towards creating a synthetic user relevance feedback data, based on insights from query log analysis. We call this simulated feedback. We believe that simulated feedback can be immensely beneficial to web search engine and personalization research communities by greatly reducing efforts involved in collecting user feedback. The benefits from "Simulated feedback" are - it is easy to obtain and also the process of obtaining the feedback data is repeatable, customizable and does not need the interactions of the user. In this paper, we describe a simple yet effective approach for creating simulated feedback. We have evaluated our system using the clickthrough data of the users and achieved 77% accuracy in generating click-through data.

1 Introduction

Implicit relevance feedback serves as a great source of information about user behaviour and search context. A lot of research went through in the recent past in making use of this great pool of information. Relevance feedback is proven to significantly improve retrieval performance (Harman, 1992; Salton and Buckley, 1990). It has also been successfully used to improve searching ranking, query expansion, personalization, user profiling et cetera (Steve Fox et al.,, 2005; Rocchio, 1999; Xuehua et al., 2005).

Clickthrough data is the most prevalent form of implicit feedback used by researchers for personalization purposes. Click log data provides valuable information about the interests, preferences and semantic search intent of the user (Daniel and Levinson, 2004; Kelly and Belkin, 2001). Unlike explicit feedback, clicks logs do not require any special effort from the user (Rocchio, 1999). It is collected in the background while the user interacts with the search engine to quench his information need. Hence, it is easy and feasible to collect large amounts of clickthrough data.

However, using clickthrough data has its own share of problems. Firstly, it is not available for public or even research communities at large for reasons like being a potential threat to privacy of web users. Secondly, it only contains the URLs of the results that the user clicked and does not contain the documents that the user has chosen. Given the dynamic nature of the web, content of many of the urls is prone to change and in some cases it might not exist. In other cases, even if the old expected results remain good resources, search engines might not retrieve them in response to queries. It will return near-duplicate pages that have equivalent content but different URLs. Thus feedback data may rapidly become stale with new pages replacing old ones as more approporiate resources. And also, given the rapidly changing ranking algorithms of web search engines, feed-

Coling 2008: Poster Volume, pages 597–604,
Beijing, August 2010

back data collected from the users becomes outdated. Hence researchers who rely on feedback data either for testing their algorithms or other personalization related problems are faced with the problems of non-availability of user feedback data.

In this paper, we strive to address the above problems by generating simulated relevance feedback using prognostic search techniques. *Prognostic search* is a process of simulating user's search process and emulating their actions, through preferences captured in their profile. Such generated feedback can be used for research in personalization techniques and analyzing personalization algorithms and search ranking functions(Harman, 1988). The main advantage with this system is that we can create data on the fly and hence not fear of it becoming stale. Since it does not involve user's actions, it is feasible to generate large amounts of data in this way.

2 Contributions and Organization

In this paper, we propose a novel way of creating simulated feedback. The data thus produced can be used for evaluating/training personalization systems. Using our proposed method, given a user's training data, we can produce synthetic implicit feedback data - simulated feedback data on the fly. We also propose a novel user browsing model which extends the high performing cascade model of (Craswell et al., 2008). Our *Patience* parameter can be used to build more complex user browsing models to bring the whole process of generating implicit feedback data a step nearer to the real world mechanisms.

In section 3, we describe our approach to generate simulated feedback data. In sections 3.2.3 and 3.2.4, we describe the process of browsing results and generating clicks which form the crux of our approach. We evaluate our system and prove the usefulness of it in section 4. Section 5 and 6 give an account of our experiments and the study of works related to ours already present in the literature. We conclude that our proposed approach can be highly useful in personalization research and give an account of our future directions in section 7.

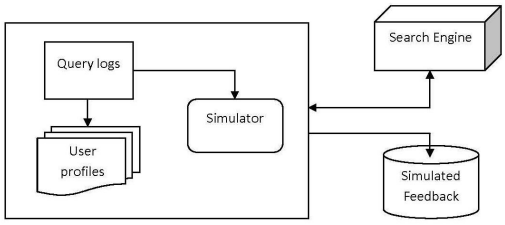

Figure 1: System architecture

3 Proposed Approach

Simulated feedback is a new type of feedback similar to implicit and explicit relevance feedback. Simulated feedback is created by observing and analyzing real world search log data. We propose a two phase process to create simulated relevance feedback as follows: In phase 1, we process real world click-through data of a search engine and build user profiles using the data. In phase 2, we simulate a user's search process and emulate their actions based on their profile. We call this process as "*Prognostic Search*".

3.1 Creating Profiles

After closely examining and analyzing the semantics of the query log, we have chosen the following parameters to characterize a user: an anonymous user-id, *perceived relevance threshold*, *patience*, previous queries issued and search history of the user.

A user-id is used to distinguish and uniquely identify each and every user. *Perceived relevance* is the relevance estimate of the result according to the user on examining the title, snippet and the url of the result. And *Perceived relevance threshold* is the threshold limit of *perceived relevance* of a result for the user to click it. *Patience* of the user is the trait which determines the number of clicks and the depth to which the user examines the results. We explain the process of computing a user's patience parameter in detail in section 3.2.3. We stored the previous queries and clicks of the user to capture the preferences of the user.

To make use of the search history, we used the previous queries issued and previous results clicked by the user. We store the titles and snippets of those results to capture the interests of the

user. Here, our aim is to generate implicit relevance feedback which is very close to the real world data. To generate synthetic relevance feedback, we instantiate these parameters with appropriate values using real world data.

3.2 Prognostic Search

Prognostic search is simulation of a user's search process and emulating their actions based on their interests and preferences captured in their user profile. Simulating search process involves four steps viz., i)Query formulation, ii)Searching, iii)Browsing results and iv)Generating Clicks. Each of these processes are explained below.

3.2.1 Query Formulation

Query formulation involves cognitive process of the user and requires background knowledge about the user like their interests, preferences and their knowledge base. It is highly impossible to capture the cognitive thought process of a user and emulate their method of generating a query. To solve this problem, we randomly select a search session from a user's history and send all the queries in it sequentially to the search engine. This helps us to preserve the inter query relations that naturally exist between the subsequent queries in a session.

3.2.2 Searching

This step involves retrieving documents relevant to the query generated in the previous step. We used yahoo search engine which is very much similar to the search engine from which the training data is collected.

3.2.3 Browsing results

In this step, we simulate the manner in which a user browses the results in the real world. Based on the observations in (Granka et al., 2004; Filip and Joachims, 2005), we assume that the user in the real world follows the browsing model explained in Algorithm 1. In real world, a user may follow more complex browsing models, but presently we have considered this browsing model to simplify things.

Accordingly, to simulate the browsing process of the user explained in algorithm 1, we followed the Algorithm 2.

Algorithm 1 User browsing model in real world

Step1: Start browsing with the top-most result.
Step2: Examine title, snippet and URL of the result.
Step3: Click if the result looks promising.
Step4: If(user has patience) go to step 5, else go to step 6.
Step5: Select next result and go to step 2.
Step6: Start examining the clicked results.
Step7: If(information need satisfied) end the process, else go to step 8.
Step8: Reformulate the query and go to step 1.

Algorithm 2 Simulated User browsing model

Step 1: Determine the number of results to be browsed based on *patience* parameter.
Step 2: Browse the results in increasing order of their ranks and examine them.
Step 3: Compute the perceived relevance score of the results.
Step 4: In the same order, generate clicks based on the perceived relevance scores of the results.
Step 5: If(session has more queries) go to step 6, else end the process.
Step 6: Select next query in the session and go to step 1.

Thus based on the *patience* parameter, we determine the number of results that the user browses. In our analysis of query log parameters, we learned that the *patience* value of a user can be characterized by the following parameters: number of clicks per session, maximum rank of the result clicked in a session, time spent in a session, the number of queries issued per second and the average semantic relevance of the top ten results of that session to the user. We found out that the patience of the user is directly proportional to the maximum rank of the result he has clicked in a session. We also found out that the number of clicks a user generates is inversely proportional to the number of queries he issues per second and directly proportional to the amount of time he spends per session. Thus, a user with

more *patience* tends to examine more search results and thus generate more clicks based on their relevance. We explain these dependencies in detail in the experiments section. So in order to learn the Patience parameter of the user, we devised the following formula:

$$\text{Patience} = \alpha \times \frac{(MR \times T \times C \times S_{q_i})}{Q} \quad (1)$$

Here MR denotes the average of maximum rank of the results clicked by the user in a session, T denotes the average time spent in a session, C is the average number of clicks in a session and Q denotes the average number of queries issued per session and S_{q_i} is the average semantic distance of the top ten results of the query 'q_i'. Here, "α'' is an equalization constant.

3.2.4 Generating clicks

This is the most important step in our simulation process. Typically, a user observes the visual information viz., title, snippet and the URL of a result(Joachims et al., 2005). Then based on their interests, they choose the results relevant to them. Similarly, we closely examine the results selected in the previous step and then score them according to their relevance to the user. We consider the title, snippet and the page-rank of the result and determine its relevance to the user known as *perceived relevance* score.

We first compute the semantic distance between the title and snippet of the present result from the titles and snippets of previously clicked results of the user. The results already clicked by the user serve as a knowledge base of the interests and preferences of the user. Thus, the semantic distance between the present result and the previous result gives us an account of the relevance that the present result carries to the user.

We used latent semantic analysis (LSA) to compute the semantic distance between the results. LSA does not take the dictionary meaning of the words as input; it rather extracts the contextual meaning of the word with respect to all other words in semantic space(Landauer et al., 2007). This property of LSA is very much useful in the present context. A particular word may have a lot of meanings but we are concerned about only those meanings of the word which the user interprets, which are captured in the sentences present in the user's click history. Hence, we used LSA to compute the semantic distance between the results.

We also consider the page-rank of the result, which has proven to be an important factor in making the decision of a click. In our study, we found that for about 89% of the queries with clicks, the top ranked document has been clicked and for 56% of the queries second ranked document has been clicked. In Figure 3, we show the click ratio for each of the top ten ranked documents[1]. Thereby, we derive that the rank of the result is also a very important factor in deciding whether a result has to be clicked or not. We also consider the distance of the present result from the previous click of the user. In (Joachims et al., 2005), it is shown that the user is more biased to click the result that immediately follows the result he previously clicked. In our simulation process, if this distance for any result exceeds 10, then we terminate the browsing process and reformulate the query. We believe that when this distance exceeds 10, it signifies that the quality of the results is low and hence can be ignored.

We used the bayesian probabilistic techniques to calculate the probability of the user clicking a result based on the above discussed factors. Hence *Click* being a Bernoulli variable, we have

$$P(c/R, q, u) = \alpha_{R,q,u}^{c} \left(1 - \alpha_{R,q,u}\right)^{1-c} \quad (2)$$

Where $\alpha_{R,q,u}$ is the probability that user 'u' clicks the result 'R' for a query 'q'. We model the probability of a click, $P\left(c/R, q, u\right)$ as a joint probability of P(c,r,Rel,D) where 'r' denotes the rank of the result, 'Rel' denotes the semantic relevance score of the result to the user – precisely to his previous clicks – and 'D' denotes the distance of the previous click of the user. We use this probability of the result as the *Perceived relevance* score of the result. Thus, we have:

[1] In figure 3, we have normalized the clicks statistics with the number of clicks for top ranked document. So, the click-ratio for the top ranked document will be 1.

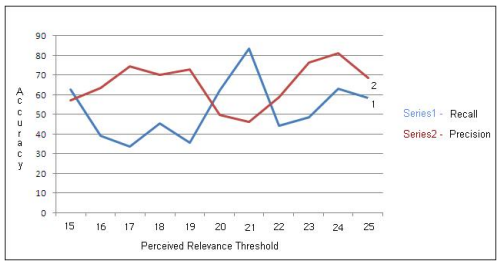

Figure 2: Graph showing Precision and Recall of generating clicks for a particular user

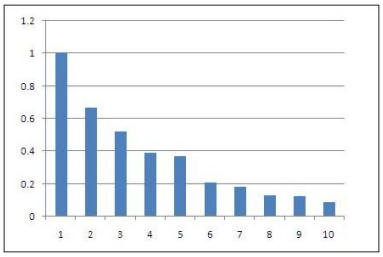

Figure 3: Ranks Vs Clicks-ratio

$$\text{Perceived relevance} = P\left(c/R, q, u\right) = P\left(c/r, Rel, D\right) \propto ln\left[P\left(r/c\right)\right] + ln\left[P\left(Rel/c\right)\right] + ln\left[P\left(D/c\right)\right] + ln\left[P\left(c_{i+1}\right)\right] \quad (3)$$

Here, 'r' denotes the rank of the result, 'Rel' denotes the *perceived relevance* of the result to the user and 'D' denotes the distance of the result from the user's previous clicked result. Prior probablities of each of these factors are calculated from the data stored in the user profile. We used Laplace smoothing techniques to deal with zero probability entries. $P(c_{i+1})$ is the probability that the user may click a result after clicking 'i' results. We also believe that the behaviour of the user changes with each click he generates in a session. Hence we used the factor $P(c_{i+1})$ in determining the probability of the click[2]. Then, we compare this score with the *Perceived relevance threshold* of the user and generate the clicks accordingly.

Computing *Perceived Relevance Threshold*: Using the above formula, we generated clicks for different values of *Perceived Relevance Threshold* for a user. Figure 2 show the precision and recall values of generating clicks for different values of Perceived Relevance Threshold of a user. Thus, we plot the accuracy of our system for different values of *Patience Relevance Threshold* and accordingly set the threshold selecting the best values for precision and recall of the system.

4 Experiments

Clickthrough data is a valuable source of user information. In our statistical analysis of clickthrough data, we have found that the page-rank of a result can highly influence the user to make a click which can be seen in figure 3.

In our definition of *Patience*, we termed it as parameter to denote the depth to which the user examines the results and the number of clicks he generates. In equation 1, we show that the patience value is inversely proportinal to the number of queries the user issues in a session. To prove this fact, we made a statistical analysis on the real world querlogs[3]. From the graphs shown in figure 4, it can be clearly seen that the *Patience* of the user is inversely proportional to the user's number of Queries/sec. These graphs show the influence of the factor Queries/sec on the number of clicks the user generates for a query and the maximum rank clicked by the user in a session. We drew the graphs averaging the different queries/sec value of a user in a session for each value of MR and number of clicks respectively. It is evident that both the graphs are weakly decreasing functions. Since maximum rank clicked and the number of clicks per session directly affect the *Patience* parameter, we can say that Queries/sec is inversely proportional to the *Patience* of the user.

Both the graphs show occasional phases of increasing behaviour which can be attributed to a variety of reasons. While plotting the graphs, for a given value of MR/number of clicks, we take observations from numerous sessions of the user and average the queries/sec value. Thus, presence of some outlier values may affect the overall out-

[2]We used laplace smoothing technique to negate the effect of zero probability instances.

[3]We performed these experiments on the query log data of a popular commerical search engine. The data consists of 21 million web queries collected from 650,000 users. The query log data consists of anonymous id given to the user, query, the time at which the query was posed, rank of the clicked URL (if any) and the URL of the document clicked by the user (if any).

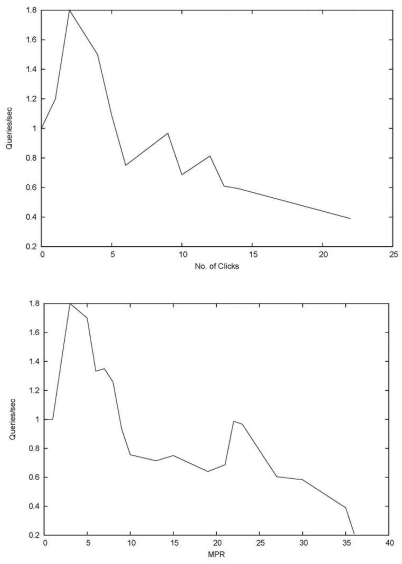

Figure 4: Clicks Vs Queries/sec and MR Vs Queries/sec

put of the graph. It can also be attributed to the low quality of results that the search engine might have returned due to various reasons.

5 Related Work

Although simulation-based methods have been used to test query modification techniques (Harman, 1988) or to detect shifts in the interests of computer users (Mostafa et al., 2003), to our knowledge not much research went into creating relevance feedback for web search based on search simulations.

Searcher simulations were created by White et al (Mostafa et al., 2003; White et al., 2005), for evaluating implicit feedback models. The simulations assume the role of a searcher, browsing the results of a retrieval. It is assumed that the actual relevant and irrelevant documents for a query are given. The system creates simulations of searchers by simulating relevance paths i.e., how the user would traverse results of retrieval. Different strategies were experimented like, the users only view relevant/non-relevant information, i.e., follow relevant paths from only relevant or only non-relevant documents, or they view all relevant or all non-relevant information, i.e., follow all relevance paths from top-ranked relevant documents or top-ranked non-relevant documents etc. Their research tries to model only certain phases of the search process like clicking the results and to some extent the process of looking and identifying the results to click. It also does not consider modeling the nature of the searcher in context and also does not calculate the relevance of a document for a user. The search process is not complete without discussing or characterizing the user that participates in the search and computing the relevance of a document for a user.

In (Agichtein et al.,, 2006), they show that clickthrough data and other implicit data of a user can be used to build user models to effectively personalize the search results. Craswell et al (Craswell et al., 2008) have also done some good work in this area. They try to model the results browsing pattern of the user. (Craswell et al., 2008) brings out the position bias in the user's click-decision making process. It provides some interesting browsing models which can be used in our prognostic search process. We used the cascade model – best performing model – proposed by them to compare the effectiveness of our approach.

In our approach, we address some of these issues to improve the reliability of the simulated feedback and the scalability of the simulations. We first identify certain parameters that are natural to the search process on the whole and are generic to hold well across search engines and users. Wherever applicable we try to characterize these parameters as probabilistic distributions, using large volumes of data from existing search engine clickthrough logs. We then instantiate these parameters by drawing values from these probabilistic distributions. This ensures that the simulated feedback resembles as closely as possible to the real world scenario and thus is of high quality. We can easily run the simulations on large sets of documents to create large amounts of simulated feedback, as there are no interventions of a human to provide any kind of extra information or relevance information on the document set.

6 Evaluation

In this section, we present the evaluation procedure of our approach. We first collected query

Table 1: System Configurations

System	Patience	Clicks
System1	Random	Random
System2	Random	Proposed method
System3	Proposed method	Proposed method

log data of 60 users using a browser plug-in for two months. Our query log data consists user-id, queries and the time at which they are entered, list of search results – rank, title, snippet and url of the result –[4] and the results clicked by the user. We used 70% of this query log data to build profiles of the searchers and the rest of the data is used for evaluation purpose. Using the rest of the query log data, we initiated the prognostic search process giving the queries sequentially in the order given by the user. We compared the simulated clicks with the clicks already generated by the user. We found that the data generated by us is 77% accurate and its recall[5] value is 68%. We measured the accuracy of our system as follows.

$$\text{Accuracy} = \frac{\text{No. of simulated clicks clicked by the user}}{\text{Total no. of results clicked by the user}} \quad (4)$$

We also built two more systems which we considered as the baseline systems. The first system gives a random value for the patience value of the user – random value is used to determine the number of documents to be browsed during the prognostic search process – and random value is given for the user's *Perceived relevance threshold* parameter. The second system generates the patience value of the user according to the process described by us in section 3.2.3 and gives a random value for the *Perceived relevance threshold* value of the user. Systems built by us can be summarized as shown in table 1:

Figure 5 shows a comparision of the accuracies of the three systems. Here, we can see that the

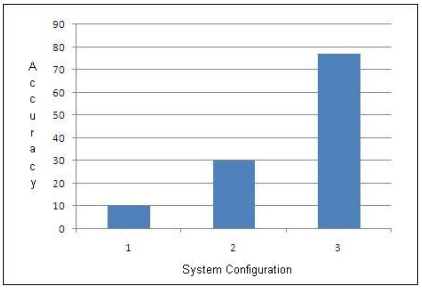

Figure 5: Results comparision

baseline 1 which uses random values for *patience* and *generating clicks* is only 10% accurate in generating clickthrough data. However, with the addition of our *generating clicks* approach to the baseline 1, the performance increased by 200%. And the system 3 which uses our proposed models for both *patience* and *generating clicks* generates 77% accurate data which is a 670% improvement over the baseline 1.

We also performed manual evaluation of our system. Since manual evaluation requires a lot of effort, we performed it using 25 judges. We randomly selected 25 users from our query log data and used their data to build profiles. Then we showed the clicks generated by our system to these users. Based on their judgements, we found our system to be 79.5% accurate[6]. Figure 6 shows the accuracy levels of our system according to different judges. We also studied the reason behind the increase in accuracy of our system during human evaluation. We re-examined the clicks generated by the users and found that the users selected the results which they have not selected during their regular search. And the reasons behind these extra clicks are: they have missed examining these results or they have already reached their desired document. Thus it certifies that our system is able to personalize the results and the perceived relevance technique can be used to re-rank the results to personalize them.

As the *cascade* model is the best performing model in (Craswell et al., 2008), we evaluated our system on that model for comparision. We found our system to be 96% accurate. We used the data collected in our clickthrough logs for evaluating

[4]A typical search engine query log does not contain the snippets of the results and the whole list of search results. It only contains the link clicked by the user and the rank of that result.

[5]Recall is the fraction of results clicked for this query and simulated successfully

[6]We took the average of the accuracies of our system for each of these judges/users.

our system using this model.

7 Conclusion and Future work

In this paper, we proposed Simulated Feedback based on insights from clickthrough data and using prognostic search methods to generate feedback. There is a lot of scope for interesting future directions to the current work. It would be an interesting experiment to see the use of the simulated feedback in evaluation of personalized search algorithms. Consider a personalized search algorithm, and use it to learn a user model from existing explicit/implicit feedback data. Learn a user model using the same algorithm from simulated feedback and compare the results. We plan to pursue the same in future.

As an extension to the current work, we aim to improve the web search process especially the query formulation step with insights from a user study. We are working towards incorporating much richer and complex models for query formulation like HMMs etc. Ability of the system to automatically create query reformulations of the original when no clicks are found is another interesting future work. We also plan to dig more information about the user by analysing the query log data. For example, the difference in the time between the clicks and the distance between the clicks can be used to analyze the browsing behaviour of the user. These observations can inturn be used in generation of simulated feedback thus reducing its gap with real world implicit feedback.

Abstract

This paper presents the novel task of best topic word selection, that is the selection of the topic word that is the best label for a given topic, as a means of enhancing the interpretation and visualisation of topic models. We propose a number of features intended to capture the best topic word, and show that, in combination as inputs to a reranking model, we are able to consistently achieve results above the baseline of simply selecting the highest-ranked topic word. This is the case both when training in-domain over other labelled topics for that topic model, and cross-domain, using only labellings from independent topic models learned over document collections from different domains and genres.

1 Introduction

In the short time since its inception, topic modelling (Blei et al., 2003) has become a mainstream technique for tasks as diverse as multi-document summarisation (Haghighi and Vanderwende, 2009), word sense discrimination (Brody and Lapata, 2009), sentiment analysis (Titov and McDonald, 2008) and information retrieval (Wei and Croft, 2006). For many of these tasks, the multinomial topics learned by the topic model can be interpreted natively as probabilities, or mapped onto a pre-defined discrete class set. However, for tasks where the learned topics are provided to humans as a first-order output, e.g. for use in document collection analysis/navigation, it can be difficult for the end-user to interpret the rich statistical information encoded in the topics. This research is concerned with making topics more readily human interpretable, by selecting a single term with which to label the topic.

Although topics are formally a multinomial distribution over terms, with every term having finite probability in every topic, topics are usually displayed by printing the top-10 terms (i.e. the 10 most probable terms) in the topic. These top-10 terms typically account for about 30% of the topic mass for reasonable setting of number of topics, and usually provide sufficient information to determine the subject area and interpretation of a topic, and distinguish one topic from another.

Our research task can be illustrated via the top-10 terms in the following topic, learned from a book collection. Terms w_i are presented in descending order of $P(w_i|t_j)$ for the topic t_j:

trout fish fly fishing water angler stream rod flies salmon

Clearly the topic relates to fishing, and indeed, the fourth term *fishing* is an excellent label for the topic. The task is thus termed *best word* or *most representative word* selection, as we are selecting the label from the closed set of the top-N topic words in that topic.

Naturally, not all topics are equally coherent, however, and the lower the topic coherence, the more difficult the label selection task becomes. For example:

oct sept nov aug dec july sun lite adv globe

appears to conflate months with newspaper names, and no one of these topic words is able to capture the topic accurately. As such, our methodology presupposes an automatic means of rating topics for coherence. Fortunately, recent research by Newman et al. (2010) has shown that this is achievable at levels approaching human performance, meaning that this is not an unreasonable assumption.

Labelling topics has applications across a diverse range of tasks. Our original interest in the

Coling 2008: Poster Volume, pages 605–613,
Beijing, August 2010

problem stems from work in document collection visualisation/navigation, and the realisation that presenting users with topics natively (e.g. as represented by the top-N terms) is ineffective, and would be significantly enhanced if we could automatically predict succinct labels for each topic. Another application area where labelling has been shown to enhance the utility of topic models is selectional preference learning via topic modelling (Ritter et al., to appear). Here, topic labelling via taxonomic classes (e.g. WordNet synsets) can lead to better topic generalisation, in addition to better human readability.

This paper is based around the assumption that an appropriate label for a topic can be found among the high-ranking (high probability) terms in that topic. We assess the suitability of each term by way of comparison with other high-ranking terms in that same topic, using simple pointwise mutual information and conditional probabilities. We first experiment with a simple ranking method based on the component scores, and then move on to using those scores, along with features from WordNet and from the original topic model, in a ranking support vector regression (SVR) framework. Our experiments demonstrate that we are able to perform the task significantly better than the baseline of selecting the topic word of highest marginal probability, including when training the ranking model on labelled topics from other document collections.

2 Related Work

Predictably, there has been significant work on interpreting topics in the context of topic modelling. Topic are conventionally interpreted via the top-N words in each topic (Blei et al., 2003; Griffiths and Steyvers, 2004), or alternatively by post-hoc manual labelling of each topic based on domain knowledge and subjective interpretation of each topic (Wang and McCallum, 2006; Mei et al., 2006).

Mei et al. (2007) proposed various approaches for automatically suggesting phrasal labels for topics, based on first extracting phrases from the document collection, and subsequently ranking the phrases based on KL divergence with a given topic.

Magatti et al. (2009) proposed a method for labelling topics induced by hierarchical topic modelling, based on ontological alignment with the Google Directory (gDir) hierarchy, and optionally expanding topics based on a thesaurus or WordNet. Preliminary experiments suggest the method has promise, but the method crucially relies on both a hierarchical topic model and a pre-existing ontology, so has limited applicability.

Over the general task of labelling a learned semantic class, Pantel and Ravichandran (2004) proposed the use of lexico-semantic patterns involving each member of that class to learn a (usually hypernym) label. The proposed method was shown to perform well over the semantically homogeneous, fine-grained clusters learned by CBC (Pantel and Lin, 2002), but for the coarse-grained, heterogeneous topics learned by topic modelling, it is questionable whether it would work as well.

The first works to report on human scoring of topics were Chang et al. (2009) and Newman et al. (2010). The first study used a novel but synthetic intruder detection task where humans evaluate both topics (that had an intruder word), and assignment of topics to documents (that had an intruder topic). The second study had humans directly score topics learned by a topic model. This latter work introduced the pointwise mutual information (PMI) score to model human scoring. Following this work, we use PMI as features in the ranking SVR model.

3 Methodology

Our task is to predict which words annotators tend to select as most representative or best words when presented with a list of ten words. Since annotators are not generally unanimous in their choice of best word, we formulate this as a ranking task, and treat the top-1, 2 and 3 system-ranked items as the best words, and compare that to the top-1, 2 and 3 words chosen most frequently by annotators. In this section, we describe the features that may be useful for this ranking task. We start with features motivated by word association.

An obvious idea is that the most representative word should be readily evoked by other words in the topic. For example, given a list of words $\langle$*space, earth, moon, nasa, mission*$\rangle$, which is a

Space Exploration topic, *space* could arguably be the most representative word. This is because it is natural to think about the word *space* after seeing the words *earth, moon* and *nasa* individually. A good candidate for best word could be the word that has high average conditional probability given each of the other words. To calculate conditional probability, we use word counts from the entire collection of English Wikipedia articles. Conditional probability is defined as:

$$P(w_i|w_j) = \frac{P(w_i, w_j)}{P(w_j)},$$

where $i \neq j$ and $P(w_i, w_j)$ is the probability of observing both w_i and w_j in the same sliding window, and $P(w_i)$ is the overall probability of word w_i in the corpus. In the above example, *evoked by* means that *space* would fill the slot of w_i. The average conditional probability for word w_i is given by:

$$\text{avg-CP1}(w_i) = \frac{1}{9}\sum_j P(w_i|w_j),$$

for $j = 1 \ldots 10, j \neq i$ (this range of indices applies to all following average quantities).

In other cases, we have the flip situation, where the most representative word may evoke (rather than be evoked by) other words in the list of ten words. Imagine a *NASCAR Racing* topic, which has a list of words ⟨*race, car, nascar, driver, racing*⟩. Given the word *nascar*, words from the list such as *race, car, racing* and *driver* might come to mind because *nascar* is heavily associated with these words. Therefore, a good candidate, w_i, might also correlate with high $P(w_j|w_i)$. As before, the average conditional probability (here denoted with CP2) for word w_i is given by:

$$\text{avg-CP2}(w_i) = \frac{1}{9}\sum_j P(w_j|w_i).$$

Another approach to measuring word association is by calculating pointwise mutual information (PMI) between word pairs. Unlike conditional probability, PMI is symmetric and thus the order of words in a pair does not matter. We calculate PMI using word counts from English Wikipedia as follows:

$$\text{PMI}(w_i, w_j) \quad = \quad log\frac{P(w_i, w_j)}{P(w_i)P(w_j)}.$$

The average PMI for word w_i is given by:

$$\text{avg-PMI}(w_i) = \frac{1}{9}\sum_j \text{PMI}(w_i, w_j).$$

The topic model produces an ordered list of words for each topic, and the ordering is given by the marginal probability of each word given that topic, $P(w_i|t_j)$. The ranking of words based on these probabilities indicates the importance of a word in a topic, and it is also a feature that we use for predicting the most representative word.

We also observe that sometimes the most representative words are generalized concepts of other words. As such, hypernym relations could be another feature that may be relevant to predicting the best word. To this end, we use WordNet to find hypernym relations between pairs of words in a topic and obtain a set of boolean-valued relationships for each topic word.

Our last feature is the distributional similarity scores of Pantel et al. (2009), as trained over Wikipedia.[1] This takes the form of representing the distributional similarity between each pairing of terms $\text{sim}(w_i|w_j)$; if w_i is not in the top-200 most similar terms for a given w_j, we assume it to have a similarity of 0.

While the above features can be used alone to get a ranking on the ten topic words, we can also use various combinations of features in a reranking model such as support vector regression (SVM^{rank}: Joachims (2006)). Applying the features described above — conditional probabilities, PMI, WordNet hypernym relations, the topic model word rank, and Pantel's distributional similarity score — as features for SVM^{rank}, a ranking of words is produced and candidates for the most representative word are selected by choosing the top-ranked words.

Figure 1: Selected topics from the two collections (each line is one topic, with fewer than ten topic words displayed because of limited space)

Features	Description
PMI	Pointwise mutual information
CP1	Conditional probability $P(w_i\|*)$
CP2	Conditional probability $P(*\|w_i)$
TM Rank	Original topic model word rank
Hypernym	WordNet hypernym relationships
PDS	Pantel distributional similarity score

Table 1: Description of feature sets

4 Datasets

We used two collections of text documents from different genres for our experiments. The first collection (NEWS) was created by selecting 55,000 news articles from the LDC Gigaword corpus. The second collection (BOOKS) was 12,000 English language books selected from the Internet Archive American Libraries collection. The NEWS and BOOKS collections provide a diverse range of content for topic modeling. In the first case – news articles from the past decade written by journalists — each article usually attempts to clearly and concisely convey information to the reader, and hence the learned topics tend to be fairly interpretable. For BOOKS (with publication dates spanning more than a century), the writing style often uses lengthy and descriptive prose, so one sees a different style to the learned topics.

The input to the topic model is a bag-of-words representation of the collection of text documents, where word counts are preserved, but word order is lost. After performing fairly standard tokenization and limited lemmatisation, and creating a vocabulary of terms that occurred at least ten times, each corpus was converted into its bag-of-words representation. We learned topic models for the two collections, choosing a setting of $T = 200$ topics for NEWS and $T = 400$ topics for BOOKS. After computing the PMI-score for each topic (according to Newman et al. (2010)), we selected 60 topics with high PMI-score, and 60 topics with low PMI-score, from both corpora, resulting in a total of 240 topics for human evaluation.

The 240 topics selected for human scoring were each evaluated by between 10 and 20 users. For the two topic models, we used the conventional approach of displaying each topic with its top-10 terms. In a typical survey, a user was asked to evaluate anywhere from 60 to 120 topics. The instructions asked the user to perform the following tasks, for each topic in the survey: (a) score the topic for "usefulness" or "coherence" on a scale of 1 to 3; and (b) select the single best word that exemplifies the topic (when score=3).

From both NEWS and BOOKS, the 40 topics with the highest average human scores had relatively complete data for the 'best word' selection task (i.e. every time a user gave a topics score=3, they also selected a 'best word'). The remainder of this paper is concerned with the 40 NEWS topics and 40 BOOKS topics where we had 'best word' data from the annotators. Sample topics from these two sets are given in Figure 1.

To measure presentational bias (i.e. the extent to which annotators tend to choose a word seen earlier rather than later, particularly when armed with the knowledge that words are presented in order of probability), we reissued a survey using the 40 NEWS topics to ten additional annotators, but this time the top-10 topic words were presented in random order. Again, these ten new annotators were asked to select the best word.

5 Experiments

We used average PMI and conditional probabilities, CP1 and CP2, to rank the ten words in each topic. Candidates for the best words were selected by choosing the top-1, 2 and 3 ranked words.

We used the following weighted scoring function for evaluation:

$$\text{Best-N score} = \frac{\sum_{i=1}^{N} n(w_{\text{rev}_i})}{\sum_{i=1}^{N} n(w_i)}$$

Features	Best-1	Best-2	Best-3
Baseline	0.38	0.48	0.60
PMI	0.25	0.38	0.49
CP1	0.30	0.38	0.47
CP2	0.15	0.30	0.49
Upper bound	0.64	—	—

Table 3: Best-1,2,3 scores for ranking with single feature sets (PMI and both conditional probabilities) for BOOKS

where w_{rev_i} is the i^{th} term ranked by the system and w_i is the i^{th} most popular term selected by annotators; rev_i gives the index of the word w_i in the annotator's list; and $n(w)$ is the number of votes given by annotators for word w.

The baseline is obtained using the original word rank produced by the topic model based on topic word probabilities $P(w_i|t_j)$. An upperbound is calculated by evaluating the decision of an annotator against others for each topic. This upperbound signifies the maximum accuracy for human annotators on average; since the annotators were asked to pick a single best word in the survey, only the Best-1 upperbound can be obtained.

The Best-1/2/3 results are summarized in Table 2 for NEWS and Table 3 for BOOKS. These Best-N scores are computed just using the single feature of PMI, CP1 and CP2 (each in turn) to rank the words in each topic. None of these features alone produces a result that exceeds baseline performance.

To make better use of all the features described in Section 3, namely the PMI score, conditional probabilities (both directions), topic model word rank, WordNet Hypernym relationships and Pantel's distributional similarity score, we build a ranking classifier using SVM^{rank} and evaluating

Feature Set	Best-1	Best-2	Best-3

Upper bound	0.64	—	—

Table 5: SVR-based best topic word results for BOOKS for all six feature types, and feature ablation over each (numbers in brackets show the relative change over the full feature set)

using 10-fold cross validation. Our first approach is to use the entire set of features to train the classifier. Following this, we also measure the effect of each feature by ablating (removing) one feature at a time. The drop in Best-N score indicates which features are the strongest predictors of the best words (a larger drop in score indicates that feature is more important). The results for Best-1, Best-2 and Best-3 scores are summarized in Table 4 for NEWS, and Table 5 for BOOKS (averaged across the 10 iterations of cross validation).

We then produced a condensed set of features, consisting of the conditional probabilities, the original topic model word rank and the WordNet hypernym relationships. This "best" set of features is used to make predictions of best words. Results are improved in most cases, and are summarized in Table 6 for both NEWS and BOOKS.

Dataset		Best-1	Best-2	Best-3
NEWS	Baseline	0.35	0.50	0.59
	Best Feat. Set	0.45	0.50	0.65
	Upper bound	0.48	—	—

BOOKS upper bound	0.64	—	—

Table 7: Results for cross-domain learning

We also tested whether the SVM classifier could be trained using data from one domain, and run on data from another domain. Using our two datasets as these different domains, we trained a model using BOOKS data and made predictions for NEWS, and then we trained a model using NEWS data and made predictions for BOOKS.

The results, shown in Table 7, indicate that we are still able to outperform the baseline, even when the ranking classifier is trained on a different domain. In fact, when we trained a model using NEWS, we saw almost no drop in performance for predicting best words for BOOKS, and improvement is seen for Best-2 score from NEWS. This implies that the SVM classifier generalizes well across domains and suggests the possibility of having a fixed training model to predict best words for any data.

In these experiments, topic words are presented in the original order that the topic model produces, i.e. in descending order of probability of a word under a topic $P(w_i|t_j)$. We noticed that the first words of the topics are frequently selected as the best words by annotators, and suspected that this was introducing a bias towards the first word. As our baseline scores are derived from this topic word ordering, such a bias could give rise to an artificially high baseline.

To investigate this effect, we ran a second annotation exercise over the same set of topics (but different annotators), to obtain a new set of best word annotations for NEWS, with the topic words presented in random order. In Figure 2, we plot the cumulative proportion of words selected as best word by the annotators across the topics, in the case of the random topic word order, mapping the topic words back onto their original ranks in the topic model. A slight drop can be observed in the proportion of first- and second-ranked topic words being selected when we randomise the topic word order. When we recalculate the baseline accuracy for NEWS on the basis of the new set of annotations, we observe an appreciable drop in the scores (see Table 8).

Word Order	Best-1	Best-2	Best-3
Original	0.35	0.50	0.59
Randomized	0.23	0.33	0.46

6 Discussion

From the experiments in Section 5, perhaps the first thing to observe is: (a) the high performance of the baseline, and (b) the relatively low (Best-1) upper bound accuracy for the task. The first is perhaps unsurprising, given that it represents the

topic model's own interpretation of the word(s) which are most representative of that topic. In this sense, we have set our sights high in attempting to better the baseline. The upper bound accuracy is a reflection of both the inter-annotator agreement, and the best that we can meaningfully expect to do for the task. That is, any result higher than this would paradoxically suggest that we are able to do better at a task than humans, where we are evaluating ourselves relative to the labellings of those humans. The upper bound for NEWS was slightly less than 0.5, indicating that humans agree on the best topic word only 50% of the time. To better understand what is happening here, consider the following topic from Figure 1:

health drug patient medical doctor hospital care cancer treatment disease

This is clearly a coherent topic, but at least two topic words suggest themselves as labels: *health* and *medical*. By way of having between 10 and 20 annotators (uniquely) label a given topic, and interpreting the multiple labellings probabilistically, we are side-stepping the inter-annotator agreement issue, but ultimately, for the Best-1 evaluation, we are forced to select one term only, and consider any alternative to be wrong. Because annotators selected only one best topic word, we unfortunately have no way of performing Best-2 or Best-3 upper bound evaluation and deal with topics such as this, but would expect the numbers to rise appreciably.

Looking at the original feature rankings in Tables 2 and 3, no clear picture emerges as to which of the three methods (PMI, CP1 and CP2) was most successful, but there were certainly clear differences in the relative numbers for each, pointing to possible complementarity in the scoring. This expectation was born out in the results for the reranking model in Tables 4 and 5, where the combined feature set surpassed the baseline in all cases, and feature ablation tended to lead to a drop in results, with the single most effective feature set being CP1 ($P(w_i|*)$), followed by CP2 ($P(*|w_i)$) and topic model rank. The lexical semantic features of WordNet hypernymy and PDS (Pantel's distributional similarity) were the worst performers, often having no or negative impact on the results.

Comparing the best results for the SVR-based reranking model and the upper bound Best-1 score, we approach the upper bound performance for NEWS, but are still quite a way off with BOOKS when training in-domain. This is encouraging, but a slightly artificial result in terms of the broader applicability of this research, as what it means in practical terms is that if we can access multi-annotator best word labelling for the majority of topics in a given topic model, we can use those annotations to predict the best word for the remainder of the topics with reasonably success. When we look to the cross-domain results, however, we see that we almost perfectly replicate the best-achieved Best-1, Best-2 and Best-3 in-domain results for BOOKS by training on NEWS (making no use of the annotations for BOOKS). Applying the annotations for BOOKS to NEWS is less successful in terms of Best-1 accuracy, but we actually achieve higher Best-2, and largely mirror the Best-3 results as compared to the best of the in-domain results in Table 6. This leads to the much more compelling conclusion that we can take annotations from an independent topic model (based on a completely unrelated document collection), and apply them to successfully model the best topic word for a new topic model, without requiring any additional annotation. As we now have two sets of topics multiply-annotated for best words, this result suggests that we can perform the best topic word selection task with high success over novel topic models.

We carried out manual analysis of topics where the model did particularly poorly, to get a sense for how and where our model is being led astray. One such example is the topic:

race car nascar driver racing cup winston team gordon season

where the following topic words were selected by our annotators: *nascar* (8 people), *race* (2 people), and *racing* (2 people). First, we observe the split between *race* and *racing*, where more judicious lemmatisation/stemming would make both the annotation easier and the evaluation cleaner. The SVR model tends to select more common, general terms, so in this case chose *race* as the best word, and ranked *nascar* third. This is one

instance were *nascar* evokes all of the other words effectively, but not conversely (*racing* is associated with many events/sports beyond *nascar*, e.g.).

Another topic where our model had difficulty was:

window nave aisle transept chapel tower arch pointed arches roof

where our best model selected *nave*, while the human annotators selected *chapel* (6 people), *arch* (2 people), *nave*, *roof*, *tower* and *transept* (1 person each). Clearly, our annotators struggled to come up with a best word here, despite the topic again being coherent. This is an obvious candidate for labelling with a hypernym/holonym of the topic words (e.g. *church* or *church architecture*), and points to the limitations of best word labelling — there are certainly many topics where best word labelling works, as our upper bound analysis demonstrated, but there are equally many topics where the most natural label is not found in the top-ranked topic words. While this points to slight naivety in the current task set up — we are forcing annotators to label words with topic words, where we know that this is sub-optimal for a significant number of topics — we contend that our numbers suggest that: (a) consistent best topic word labelling is possible at least 50% of the time; and (b) we have developed a method which is highly adept at labelling these topics. As a way forward, we intend to relax the constraint on the topic label needing to be based on a topic word, and explore the possibility of predicting which topics are best labelled with topic words, and which require independent labels. For topics which can be labelled with topic words, we can use the methodology developed here, and for topics where this is predicted to be sub-optimal, we intend to build on the work of Mei et al. (2007), Pantel and Ravichandran (2004) and others in selecting phrasal/hypernym labels for topics. We are also interested in applying the methodology proposed herein to the closely-related task of intruder word, or *worst* topic word, detection, as proposed by Chang et al. (2009).

Finally, looking to the question of the impact of the presentation order of the topic words on best word selection, it would appear that our baseline is possibly an over-estimate (based on Table 8). Having said that, the flipside of the bias is that it leads to more consistency in the annotations, and tends to help in tie-breaking of examples such as *race* and *racing* from above, for example. In support of this claim, the upper bound Best-1 accuracy of the randomised annotations, relative to the original gold-standard is 0.44, slightly below the original upper bound for NEWS. More work is needed to determine the real impact of this bias on the overall task setup and evaluation.

7 Conclusion

This paper has presented the novel task of best topic word selection, that is the selection of the topic word that is the best label for a given topic. We proposed a number of features intended to capture the best topic word, and demonstrated that, while they were relatively unsuccessful in isolation, in combination as inputs to a reranking model, we were able to consistently achieve results above the baseline of simply selecting the highest-ranked topic word, both when training in-domain over other labelled topics for that topic model, and cross-domain, using only labellings from independent topic models learned over document collections from different domains and genres.

A Linguistically Grounded Graph Model for Bilingual Lexicon Extraction

Florian Laws, Lukas Michelbacher, Beate Dorow, Christian Scheible, Ulrich Heid, Hinrich Schütze
Institute for Natural Language Processing
Universität Stuttgart
{lawsfn,michells,dorowbe}@ims.uni-stuttgart.de

Abstract

We present a new method, based on graph theory, for bilingual lexicon extraction without relying on resources with limited availability like parallel corpora. The graphs we use represent linguistic relations between words such as adjectival modification. We experiment with a number of ways of combining different linguistic relations and present a novel method, multi-edge extraction (MEE), that is both modular and scalable. We evaluate MEE on adjectives, verbs and nouns and show that it is superior to cooccurrence-based extraction (which does not use linguistic analysis). Finally, we publish a reproducible baseline to establish an evaluation benchmark for bilingual lexicon extraction.

1 Introduction

Machine-readable translation dictionaries are an important resource for bilingual tasks like machine translation and cross-language information retrieval. A common approach to obtaining bilingual translation dictionaries is *bilingual lexicon extraction* from corpora. Most work has used *parallel text* for this task. However, parallel corpora are only available for few language pairs and for a small selection of domains (e.g., politics). For other language pairs and domains, monolingual comparable corpora and monolingual language processing tools may be more easily available. This has prompted researchers to investigate bilingual lexicon extraction based on monolingual corpora (see Section 2) .

In this paper, we present a new graph-theoretic method for bilingual lexicon extraction. Two monolingual graphs are constructed based on syntactic analysis, with words as nodes and relations (such as adjectival modification) as edges. Each relation acts as a similarity source for the node types involved. All available similarity sources interact to produce one final similarity value for each pair of nodes. Using a seed lexicon, nodes from the two graphs can be compared to find a translation.

Our main contributions in this paper are: (i) we present a new method, based on graph theory, for bilingual lexicon extraction without relying on resources with limited availability like parallel corpora; (ii) we show that with this graph-theoretic framework, information obtained by linguistic analysis is superior to cooccurrence data obtained without linguistic analysis; (iii) we experiment with a number of ways of combining different linguistic relations in extraction and present a novel method, multi-edge extraction, which is both modular and scalable; (iv) progress in bilingual lexicon extraction has been hampered by the lack of a common benchmark; we therefore publish a benchmark and the performance of MEE as a baseline for future research.

The paper discusses related work in Section 2. We then describe our translation model (Section 3) and multi-edge extraction (Section 4). The benchmark we publish as part of this paper is described in Section 5. Section 6 presents our experimental results and Section 7 analyzes and discusses them. Section 8 summarizes.

2 Related Work

Rapp (1999) uses word cooccurrence in a vector space model for bilingual lexicon extraction. Details are given in Section 5.

Fung and Yee (1998) also use a vector space approach, but use TF/IDF values in the vector components and experiment with different vector similarity measures for ranking the translation candidates. Koehn and Knight (2002) combine

Coling 2008: Poster Volume, pages 614–622,
Beijing, August 2010

a vector-space approach with other clues such as orthographic similarity and frequency. They report an accuracy of .39 on the 1000 most frequent English-German noun translation pairs.

Garera et al. (2009) use a vector space model with dependency links as dimensions instead of cooccurring words. They report outperforming a cooccurrence vector model by 16 percentage points accuracy on English-Spanish.

Haghighi et al. (2008) use a probabilistic model over word feature vectors containing cooccurrence and orthographic features. They then use canonical correlation analysis to find matchings between words in a common latent space. They evaluate on multiple languages and report high precision even without a seed lexicon.

Most previous work has used vector spaces and (except for Garera et al. (2009)) cooccurrence data. Our approach uses linguistic relations like subcategorization, modification and coordination in a graph-based model. Further, we evaluate our approach on different parts of speech, whereas some previous work only evaluates on nouns.

3 Translation Model

Our model has two components: (i) a graph representing words and the relationships between them and (ii) a measure of similarity between words based on these relationships. Translation is regarded as cross-lingual word similarity. We rank words according to their similarity and choose the top word as the translation.

We employ undirected graphs with typed nodes and edges. Node types represent parts of speech (POS); edge types represent different kinds of relations. We use a modified version of SimRank (Jeh and Widom, 2002) as a similarity measure for our experiments (see Section 4 for details).

SimRank is based on the idea that two nodes are similar if their neighbors are similar. We apply this notion of similarity across two graphs. We think of two words as translations if they appear in the same relations with other words that are translations of each other. Figure 1 illustrates this idea with verbs and nouns in the direct object relation. Double lines indicate *seed* translations, i.e., known translations from a dictionary (see Section 5). The nodes *buy* and *kaufen* have the same

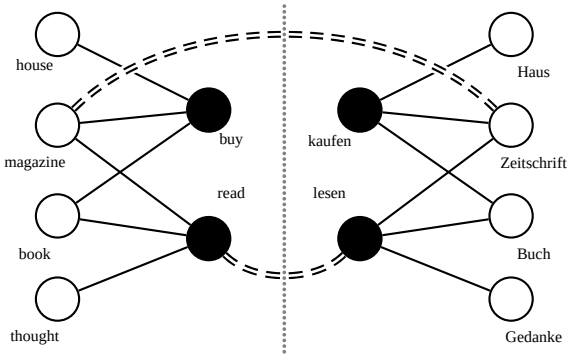

Figure 1: Similarity through seed translations

objects in the two languages; one of these (*magazine – Zeitschrift*) is a seed translation. This relationship contributes to the similarity of *buy – kaufen*. Furthermore, *book* and *Buch* are similar (because of *read – lesen*) and this similarity will be added to *buy – kaufen* in a later iteration. By repeatedly applying the algorithm, the initial similarity introduced by seeds spreads to all nodes.

To incorporate more detailed linguistic information, we introduce typed edges in addition to typed nodes. Each edge type represents a linguistic relation such as verb subcategorization or adjectival modification. By designing a model that combines multiple edge types, we can compute the similarity between two words based on *multiple sources* of similarity. We superimpose different sets of edges on a fixed set of nodes; a node is not necessarily part of every relation.

The graph model can accommodate any kind of nodes and relations. In this paper we use nodes to represent content words (i.e., non-function words): adjectives (a), nouns (n) and verbs (v). We extracted three types of syntactic relations from a corpus: see Table 1.

Nouns participate in two bipartite relations (amod, dobj) and one unipartite relation (ncrd). This means that the computation of noun similarities will benefit from three different sources.

Figure 2 depicts a sample graph with all node and edge types. For the sake of simplicity, a monolingual example is shown. There are four nouns in the sample graph all of which are (i) modified by the adjectives *interesting* and *political* and (ii) direct objects of the verbs *like* and

relation	entities	description	example
used in this paper			
amod	a, n	adjectival modification	a *fast car*
dobj	v, n	object subcategorization	*drive* a *car*
ncrd	n, n	noun coordination	*car*s and *buss*es
other possible relations			
vsub	v, n	subject subcategorization	a *man sleep*s
poss	n, n	possessive	the *child's toy*
acrd	a, a	adjective coordination	*red* or *blue* car

Table 1: Relations used in this paper (top) and possible extensions (bottom).

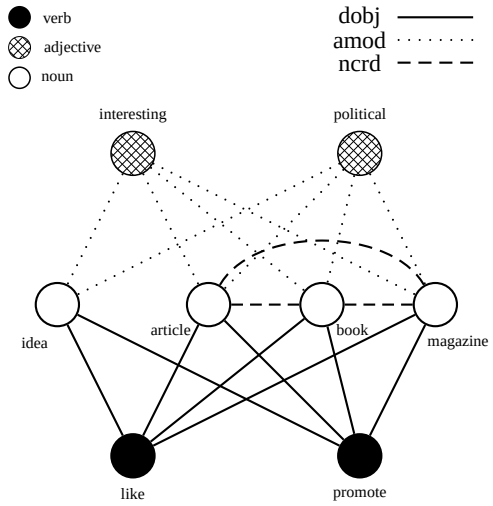

Figure 2: Graph snippet with typed edges

promote. Based on amod and dobj, the four nouns are equally similar to each other. However, the greater similarity of *article*, *book*, and *magazine* to each other can be deduced from the fact that these three nouns also occur in the relation ncrd. We exploit this information in the MEE method.

Data and Preprocessing. Our corpus in this paper is the Wikipedia. We parse all German and English articles with BitPar (Schmid, 2004) to extract verb-argument relations. We extract adjective-noun modification and noun coordinations with part-of-speech patterns based on a version of the corpus tagged with TreeTagger (Schmid, 1994). We use lemmas instead of surface forms. Because we perform the SimRank matrix multiplications in memory, we need to filter out rare words and relations; otherwise, running SimRank to convergence would not be feasible. For adjective-noun pairs, we apply a filter on pair frequency (≥ 3). We process noun pairs by applying a frequency threshold on words (≥ 100) and pairs (≥ 3). Verb-object pairs (the smallest data set) were not frequency-filtered. Based on the resulting frequency counts, we calculate association scores for all relationships using the log-likelihood measure (Dunning, 1993). For noun pairs, we discard all pairs with an association score < 3.84 (significance at $\alpha = .05$). For all three relations, we discard pairs whose observed frequency was smaller than their expected frequency (Evert, 2004, p. 76). As a last step, we further reduce noise by removing nodes of degree 1. Key statistics for the resulting graphs are given in Table 2.

We have found that accuracy of extraction is poor if unweighted edges are used. Using the log-likelihood score directly as edge weight gives too much weight to "semantically weak" high-frequency words like *put* and *take*. We therefore use the logarithms of the log-likelihood score as edge weights in all SimRank computations reported in this paper.

Table 2: Node and edge statistics

4 SimRank

Our work is based on the SimRank graph similarity algorithm (Jeh and Widom, 2002). In (Dorow et al., 2009), we proposed a formulation of SimRank in terms of matrix operations, which can be applied to (i) weighted graphs and (ii) bilingual problems. We now briefly review SimRank and its bilingual extension. For more details we refer to (Dorow et al., 2009).

The basic idea of SimRank is to consider two nodes as similar if they have similar neighborhoods. Node similarity scores are recursively computed from the scores of neighboring nodes: the similarity S_{ij} of two nodes i and j is computed

as the normalized sum of the pairwise similarities of their neighbors:

$$S_{ij} = \frac{c}{|N(i)|\ |N(j)|} \sum_{k \in N(i), l \in N(j)} S_{kl}.$$

where $N(i)$ and $N(j)$ are the sets of i's and j's neighbors. As the basis of the recursion, S_{ij} is set to 1 if i and j are identical (self-similarity). The constant c ($0 < c < 1$) dampens the contribution of nodes further away. Following Jeh and Widom (2002), we use $c = 0.8$. This calculation is repeated until, after a few iterations, the similarity values converge.

For bilingual problems, we adapt SimRank for comparison of nodes across two graphs A and B. In this case, i is a node in A and j is a node in B, and the recursion basis is changed to $S(i, j) = 1$ if i and j are a pair in a predefined set of node-node equivalences (seed translation pairs).

$$S_{ij} = \frac{c}{|N_A(i)|\ |N_B(j)|} \sum_{k \in N_A(i), l \in N_B(j)} S_{kl}.$$

Multi-edge Extraction (MEE) Algorithm To combine different information sources, corresponding to edges of different types, in one SimRank computation, we use multi-edge extraction (MEE), a variant of SimRank (Dorow et al., 2009). It computes an aggregate similarity matrix after each iteration by taking the average similarity value over all edge types $\mathcal{T}$:

$$S_{ij} = \frac{c}{|\mathcal{T}|} \sum_{t \in \mathcal{T}} \frac{1}{f(|N_{A,t}(i)|) f(|N_{B,t}(j)|)} \sum_{\substack{k \in N_{A,t}(i), \\ l \in N_{B,t}(j)}} S_{kl}.$$

f is a normalization function (either $f = g$, $g(n) = n$ as before or the normalization discussed in the next section).

While we have only reviewed the case of unweighted graphs, the extended SimRank can also be applied to weighted graphs. (See (Dorow et al., 2009) for details.) In what follows, all graph computations are weighted.

Square Root Normalization Preliminary experiments showed that SimRank gave too much influence to words with few neighbors. We therefore modified the normalization function $g(n) = n$. To favor words with more neighbors, we want f to grow sublinearly with the number of neighbors. On the other hand, it is important that, even for nodes with a large number of neighbors, the normalization term is not much smaller than $|N(i)|$, otherwise the similarity computation does not converge. We use the function $h(n) = \sqrt{n} * \sqrt{\max_k(|N(k)|)}$. h grows quickly for small node degrees, while returning values close to the linear term for large node degrees. This guarantees that nodes with small degrees have less influence on final similarity scores. In all experiments reported in this paper, the matrices $\tilde{A}$, $\tilde{B}$ are normalized with $f = h$ (rather than using the standard normalization $f = g$). In one experiment, accuracy of the top-ranked candidate (acc@1) was .52 for h and .03 for g, demonstrating that the standard normalization does not work in our application.

Threshold Sieving For larger experiments, there is a limit to scalability, as the similarity matrix fills up with many small entries, which take up a large amount of memory. Since these small entries contribute little to the final result, Lizorkin et al. (2008) proposed *threshold sieving*: an approximation of SimRank using less space by deleting all similarity values that are below a threshold. The quality of the approximation is set by a parameter δ that specifies maximum acceptable difference of threshold-sieved similarity and the exact solution. We adapted this to the matrix formulation by integrating the thresholding step into a standard sparse matrix multiplication algorithm.

We verified that this approximation yields useful results by comparing the ranks of exact and approximate solutions. We found that for the high-ranked words that are of interest in our task, sieving with a suitable threshold does not negatively affect results.

5 Benchmark Data Set

Rapp's (1999) original experiment was carried out on newswire corpora and a proprietary Collins dictionary. We use the free German (280M tokens) and English (850M tokens) Wikipedias as source and target corpora. Reinhard Rapp has generously provided us with his 100 word test set

	n	a	v
training set	.61	.31	.08
TS100	.65	.28	.07
TS1000	.66	.14	.20

Table 3: Percentages of POS in test and training

(TS100) and given us permission to redistribute it. Additionally, we constructed a larger test set (TS1000) consisting of the 1000 most frequent words from the English Wikipedia. Unlike the noun-only test sets used in other studies, (e.g., Koehn and Knight (2002), Haghighi et al. (2008)), TS1000 also contains adjectives and verbs. As seed translations, we use a subset of the dict.cc online dictionary. For the creation of the subset we took raw word frequencies from Wikipedia as a basis. We extracted all verb, noun and adjective translation pairs from the original dictionary and kept the pairs whose components were among the $5{,}000$ most frequent nouns, the $3{,}500$ most frequent adjectives and the 500 most frequent verbs for each language. These numbers are based on percentages of the different node types in the graphs. The resulting dictionary contains $12{,}630$ pairs: $7{,}767$ noun, $3{,}913$ adjective and 950 verb pairs. Table 3 shows the POS composition of the training set and the two test sets. For experiments evaluated on TS100 (resp. TS1000), the set of 100 (resp. 1000) English words it contains and all their German translations are removed from the seed dictionary.

Baseline. Our baseline is a reimplementation of the vector-space method of Rapp (1999). Each word in the source corpus is represented as a word vector, the dimensions of which are words of seed translation pairs. The same is done for corpus words in the target language, using the translated seed words as dimensions. The value of each dimension is determined by association statistics of word cooccurrence. For a test word, a vector is constructed in the same way. The labels on the dimensions are then translated, yielding an input vector in the target language vector space. We then find the closest corpus word vector in the target language vector space using the city block distance measure. This word is taken as the translation of the test word.

We went to great lengths to implement Rapp's method, but omit the details for reasons of space. Using the Wikipedia/dict.cc-based data set, we achieve 50% acc@1 when translating words from English to German. While this is somewhat lower than the performance reported by Rapp, we believe this is due to Wikipedia being more heterogeneous and less comparable than news corpora from identical time periods used by Rapp.

Publication. In conjunction with this paper we publish the benchmark for bilingual lexicon extraction described. It consists of (i) two Wikipedia dumps from October 2008 and the linguistic relations extracted from them, (ii) scripts to recreate the training and test sets from the dict.cc data base, (iii) the TS100 and TS1000 test sets, and (iv) performance numbers of Rapp's system and MEE. These can serve as baselines for future work. Note that (ii)–(iv) can be used independently of (i) – but in that case the effect of the corpus on performance would not be controlled. The data and scripts are available at `http://ifnlp.org/wiki/extern/WordGraph`

6 Results

In addition to the vector space baseline experiment described above, we conducted experiments with the SimRank model. Because TS100 only contains one translation per word, but words can have more than one valid translation, we manually extended the test set with other translations, which we verified using dict.cc and leo.org. We report the results separately for the original test set ("strict") and the extended test set in Table 4. We also experimented with *single*-edge models consisting of three separate runs on each relation.

The accuracy columns report the percentage of test cases where the correct translation was found among the top 1 (acc@1) or top 10 (acc@10) candidate words found by the translation models. Some test words are not present in the data at all; we count these as 0s when computing acc@1 and acc@10. The acc@10 measure is more useful for indicating topical similarity while acc@1 measures translation accuracy.

MRR is Mean Reciprocal Rank of correct translations: $\frac{1}{n}\sum_i^n \frac{1}{\text{rank}_i}$ (Voorhees and Tice, 1999). MRR is a more fine-grained measure than acc@n,

	TS100, strict			TS100, extended			TS1000		
	acc@1	acc@10	MRR	acc@1	acc@10	MRR	acc@1	acc@10	MRR
baseline	.50	.67	.56	.54	.70	.60	.33	.56	.41
single	.44	.67	.52	.49	.68	.56	.40‡	.70‡	.50
MEE	.52	.79†	.62	.58	.82†	.68	**.48**‡	.76‡	.58

Table 4: Results compared to baseline*

e.g., it will distinguish ranks 2 and 10. All MRR numbers reported in this paper are consistent with acc@1/acc@10 and support our conclusions.

The results for acc@1, the measure that most directly corresponds to utility in lexicon extraction, show that the SimRank-based models outperform the vector space baseline – only slightly on TS100, but significantly on TS1000. Using the various relations separately (single) already yields a significant improvement compared to the baseline. Using all relations in the integrated MEE model further improves accuracy. With an acc@1 score of 0.48, MEE outperforms the baseline by .15 compared to TS1000. This shows that a combination of several sources of information is very valuable for finding the correct translation.

MEE outperforms the baseline on TS1000 for all parts of speech, but performs especially well compared to the baseline for adjectives and verbs (see Table 5). It has been suggested that vector space models perform best for nouns and poorly for other parts of speech. Our experiments seem to confirm this. In contrast, MEE exhibits good performance for nouns and adjectives and a marked improvement for verbs.

On acc@10, MEE is consistently better than the baseline, on both TS100 and TS1000. All three differences are statistically significant.

6.1 Relation Comparison

Table 5 compares baseline, single-edge and MEE accuracy for the three parts of speech covered. Each single-edge experiment can compute noun similarity; for adjectives and verbs, only amod, dobj and MEE can be used.

Performance for nouns varies greatly depending on the relation used in the model. ncrd performs best, while dobj shows the worst performance. We hypothesize that dobj performs badly because (i) many verbs are semantically non-restrictive with respect to their arguments, (e.g., *use*, *contain* or *include*) and as a result semantically unrelated nouns become similar because they share the same verb as a neighbor; (ii) light verb constructions (e.g., *take a walk* or *give an account*) dilute the extracted relations; and (iii) dobj is the only relation we extracted with a syntactic parser. The parser was trained on newswire text, a genre that is very different from Wikipedia. Hence, parsing is less robust than the relatively straightforward POS patterns used for the other relations.

Similarly, many semantically non-restrictive adjectives such as *first* and *new* can modify virtually any noun, diluting the quality of the amod source. We conjecture that ncrd exhibits the best performance because there are fewer semantically non-restrictive nouns than non-restrictive adjectives and verbs.

MEE performance for nouns (.45) is significantly better than that of the single-edge models. The information about nouns that is contained in the verb-object and adjective-noun data is integrated in the model and helps select better translations. This, however, is only true for the noun

		noun	adj	verb	all
TS100	baseline	.55	.43	.29	.50
	amod	.15	.71	-	.30
	ncrd	.34	-	-	.22
	dobj	.02	-	.43	.04
	MEE	.45	.71	.43	.52
TS1000	baseline	.42	.26	.18	.33
	MEE	.53	.55	.27	.48

Table 5: Relation comparison, acc@1

*We indicate statistical significance at the $\alpha = 0.05$ (†) and 0.01 level (‡) when compared to the baseline. We did not calculate significance for MRR.

source	acc@1	acc@10
dobj	.02	.10
amod	.15	.37
amod+dobj	.22	.43
ncrd+dobj	.32	.65
ncrd	.34	.60
ncrd+amod	.49	.74
MEE	.45	.77

Table 6: Accuracy of sources for nouns

node type, the "pivot" node type that takes part in edges of all three types. For adjectives and verbs, the performance of MEE is the same as that of the corresponding single-edge model.

We ran three additional experiments each of which combines only two of the three possible sources for noun similarity, namely ncrd+amod, ncrd+dobj and amod+dobj and performed strict evaluation (see Table 6). We found that in general combination increases performance except for ncrd+dobj vs. ncrd. We attribute this to the lack of robustness of dobj mentioned above.

6.2 Comparison MEE vs. All-in-one

An alternative to MEE is to use untyped edges in one large graph. In this *all-in-one* model (AIO), we connect two nodes with an edge if they are linked by any of the different linguistic relations. While MEE consists of small adjacency matrices for each type, the two adjacency matrices for AIO are much larger. This leads to a much denser similarity matrix taking up considerably more memory. One reason for this is that AIO contains similarity entries between words of different parts of speech that are 0 (and require no memory in a sparse matrix representation) in MEE.

Since AIO requires more memory, we had to filter the data much more strictly than before to be able to run an experiment. We applied the following stricter thresholds on relationships to obtain a small graph: 5 instead of 3 for adjective-noun pairs, and 3 instead of 0 for verb-object pairs, thereby reducing the total number of edges from 2.1M to 1.4M. We also applied threshold sieving (see Section 4) with $\delta = 10^{-10}$ for AIO. The results on TS100 (strict evaluation) are reported in Table 7. For comparison, MEE was also run on the smaller graph. Performance of the two models is very similar, with AIO being slightly better (not significant). The slight improvement does not justify the increased memory requirements. MEE is able to scale to more nodes and edge types, which allows for better coverage and performance.

	$\textbf{MEE}_{small}$	$\textbf{AIO}_{small}$
acc@1	.51	.52
acc@10	.72	.75
MRR	.62	.59

Table 7: MEE vs. AIO

7 Analysis and Discussion

Error analysis. We examined the cases where a reference translation was not at the top of the suggested list of translation candidates. There are a number of elements in the translation process that can cause or contribute to this behavior.

Our method sometimes picks a cohyponym of the correct translation. In many of these cases, the correct translation is in the top 10 (together with other words from the same semantic field). For example, the correct translation of *moon*, *Mond*, is second in a list of words belonging to the semantic field of celestial phenomena: Komet *(comet)*, **Mond** *(moon)*, Planet *(planet)*, Asteroid *(asteroid)*, Stern *(star)*, Galaxis *(galaxy)*, Sonne *(sun)*, ... While this behavior is undesirable for strict lexicon extraction, it can be exploited for other tasks, e.g. cross-lingual semantic relatedness (Michelbacher et al., 2010).

Similarly, the method sometimes puts the antonym of the correct translation in first place. For example, the translation for *swift* (*schnell*) is in second place behind *langsam* (*slow*). Based on the syntactic relations we use, it is difficult to discriminate between antonyms and semantically similar words if their syntactic distributions are similar.

Ambiguous source words also pose a problem for the system. The correct translation of *square* (the geometric shape) is *Quadrat*. However, 8 out of its top 10 translation candidates are related to the *location* sense of *square*. The other two are geometric shapes, *Quadrat* being listed second. This is only a concern for strict evaluation, since correct translations of a different sense were included in the extended test set.

bed is also ambiguous (piece of furniture vs. river bed). This introduces translation candidates from the geographical domain. As an additional source of errors, a number of *bed*'s neighbors from the furniture sense have the German translation *Bank* which is ambiguous between the furniture sense and the financial sense. This ambiguity in the target language German introduces spurious translation candidates from the financial domain.

Discussion. The error analysis demonstrates that most of the erroneous translations are words that are incorrect, but that are related, in some obvious way, to the correct translation, e.g. by cohyponymy or antonymy. This suggests another application for bilingual lexicon extraction. One of the main challenges facing statistical machine translation (SMT) today is that it is difficult to distinguish between minor errors (e.g., incorrect word order) and major errors that are completely implausible and undermine the users' confidence in the machine translation system. For example, at some point Google translated "sarkozy sarkozy sarkozy" into "Blair defends Bush". Since bilingual lexicon extraction, when it makes mistakes, extracts closely related words that a human user can understand, automatically extracted lexicons could be used to discriminate smaller errors from grave errors in SMT.

As we discussed earlier, parallel text is not available in sufficient quantity or for all important genres for many language pairs. The method we have described here can be used in such cases, provided that large monolingual corpora and basic linguistic processing tools (e.g. POS tagging) are available. The availability of parsers is a more stringent constraint, but our results suggest that more basic NLP methods may be sufficient for bilingual lexicon extraction.

In this work, we have used a set of seed translations (unlike e.g., Haghighi et al. (2008)). We believe that in most real-world scenarios, when accuracy and reliability are important, seed lexica will be available. In fact, seed translations can be easily found for many language pairs on the web. Although a purely unsupervised approach is perhaps more interesting from an algorithmic point of view, the semisupervised approach taken in this paper may be more realistic for applications.

In this paper, we have attempted to reimplement Rapp's system as a baseline, but have otherwise refrained from detailed comparison with previous work as far as the accuracy of results is concerned. The reason is that none of the results published so far are easily reproducible. While previous publications have tried to infer from differences in performance numbers that one system is better than another, these comparisons have to be viewed with caution since neither the corpora nor the gold standard translations are the same. For example, the paper by Haghighi et al. (2008) (which demonstrates how orthography and contextual information can be successfully used) reports 61.7% accuracy on the 186 most confident predictions of nouns. But since the evaluation data sets are not publicly available it is difficult to compare other work (including our own) with this baseline. We simply do not know how methods published so far stack up against each other.

For this reason, we believe that a benchmark is necessary to make progress in the area of bilingual lexicon extraction; and that our publication of such a benchmark as part of the research reported here is an important contribution, in addition to the linguistically grounded extraction and the new graph-theoretical method we present.

8 Summary

We have presented a new method, based on graph theory, for bilingual lexicon extraction without relying on resources with limited availability like parallel corpora. We have shown that with this graph-theoretic framework, information obtained by linguistic analysis is superior to cooccurrence data obtained without linguistic analysis. We have presented multi-edge extraction (MEE), a scalable graph algorithm that combines different linguistic relations in a modular way. Finally, progress in bilingual lexicon extraction has been hampered by the lack of a common benchmark. We publish such a benchmark with this paper and the performance of MEE as a baseline for future research.

Abstract

Statistical word alignment often suffers from data sparseness. Part-of-speeches are often incorporated in NLP tasks to reduce data sparseness. In this paper, we attempt to mitigate such problem by reflecting alignment tendency between part-of-speeches to statistical word alignment. Because our approach does not rely on any language-dependent knowledge, it is very simple and purely statistic to be applied to any language pairs. End-to-end evaluation shows that the proposed method can improve not only the quality of statistical word alignment but the performance of statistical machine translation.

1 Introduction

Word alignment is defined as mapping corresponding words in parallel text. A word aligned parallel corpora are very valuable resources in NLP. They can be used in various applications such as word sense disambiguation, automatic construction of bilingual lexicon, and statistical machine translation (SMT). In particular, the initial quality of statistical word alignment dominates the quality of SMT (Och and Ney 2000; Ganchev et al., 2008); almost all current SMT systems basically refer to the information inferred from word alignment result.

One of the widely used approaches to statistical word alignment is based on the IBM models (Brown et al., 1993). IBM models are constructed based on words' co-occurrence and positional information. If sufficient training data are given, IBM models can be successfully applied to any language pairs. However, for minority language pairs such as English-Korean and Swedish-Japanese, it is very difficult to obtain large amounts of parallel corpora. Without sufficient amount of parallel corpus, it is very difficult to learn the correct correspondences between words that infrequently occur in the training data.

Part-of-speeches (POS), which represent morphological classes of words, can give valuable information about individual words and their neighbors. Identifying whether a word is a noun or a verb can let us predict which words are likely to be mapped in word alignment and which words are likely to occur in its vicinity in target sentence generation.

Many studies incorporate POS information in SMT. Some researchers perform POS tagging on their bilingual training data (Lee et al., 2006; Sanchis and Sánchez, 2008). Some of them replace individual words as new words, such as in "word/POS" form, producing new, extended vocabulary. The advantage of this approach is that POS information can help to resolve lexical ambiguity and thus improve translation quality.

On the other hand, Koehn et al. (2007) propose a factored translation model that can incorporate any linguistic factors including POS information in phrase-based SMT. The model provides a generalized representation of a translation model, because it can map multiple source and target factors.

Although all of these approaches are shown to improve SMT performance by utilizing POS information, we observe that the influence is virtually marginal in two ways:

Coling 2008: Poster Volume, pages 623–629,
Beijing, August 2010

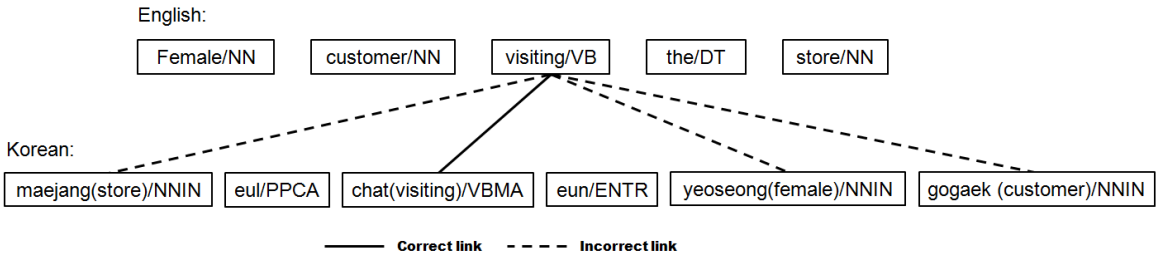

Figure 1. An example of inaccurate word alignment

1) The POS information tagged to each word may help to disambiguate in selecting word correspondences, but the increased vocabulary can also make the training data more sparse.
2) The factored translation model may help to effectively handle out-of-vocabulary (OOV) by incorporating many linguistic factors, but it still crucially relies on the initial quality of word alignment that will dominate the translation probabilities.

This paper focuses on devising a better method for incorporating POS information in word alignment. It attempts to answer the following questions:

1) Can the information regarding POS alignment tendency affect the post-processing of word alignment?
2) Can the result of word alignment affected by such information help improving the quality of SMT?

2 POS Alignment Tendency

Despite the language pairs, words with similar POSs often correspond to each other in statistical word alignment. Similarly, words with different POSs are seldom aligned. For example, Korean proper nouns very often align with English proper nouns very often but seldom align with English adverbs. We believe that this phenomenon occurs not only on English-Korean pairs but also on most of other language pairs.

Thus, in this study we hypothesize that all source language (SL) POSs have some relationship with target language (TL) POSs. Figure 1 exemplifies some results of using the IBM Models in English-Korean word alignment. As can be seen in the figure, the English word "*visiting*" is incorrectly and excessively aligned to four Korean morphemes "*maejang*", "*chat*", "*yeoseong*", and "*gogaek*". One reason for this is the sparseness of the training data; the only correct Korean morpheme "*chat*" does not sufficiently co-occur with "*visiting*" in the training data. However, it is generally believed that an English verb is more likely aligned to a Korean verb rather than a Korean noun. Likewise, we suppose that among many POSs, there are strong relationships between similar POSs and relatively weak relationships between different POSs. We hypothesize that the discovery of such relationships in advance can lead to better word alignment results.

In this paper, we propose a new method to obtain the relationship from word alignment results. The relationships among POSs, henceforth the POS alignment tendency, can be identified by the probability of the given POS pairs' alignment result where the source language POS and the target language POS co-occur in bilingual sentences. We formulate this idea using the maximum likelihood estimation as follows:

$$P\big(align = true \big| pos(f), pos(e)\big) = \frac{count(align = true | pos(f), pos(e))}{\sum_{k\in\{true,false\}} count(align = k, pos(f), pos(e))}$$

where f and e denote source word and target word respectively. *count()* is a function that returns the number of co-occurrence of f and e when they are aligned (or not aligned). Then, we adjust the formula with the existing alignment score between f and e.

$$Score(f,e) = \lambda P_{IBM}(f|e) + (1-\lambda)P\big(align = true \big| pos(f), pos(e)\big)$$

where $P_{IBM}(f \mid e)$ indicates the alignment probability estimated by the IBM models. λ is a weighting parameter to interpolate the reliabilities of both alignment factors. In the expe-

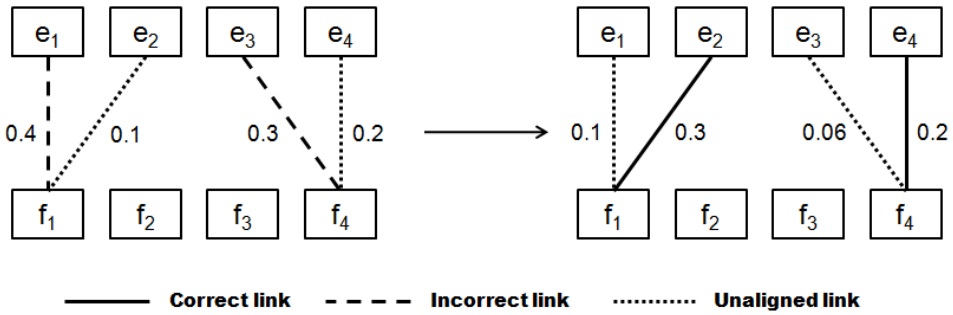

Figure 2. An example of word alignment modification

riment, λ is empirically set to improve the word alignment performance (λ=0.5).

3 Modifying Alignment

Based on the new scoring scheme as introduced in the previous section, we modify the result of the initial word alignment. The modification is performed in the following procedure:

1. For each source word *f* that has out-bound alignment link other than *null*,
2. Find the target word *e* that has the maximum alignment score according to the proposed alignment adjustment measure, and change the alignment result by mapping *f* to *e*.

This modification guarantees that the number of alignment does not change; the algorithm is designed to minimize the risk by maintaining the fertility of a word estimated by the IBM Model. Figure 2 illustrates the result before and after the alignment modification. Incorrectly links from e_1 and e_3 are deleted and missing links from e_2 and e_4 are generated during this alignment modification.

The alignment modification through the reflection of POS alignment tendency is performed on both *e*-to-*f* and *f*-to-*e* bidirectional word alignments. The bidirectional word alignment results are then symmetrized.

4 Experiments

In this paper, we attempt to reflect the POS alignment tendency in improving the word alignment performance. This section provides the experimental setup and the results that demonstrate whether the proposed approach can improve the statistical word alignment performance.

We collected bilingual texts from major bilingual news broadcasting sites. 500K sentence pairs are collected and refined manually to construct correct parallel sentences pairs. The same number of monolingual sentences is also used from the same sites to train Korean language. We also prepared a subset of the bilingual text with the size of 50K to show that the proposed model is very effective when the training set is small.

In order to evaluate the performance of word alignment, we additionally constructed a reference set with 400 sentence pairs. The evaluation is performed using precision, recall, and F-score. We use the GIZA++ toolkit for word alignment as well as four heuristic symmetrizations: intersection, union, grow-diag-final, and grow-diag (Och, 2000).

4.1 Word Alignment

We now evaluate the effectiveness of the proposed word alignment method. Table 1 and 2 report the experimental results by adding POS information to the parallel corpus. “Lexical” denotes the result of conventional word alignment produced by GIZA++. No pre-processing or post-processing is applied in this result. “Lemma/POS” is the result of word alignment with the pre-processing introduced Lee et al. (2006). Compared to the result, lemmatized lexical and POS tags are proven to be useful information for word alignment. “Lemma/POS” consistently outperforms “Lexical” despite the symmetrization heuristics in terms of precision, recall and F-score. We expect this improvement is benefited from the alleviated data sparseness by using lemmatized lexical and POS tags rather than using the lexical itself.

	Alignment heuristic	Precision	Recall	F-score
Lexical	Intersection	94.0%	50.8%	**66.0%**
	Union	53.2%	81.2%	64.3%
	Grow-diag-final	54.6%	80.9%	65.2%
	Grow-diag	60.9%	67.2%	63.9%
Lemma/POS	Intersection	95.8%	55.3%	**70.1%**
	Union	58.1%	83.3%	68.4%
	Grow-diag-final	59.7%	83.0%	69.5%
	Grow-diag	67.0%	71.6%	69.2%
Lemma/POS + POS alignment tendency	Intersection	96.1%	63.5%	76.5%
	Union	67.4%	85.1%	75.2%
	Grow-diag-final	69.8%	84.9%	76.6%
	Grow-diag	80.0%	77.0%	**78.5%**

Table 1. The performance of word alignment using small training set (50k pairs)

Experimental Setup	Alignment heuristic	Precision	Recall	F-score
Lexical	Intersection	96.8%	64.9%	**77.7%**
	Union	66.6%	87.4%	75.6%
	Grow-diag-final	67.8%	87.1%	76.2%
	Grow-diag	74.4%	79.2%	76.7%
Lemma/POS	Intersection	97.3%	66.2%	78.8%
	Union	70.7%	89.0%	78.8%
	Grow-diag-final	72.1%	88.8%	79.6%
	Grow-diag	78.8%	80.5%	**79.7%**
Lemma/POS + POS alignment tendency	Intersection	97.2%	69.3%	80.9%
	Union	73.9%	86.7%	79.8%
	Grow-diag-final	75.6%	86.4%	80.7%
	Grow-diag	85.2%	81.5%	**83.4%**

Table 2. The performance of word alignment using a large training set (500k pairs)

Experimental Setup	Symmetrization Heuristic	BLEU(50k)	BLEU (500k)
Lexical	Intersection	20.1%	29.2%
	Union	18.6%	27.2%
	Grow-diag-final	19.9%	27.7%
	Grow-diag	**20.2**%	**29.4**%
Lemma/POS	Intersection	20.3%	26.4%
	Union	18.5%	27.8%
	Grow-diag-final	20.1%	29.2%
	Grow-diag	**20.4**%	**30.8**%
Factored Model (Lemma, POS)	Intersection	20.5%	30.0%
	Union	18.1%	27.5%
	Grow-diag-final	20.3%	28.2%
	Grow-diag	**20.9**%	**31.1**%
Lemma/POS + POS alignment tendency	Intersection	**21.8**%	**29.3**%
	Union	19.5%	27.2%
	Grow-diag-final	21.3%	28.4%
	Grow-diag	20.8%	29.1%

Table 3. The performance of translation

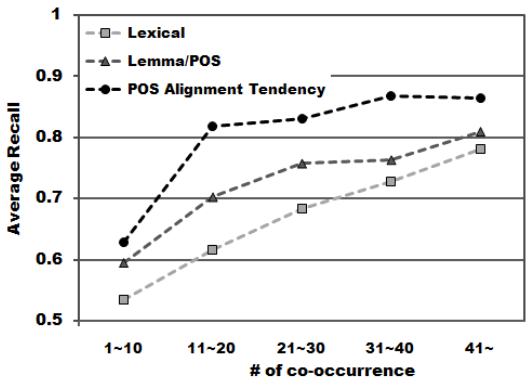

Figure 3. Average recall of word alignment pairs according to the number of their co-occurrence

Since lemmatized lexical and POS tags are shown to be useful, our post-processing method is applied to "Lemma/POS".

The experimental results show that the proposed method consistently improves word alignment in terms of F-score. It is interesting that the proposed method improves the recall of the intersection result and the precision of the union result. Thus, the proposed method achieves the best alignment performance.

As can be seen in Table 1 and 2, our method consistently improves the performance of word alignment despite the size of training data. In a small data set, the improvement of our method is much higher than that in a large set. This implies that our method is more helpful when the training data set is insufficient.

We investigate whether the proposed method actually alleviates the data sparseness problem by analyzing the aligned word pairs of low co-occurrence frequency. There are multiple word pairs that share the same number of co-occurrence in the corpus. For example, let us assume that "report-*bogoha*", "newspaper-*sinmun*" and "China-*jungguk*" pairs are co-occurred 1,000 times. We can calculate the mean of their individual recalls. We refer to this new measurement as average recall. The average recalls of these pairs are relatively higher than those of pairs with low co-occurrence frequency such as "food-*jinji*" and "center-*chojeom*" pairs. These pairs are difficult to be linked, because the word alignment model suffers from data sparseness when estimating their translation probability.

Figure 3 shows the average recall according to the number of co-occurrence. We can observe that the word alignment model tends to link word pairs more correctly if they are more frequently co-occurred. Both "Lemma/POS" and our method consistently show higher average recall throughout all frequencies, and the proposed method shows the best performance. It is also notable that the both "Lemma/POS" and our method achieve much more improvement for low co-occurrence frequencies (e.g., 11~40). This implies that the proposed method incorporates POS information more effectively than the previous method, since the proposed method achieves much higher average recall.

4.2 Statistical Machine Translation

Next, we examine the effect of the improvement of the word alignment on the translation quality. For this, we built some SMT systems with the word alignment results. We use the Moses toolkit for translation (Koehn et al., 2007). Moses is an implementation of phrase-based statistical machine translation model that has shown a state-of-the-art performance in various evaluation sets. We also perform the evaluation of the Factored model (Koehn et al., 2007) using Moses.

To investigate how the improved word alignment affect the quality of machine translation, we calculate the BLEU score for translation results with different word alignment settings as shown in Table 3. First of all, we can easily conclude that the quality of the translation is strongly dominated by the size of the training data. We can also find that the quality of the translation is correlated to the performance of the word alignment.

For a small test set, the proposed method achieved the best performance in terms of BLEU (21.8%). For a larger test set, however, the proposed method could not improve the performance of the translation with better word alignment. It is not feasible to investigate the factors that affect this deterioration, since Moses is a black box module to our system. The training of the phrase-based SMT model involves the extraction of phrases, and the result of word alignment is reflected within this process. When the training data is small, the number of extracted phrases is also apparently small. However, abundant phrases are extracted from a large amount of training data. In this case, we hypothesize that the most plausible

Rank	IBM Model			POS Alignment Tendency		
	translation	$P_{IBM}(f\|e)$	#co-occur	translation	score(f, e)	#co-occur
1	bob/NNP	0.348	83	bob/NNP	0.214	83
2	rice/NN	0.192	73	rice/NN	0.136	73
3	*eat/VB*	0.107	57	meal/NN	0.078	43
4	meal/NN	0.075	43	food/NN	0.062	29
5	food/NN	0.043	29	*eat/VB*	0.061	57
6	bob/NN	0.038	10	bob/NN	0.059	10
7	*feed/VB*	0.010	7	*living/NN*	0.045	4
8	*cook/VB*	0.010	9	dinner/NN	0.044	10
9	*living/NN*	0.008	4	**bread/NN**	0.044	9
10	dinner/NN	0.008	10	**breakfast/NN**	0.043	6

Table 4. Top 10 translations for Korean word "bap" (food).

phrases are already obtained, and the effect of more accurate word alignment seems insignificant. More thorough analysis of this is remained as future work.

4.3 Acquisition of Bilingual Dictionary

One of the most applications of word alignment is the construction of bilingual dictionaries. By using word alignment, we can collect a (ranked) list of bilingual word pairs. Table 4 reports the top 10 translations (the most acceptable target words to align) for Korean word "*bap*" (food). The table contains the probabilities estimated by the IBM Models, the adjusted scores, and the number of co-occurrence, respectively. Italicized translations are in fact incorrect translations. Highlighted ones are new translation candidates that are correct. As can be seen in the table, the proposed approach shows a positive effect of raising new and better candidates for translation. For example, "bread" and "breakfast" have come up to the top 10 translations. This demonstrates that the low co-occurrences of "bap" with "bread" and "breakfast" are not suitably handled by alignments solely based on lexicals. However, the proposed approach ranks them at higher positions by reflecting the alignment tendency of POSs.

5 Conclusion

In this paper, we propose a new method for incorporating the POS alignment tendency to improve traditional word alignment model in post processing step. Experimental results show that the proposed method helps to alleviate the data sparseness problem especially when the training data is insufficient.

It is still difficult to conclude that better word alignment always leads to better translation. We plan on investigating the effectiveness of the proposed method using other translation system, such as Hiero (Chiang et al., 2005). We also plan to incorporate our method into other effective models, such as Factored translation model.

Abstract

We describe a new information fusion approach to integrate facts extracted from cross-media objects (videos and texts) into a coherent common representation including multi-level knowledge (concepts, relations and events). Beyond standard information fusion, we exploited video extraction results and significantly improved text Information Extraction. We further extended our methods to multi-lingual environment (English, Arabic and Chinese) by presenting a case study on cross-lingual comparable corpora acquisition based on video comparison.

1 Introduction

An enormous amount of information is widely available in various data modalities (e.g. speech, text, image and video). For example, a Web news page about "Health Care Reform in America" is composed with texts describing some events (e.g., Final Senate vote for the reform plans, Obama signs the reform agreement), images (e.g., images about various government involvements over decades) and videos/speech (e.g. Obama's speech video about the decisions) containing additional information regarding the real extent of the events or providing evidence corroborating the text part. These cross-media objects exist in redundant and complementary structures, and therefore it is beneficial to fuse information from various data modalities. The goal of our paper is to investigate this task from both mono-lingual and cross-lingual perspectives.

The processing methods of texts and images/videos are typically organized into two separate pipelines. Each pipeline has been studied separately and quite intensively over the past decade. It is critical to move away from single media processing, and instead toward methods that make multiple decisions jointly using cross-media inference. For example, video analysis allows us to find both entities and events in videos, but it's very challenging to specify some fine-grained semantic types such as proper names (e.g. "Obama Barack") and relations among concepts; while the speech embedded and the texts surrounding these videos can significantly enrich such analysis. On the other hand, image/video features can enhance text extraction. For example, entity gender detection from speech recognition output is challenging because of entity mention recognition errors. However, gender detection from corresponding images and videos can achieve above 90% accuracy (Baluja and Rowley, 2006). In this paper, we present a case study on gender detection to demonstrate how text and video extractions can boost each other.

We can further extend the benefit of cross-media inference to cross-lingual information extraction (CLIE). Hakkani-Tur et al. (2007) found that CLIE performed notably worse than monolingual IE, and indicated that a major cause was the low quality of machine translation (MT). Current statistical MT methods require large and manually aligned parallel corpora as input for each language pair of interest. Some recent work (e.g. Munteanu and Marcu, 2005; Ji, 2009) found that MT can benefit from multi-lingual comparable corpora (Cheung and Fung, 2004), but it is time-consuming to identify pairs of comparable texts; especially when there is

Coling 2008: Poster Volume, pages 630–638,
Beijing, August 2010

lack of parallel information such as news release dates and topics. However, the images/videos embedded in the same documents can provide additional clues for similarity computation because they are 'language-independent'. We will show how a video-based comparison approach can reliably build large comparable text corpora for three languages: English, Chinese and Arabic.

2 Baseline Systems

We apply the following state-of-the-art text and video information extraction systems as our baselines. Each system can produce reliable confidence values based on statistical models.

2.1 Video Concept Extraction

The video concept extraction system was developed by IBM for the TREC Video Retrieval Evaluation (TRECVID-2005) (Naphade et al., 2005). This system can extract 2617 concepts defined by TRECVID, such as "Hospital", "Airplane" and "Female-Person". It uses support vector machines to learn the mapping between low level features extracted from visual modality as well as from transcripts and production related meta-features. It also exploits a Correlative Multi-label Learner (Qi et al., 2007), a Multi-Layer Multi-Instance Kernel (Gu et al., 2007) and Label Propagation through Linear Neighborhoods (Wang et al., 2006) to extract all other high-level features. For each classifier, different models are trained on a set of different modalities (e.g., the color moments, wavelet textures, and edge histograms), and the predictions made by these classifiers are combined together with a hierarchical linearly-weighted fusion strategy across different modalities and classifiers.

2.2 Text Information Extraction

We use a state-of-the-art IE system (Ji and Grishman, 2008) developed for the Automatic Content Extraction (ACE) program[1] to process texts and automatic speech recognition output. The pipeline includes name tagging, nominal mention tagging, coreference resolution, time expression extraction and normalization, relation extraction and event extraction. Entities include coreferred persons, geo-political entities (GPE), locations, organizations, facilities, vehicles and weapons; relations include 18 types (e.g. "*a town some 50 miles south of Salzburg*" indicates a located relation.); events include the 33 distinct event types defined in ACE 2005 (e.g. "*Barry Diller on Wednesday quit as chief of Vivendi Universal Entertainment.*" indicates a "personnel-start" event). Names are identified and classified using an HMM-based name tagger. Nominals are identified using a maximum entropy-based chunker and then semantically classified using statistics from ACE training corpora. Relation extraction and event extraction are also based on maximum entropy models, incorporating diverse lexical, syntactic, semantic and ontological knowledge.

3 Mono-lingual Information Fusion and Inference

3.1 Mono-lingual System Overview

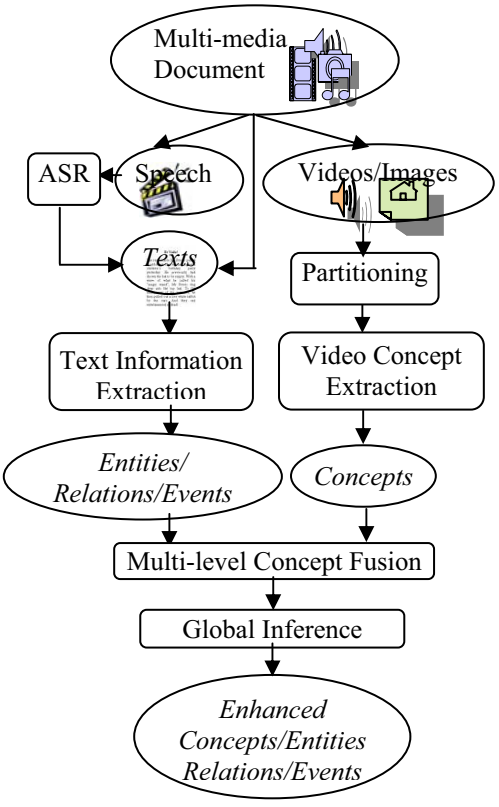

Figure 1. Mono-lingual Cross-Media Information Fusion and Inference Pipeline

Figure 1 depicts the general procedure of our mono-lingual information fusion and inference

[1] http://www.nist.gov/speech/tests/ace/

approach. After we apply two baseline systems to the multi-media documents, we use a novel multi-level concept fusion approach to extract a common knowledge representation across texts and videos (section 3.2), and then apply a global inference approach to enhance fusion results (section 3.3).

3.2 Cross-media Information Fusion

- ***Concept Mapping***

For each input video, we apply automatic speech recognition to obtain background texts. Then we use the baseline IE systems described in section 2 to extract concepts from texts and videos. We construct mappings on the overlapped facts across TRECVID and ACE. For example, "LOC.Water-Body" in ACE is mapped to "Beach, Lakes, Oceans, River, River_Bank" in TRECVID.

Due to different characteristics of video clips and texts, these two tasks have quite different granularities and focus. For example, "PER.Individual" in ACE is an open set including arbitrary names, while TRECVID only covers some famous proper names such as "Hu_Jintao" and "John_Edwards". Geopolitical entities appear very rarely in TRECVID because they are more explicitly presented in background texts. On the other hand, TRECVID defined much more fine-grained nominals than ACE, for example, "FAC.Building-Grounds" in ACE can be divided into 52 possible concept types such as "Conference_Buildings" and "Golf_Course" because they can be more easily detected based on video features. We also notice that TRECVID concepts can include multiple levels of ACE facts, for example "WEA_Shooting" concept can be separated into "weapon" entities and "attack" events in ACE. These different definitions bring challenges to cross-media fusion but also opportunities to exploit complementary facts to refine both pipelines. We manually resolved these issues and obtained 20 fused concept sets.

- ***Time-stamp based Multi-level Projection***

After extracting facts from videos and texts, we conduct information fusion at all possible levels: name, nominal, coreference link, relation or event mention. We rely on the timestamp information associated with video keyframes or shots (sequential keyframes) and background speech to align concepts. During this fusion process, we compare the normalized confidence values produced from two pipelines to resolve the following three types of cases:

- Contradiction – A video fact contradicts a text fact; we only keep the fact with higher confidence.
- Redundancy – A video fact conveys the same content as (or entails, or is entailed by) a text fact; we only keep the unique parts of the facts.
- Complementary – A video fact and a text fact are complementary; we merge these two to form more complete fact sets.

- ***A Common Representation***

In order to effectively extract compact information from large amounts of heterogeneous data, we design an integrated XML format to represent the facts extracted from the above multi-level fusion. We can view this representation as a set of directed "information graphs" $G=\{G_i (V_i, E_i)\}$, where V_i is the collection of concepts from both texts and videos, and E_i is the collection of edges linking one concept to the other, labeled by relation or event attributes. An example is presented in Figure 2. This common representation is applied in both mono-lingual and multi-lingual information fusion tasks described in next sections.

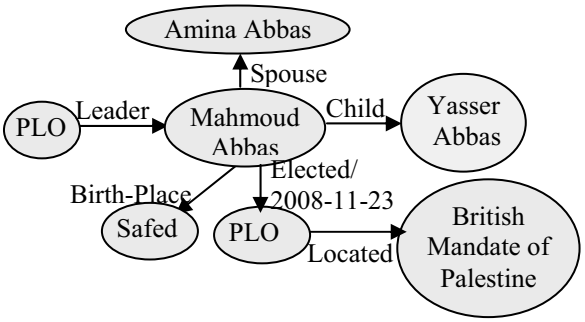

Figure 2. An example for cross-media common fact representation

3.3 Cross-media Information Inference

- ***Uncertainty Problem in Cross-Media Fusion***

However, such a simple merging approach usually leads to unsatisfying results due to uncertainty. Uncertainty in multimedia is induced from noise in the data acquisition procedure

(e.g., noise in automatic speech recognition results and low-quality camera surveillance videos) as well as human errors and subjectivity. Unstructured texts, especially those translated from foreign languages, are difficult to interpret. In addition, automatic IE systems for both videos and texts tend to produce errors.

- ***Case Study on Mention Gender Detection***

We employ cross-media inference methods to reduce uncertainty. We will demonstrate this approach on a case study of gender detection for persons. Automatic gender detection is crucial to many natural language processing tasks such as pronoun reference resolution (Bergsma, 2005). Gender detection for last names has proved challenging; Gender for nominals can be highly ambiguous in various contexts. Unfortunately most state-of-the-art approaches discover gender information without considering specific contexts in the document. The results were stored either as a knowledge base with probabilities (e.g. Ji and Lin, 2009) or as a static gazetteer (e.g. census data). Furthermore, speech recognition normally performs poorly on names, which brings more challenges to gender detection for mis-spelled names.

We consider two approaches as our baselines. The first baseline is to discover gender knowledge from Google N-grams using specific lexical patterns (e.g. "[mention] and his/her/its/their") (Ji and Lin, 2009). The other baseline is a gazetteer matching approach based on census data including person names and gender information, as used in typical text IE systems.

We introduce the third method based on male/female concept extraction from associated background videos. These concepts are detected from context-dependent features (e.g. face recognition). If there are multiple persons in one snippet associated with one shot, we propagate gender information to all instances.

We then linearly combine these three methods based on confidence values. For example, the confidence of predicting a name mention *n* as a male (M) can be computed by combining probabilities *P(n, M, method)*:

$$confidence(n,male)= \lambda_1 * P(n,M,ngram) + \lambda_2 * P(n,M,census) + \lambda_3 * P(n,M,video)$$

In this paper we used $\lambda_1=0.1$, $\lambda_2=0.1$ *and* $\lambda_3=0.8$ which are optimized from a development set.

4 Cross-lingual Comparable Corpora Acquisition

In this section we extend the information fusion approach to a task of discovering comparable corpora.

4.1 Comparable Documents

Figure 3 presents an example of cross-lingual comparable documents. They are both about the rescue activities for the Haiti earthquake.

Figure 3. An example for cross-lingual multi-media comparable documents

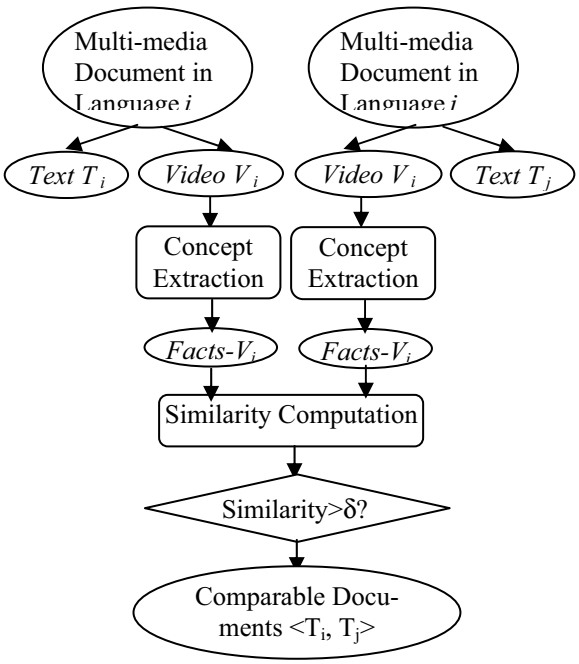

Figure 4. Cross-lingual Comparable Text Corpora Acquisition based on Video Similarity Computation

Traditional text translation based methods tend to miss such pairs due to poor translation quality of informative words (Ji et al., 2009). However, the background videos and images are language-independent and thus can be exploited to identify such comparable documents. This provides a cross-media approach to break language barrier.

4.2 Cross-lingual System Overview

Figure 4 presents the general pipeline of discovering cross-lingual comparable documents based on background video comparison. The detailed video similarity computation method is presented in next section.

4.3 Video Concept Similarity Computation

Most document clustering systems use representations built out of the lexical and syntactic attributes. These attributes may involve string matching, agreement, syntactic distance, and document release dates. Although gains have been made with such methods, there are clearly cases where shallow information will not be sufficient to resolve clustering correctly. Therefore, we should therefore expect a successful document comparison approach to exploit world knowledge, inference, and other forms of semantic information in order to resolve hard cases. For example, if two documents include concepts referring to male-people, earthquake event, rescue activities, and facility-grounds with similar frequency information, we can determine they are likely to be comparable. In this paper we represent each video as a vector of semantic concepts extracted from videos and then use standard vector space model to compute similarity.

Let A=(a_1, …$a_{|\Sigma|}$) and B=(b_1, …$b_{|\Sigma|}$) be such vectors for a pair of videos, then we use cosine similarity to compute similarity:

$$\cos(A,B) = \frac{\sum_{i=1}^{|\sum|} a_i b_i}{\sqrt{\sum_{i=1}^{|\sum|} a_i^2}\sqrt{\sum_{i=1}^{|\sum|} b_i^2}},$$

where $|\Sigma|$ contains all possible concepts. We use traditional TF-IDF (Term Frequency-Inverse Document Frequency) weights for the vector elements a_i and b_i. Let C be a unique concept, V is a video consisting of a series of k shots $V = \{S_1, ..., S_k\}$, then:

$$tf(C,V) = \sum_{i=1}^{k} tf(C,S_i) \Big/ k$$

Let $p(C, S_i)$ denote the probability that C is extracted from S_i, we define two different ways to compute term frequency $tf(C, S_i)$:

(1) $tf(C,S_i) = confidence(C,S_i)$

and

(2) $tf(C,S_i) = \alpha^{confidence(C,S_i)}$

Where $Confidence(C, S_i)$ denotes the probability of detecting a concept C in a shot S_i:

$$confidence(C,S_i) = p(C,S_i) \text{ if } p(C,S_i) > \delta,$$
otherwise 0.

Let: $df(C,S_i) = 1$ if $p(C,S_i) > \delta$, otherwise 0, assuming there are j shots in the entire corpus, we calculate *idf* as follows:

$$idf(C,V) = \log\left(j / \sum_{i=1}^{j} df(C,S_i) \right)$$

5 Experimental Results

This section presents experimental results of all the three tasks described above.

5.1 Data

We used 244 videos from TRECVID 2005 data set as our test set. This data set includes 133,918 keyframes, with corresponding automatic speech recognition and translation results (for foreign languages) provided by LDC.

5.2 Information Fusion Results

Table 1 shows information fusion results for English, Arabic and Chinese on multiple levels. It indicates that video and text extraction pipelines are complementary – almost all of the video concepts are about nominals and events; while text extraction output contains a large amount of names and relations. Therefore the results after information fusion produced much richer knowledge.

Annotation Levels		English	Chinese	Arabic
# of videos		104	84	56
Video	Concept	250880	221898	197233
Text	Name	17350	22154	20057
	Nominal	31528	21852	16253
	Relation	9645	20880	16584
	Event	31132	10348	7148

Table 1. Information Fusion Results

It's also worth noting that the number of concepts extracted from videos is similar across languages, while much fewer events are extracted from Chinese or Arabic because of speech recognition and machine translation errors. We took out 1% of the results to measure accuracy against ground-truth in TRECVID and ACE training data respectively; the mean average precision for video concept extraction is about 33.6%. On English ASR output the text-IE system achieved about 82.7% F-measure on labeling names, 80.5% F-measure on nominals (regardless of ASR errors), 66% on relations and 64% on events.

5.3 Information Inference Results

From the test set, we chose 650 persons (492 males and 158 females) to evaluate gender discovery. For baselines, we used Google n-gram (n=5) corpus Version II including 1.2 billion 5-grams extracted from about 9.7 billion sentences (Lin et al., 2010) and census data including 5,014 person names with gender information.

Since we only have gold-standard gender information on shot-level (corresponding to a snippet in ASR output), we asked a human annotator to associate ground-truth with individual persons. Table 2 presents overall precision (P), recall (R) and F-measure (F).

Methods	P	R	F
Google N-gram	89.1%	70.2%	78.5%
Census	96.2%	19.4%	32.4%
Video Extraction	88.9%	73.8%	80.6%
Combined	89.3%	80.4%	84.6%

Table 2. Gender Discovery Performance

Table 2 shows that video extraction based approach can achieve the highest recall among all three methods. The combined approach achieved statistically significant improvement on recall.

Table 3 presents some examples ("F" for female and "M" for male). We found that most speech name recognition errors are propagated to gender detection in the baseline methods, for example, "Sala Zhang" is mis-spelled in speech recognition output (the correct spelling should be "Sarah Chang") and thus Google N-gram approach mistakenly predicted it as a male. Many rare names such as "Wu Ficzek", "Karami" cannot be predicted by the baselines,

Error analysis on video extraction based approach showed that most errors occur on those shots including multiple people (males and females). In addition, since the data set is from news domain, there were many shots including reporters and target persons at the same time. For example, "Jiang Zemin" was mistakenly associated with a "female" gender because the reporter is a female in that corresponding shot.

5.4 Comparable Corpora Acquisition Results

For comparable corpora acquisition, we measured accuracy for the top 50 document pairs. Due to lack of answer-keys, we asked a bilingual human annotator to judge results manually. The evaluation guideline generally followed the definitions in (Cheung and Fung, 2004). A pair of documents is judged as comparable if they share a certain amount of information (e.g. entities, events and topics).

Without using IDF, for different parameter α and δ in the similarity metrics, the results are summarized in Figure 5. For comparison we present the results for mono-lingual and cross-lingual separately. Figure 5 indicates that as the threshold and normalization values increase, the accuracy generally improves. It's not surprising that mono-lingual results are better than cross-lingual results, because generally more videos with comparable topics are in the same language.

Mention	Google N-gram	Census	Video Extraction	Correct Answer	Context Sentence
Zhang Sala	M: 1 F: 0	-	F: 0.699 M: 0.301	F	World famous meaning violin soloist **Zhang Sala** recently again to Toronto symphony orchestra...
Peter	M: .979 F: 0.021	M: 1	M: 0.699 F: 0.301	M	Iraq, there are in Lebanon Paris pass **Peter** after 10 five Dar exile without peace...
Wu Ficzek	-		M: 0.699 F: 0.301	M	If you want to do a good job indeed **Wu Ficzek**
President	M: .953 F: 0.047	-	M: 0.704 F: 0.296	M	Labor union of Arab heritage publishers **president** to call for the opening of the Arab Book Exhibition.
Jiang Zemin	M: 1 F: 0	-	F: 0.787 M: 0.213	M	It has never stopped the including the former CPC General Secretary Jiang Zemin…
Karami	M: 1 F: 0	-	M: 0.694 F: 0.306	M	all the Gamal Ismail introduced the needs of the Akkar region, referring to the desire on the issue of the President **Karami** to give priority disadvantaged areas

Table 3. Examples for Mention Gender Detection

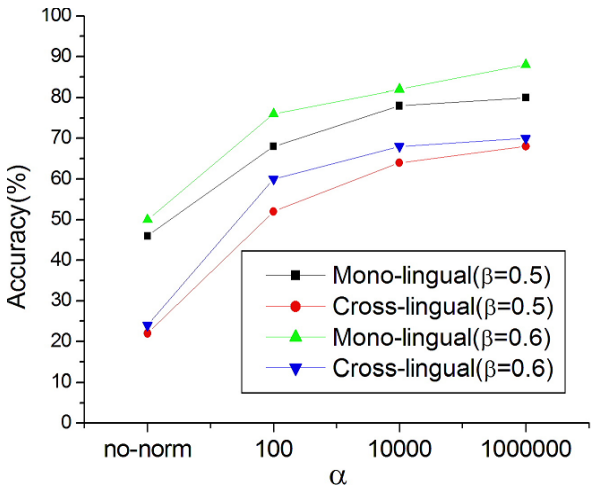

Figure 5. Comparable Corpora Acquisition without IDF

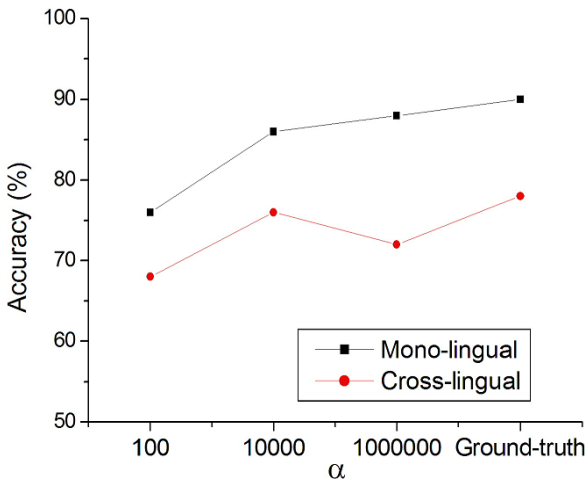

Figure 6. Comparable Corpora Acquisition with IDF (δ=0.6)

We then added IDF to the optimized threshold and obtained results in Figure 6. The accuracy for both languages was further enhanced. We can see that under any conditions our approach can discover comparable documents reliably. In order to measure the impact of concept extraction errors, we also evaluated the results for using ground-truth concepts as shown in Figure 6. Surprisingly it didn't provide much higher accuracy than automatic concept extraction, mainly because the similarity can be captured by some dominant video concepts.

6 Related Work

A large body of prior work has focused on multimedia information retrieval and document classification (e.g. Iria and Magalhaes, 2009). State-of-the-art information fusion approaches can be divided into two groups: formal "top-down" methods from the generic knowledge fusion community and quantitative "bottom-up" techniques from the Semantic Web community (Appriou et al., 2001; Gregoire, 2006). However, very limited research methods have been ex-

plored to fuse automatically extracted facts from texts and videos/images. Our idea of conducting information fusion on multiple semantic levels is similar to the kernel method described in (Gu et al., 2007).

Most previous work on cross-media information extraction focused on one single domain (e.g. e-Government (Amato et al., 2010); soccer game (Pazouki and Rahmati, 2009)) and structured/semi-structured texts (e.g. product catalogues (Labsky et al., 2005)). Saggion et al. (2004) described a multimedia extraction approach to create composite index from multiple and multi-lingual sources. We expand the task to the more general news domain including unstructured texts and use cross-media inference to enhance extraction performance.

Some recent work has exploited analysis of associated texts to improve image annotation (e.g. Deschacht and Moens, 2007; Feng and Lapata, 2008). Some recent research demonstrated cross-modal integration can provide significant gains in improving the richness of information. For example, Oviatt et al. (1997) showed that speech and pen-based gestures can provide complementary capabilities because basic subject, verb, and object constituents almost always are spoken, whereas those describing locative information invariably are written or gestured. However, not much work demonstrated an effective method of using video/image annotation to improve text extraction. Our experiments provide some case studies in this new direction. Our work can also be considered as an extension of global background inference (e.g. Ji and Grishman, 2008) to cross-media paradigm.

Extensive research has been done on video clustering. For example, Cheung and Zakhor (2000) used meta-data extracted from textual and hyperlink information to detect similar videos on the web; Magalhaes et al. (2008) described a semantic similarity metric based on key word vectors for multi-media fusion. We extend such video similarity computing approaches to a multi-lingual environment.

7 Conclusion and Future Work

Traditional Information Extraction (IE) approaches focused on single media (e.g. texts), with very limited use of knowledge from other data modalities in the background. In this paper we propose a new approach to integrate information extracted from videos and texts into a coherent common representation including multi-level knowledge (concepts, relations and events). Beyond standard information fusion, we attempted global inference methods to incorporate video extraction and significantly enhanced the performance of text extraction. Finally, we extend our methods to multi-lingual environment (English, Arabic and Chinese) by presenting a case study on cross-lingual comparable corpora acquisition.

We used a dataset which includes videos and associated speech recognition output (texts), but our approach is applicable to any cases in which texts and videos appear together (from associated texts, captions etc.). The proposed common representation will provide a framework for many byproducts. For example, the monolingual fused information graphs can be used to generate abstractive summaries. Given the fused information we can also visualize the facts from background texts effectively. We are also interested in using video information to discover novel relations and events which are missed in the text IE task.

EM-based Hybrid Model for Bilingual Terminology Extraction from Comparable Corpora

Lianhau Lee, Aiti Aw, Min Zhang, Haizhou Li
Institute for Inforcomm Research
{lhlee, aaiti, mzhang, hli}@i2r.a-star.edu.sg

Abstract

In this paper, we present an unsupervised hybrid model which combines statistical, lexical, linguistic, contextual, and temporal features in a generic EM-based framework to harvest bilingual terminology from comparable corpora through comparable document alignment constraint. The model is configurable for any language and is extensible for additional features. In overall, it produces considerable improvement in performance over the baseline method. On top of that, our model has shown promising capability to discover new bilingual terminology with limited usage of dictionaries.

1 Introduction

Bilingual terminology extraction or term alignment has been well studied in parallel corpora. Due to the coherent nature of parallel corpora, various statistical methods, like EM algorithm (Brown et. al., 1993) have been proven to be effective and have achieved excellent performance in term of precision and recall. The limitation of parallel corpora in all domains and languages has led some researchers to explore ways to automate the parallel sentence extraction process from non-parallel corpora (Munteanu and Marcu, 2005; Fung and Cheung, 2004) before proceeding to the usual term alignment extraction using the existing techniques for parallel corpora. Nevertheless, the coverage is limited since parallel sentences in non-parallel corpora are minimal.

Meanwhile, some researchers have started to exploit comparable corpora directly in a new manner. The motivations for such an approach are obvious: comparable corpora are abundantly available, from encyclopedia to daily newspapers, and the human effort is reduced in either generating or collecting these corpora. If bilingual terminology can be extracted directly from these corpora, evolving or emerging terminologies can be captured much faster than lexicography and this would facilitate many tasks and applications in accessing cross-lingual information.

There remain challenges in term alignment for comparable corpora. The structures of texts, paragraphs and sentences can be very different. The similarity of content in two documents varies through they talk about the same subject matter. Recent research in using transliteration (Udupa et. al., 2008; Knight and Graehl, 1998), context information (Morin et. al., 2007; Cao and Li, 2002; Fung, 1998), part-of-speech tagging, frequency distribution (Tao and Zhai, 2005) or some hybrid methods (Klementiev and Roth, 2006; Sadat et. al., 2003) have shone some light in dealing with comparable corpora. In particular, context information seems to be popular since it is ubiquitous and can be retrieved from corpora easily.

In this paper, we propose an EM-based hybrid model for term alignment to address the issue. Through this model, we hope to discover new bilingual terminology from comparable corpora without supervision. In the following sections, the model will be explained in details.

Coling 2008: Poster Volume, pages 639–646,
Beijing, August 2010

2 System Architecture

It is expensive and challenging to extract bilingual terminologies from a given set of comparable corpora if they are noisy with very diverse topics. Thus the first thing we do is to derive the document association relationship between two corpora of different languages. To do this, we adopt the document alignment approach proposed by Vu et. al. (2009) to harvest comparable news document pairs. Their approach is relying on 3 feature scores, namely Title-n-Content (TNC), Linguistic Independent Unit (LIU), and Monolingual Term Distribution (MTD). In the nutshell, they exploit common words, numbers and identical strings in titles and contents as well as their distribution in time domain. Their method is shown to be superior to Tao and Zai (2005) which simply make use of frequency correlation of words.

After we have retrieved comparable document pairs, we tokenize these documents with prominent monolingual noun terms found within. We are interested only in noun terms since they are more informative and more importantly they are more likely not to be covered by dictionary and we hope to find their translations through comparable bilingual corpora. We adopt the approach developed by Vu et. al. (2008). They first use the state-of-the-art C/NC-Value method (Frantzi and Ananiadou, 1998) to extract terms based on the global context of the corpus, follow by refining the local terms for each document with a term re-extraction process (TREM) using Viterbi algorithm.

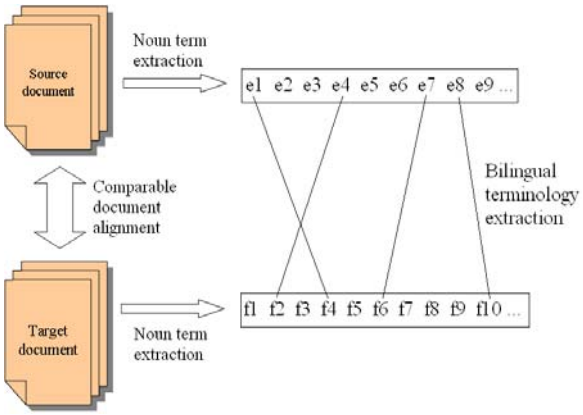

Figure 1. The procedure of bilingual terminology extraction from comparable documents.

After these preprocesses, we have a set of comparable bilingual document pairs and a set of prominent monolingual noun terms for each monolingual document. The aim of our term alignment model is to discover new bilingual terminology formed from these monolingual terms across aligned document pairs (Figure.1).

Like other approaches to comparable corpora, there exist many challenges in aligning bilingual terms due to the presence of noises and the significant text-structure disparity across the comparable bilingual documents. To overcome this, we propose using both corpus-driven and non-corpus-driven information, from which we draw various features and derive our hybrid model. These features are used to make initial guess on the alignment score of term pair candidates. Figure 2 shows the overall process of our term alignment model on comparable corpora. This model is language independent and it comprises several main components:

- EM algorithm
- Term alignment initialization
- Mutual information (MI) & TScore rescoring

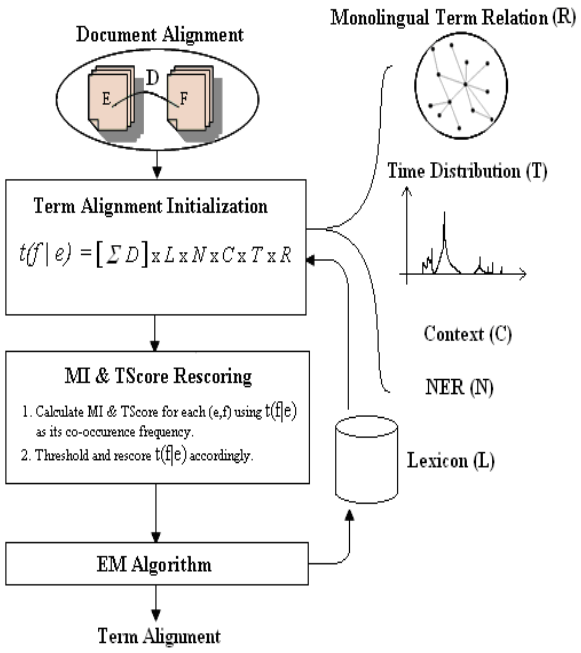

Figure 2. Term alignment model. D = document alignment score, L = lexical similarity, N = named entity similarity, C = context similarity, T = temporal similarity, R = related term similarity.

3 EM Algorithm

We make two assumptions on the preprocesses that the extracted monolingual terms are good representatives of their source documents, and the document alignment scores derived from document alignment process are good indicators of how well the contents of various documents align. Hence, the logical implication suggests that the extracted terms from both well aligned documents could well be candidates of aligned term pairs.

By reformulating the state-of-the-art EM-based word alignment framework IBM model 1 (Brown et. al., 1993), we can derive a term alignment model easily. In IBM word alignment model 1, the task is to find word alignment by using parallel sentences. In the reformulated model for term alignment, parallel sentences are replaced by comparable documents, characterized by document alignment score and their representative monolingual terms.

The significant advantage over the original IBM model 1 is the relaxation of parallel sentences or parallel corpora, by incorporating an additional feature of document alignment score. We initialize the term alignment score of the corresponding term pair candidates with the document alignment score to reflect the confidence level of document alignment. Other than that, we also employ a collection of feature similarity score: lexical similarity, named entity similarity, context similarity, temporal similarity, and related term similarity, to term alignment initialization. We will explain this further in the next section.

As we know, IBM model 1 will converge to the global maximum regardless of the initial assignment. This is truly good news for parallel corpora, but not for comparable corpora which contains a lot of noises. To prevent IBM model 1 from overfitting, we choose to run ten iterations (each iteration consists of one E-step and one M-step) for each cycle of EM in both e-f and f-e directions.

After each cycle of EM process, we simply filter off the weak term alignment pairs of both directions with a high threshold (0.8) and populate the lexicon database with the remaining pairs and use it to start another cycle of EM. The process repeats until no new term alignment pair is found. The EM algorithm for term alignment is shown as follow:

Initialize t(f|e).
for (iteration = 1 to 10)
E step

$$a[i, j, k] = \frac{t(f[k, j] \mid e[k, i])}{\sum_{i} t(f[k, j] \mid e[k, i])}, \; for \quad all \quad i, j, k$$

M step

$$tcount(e, f) = \sum_{\substack{i, j, k: \\ e[k,i]=e, \\ f[k,j]=f}} a[i, j, k], \; for \quad all \quad (e, f)$$

$$t(f \mid e) = \frac{tcount(e, f)}{\sum_{f} tcount(e, f)}, \; for \quad all \quad (e, f)$$

End for.

Figure 3. EM algorithm for e-f direction, where e[k] = k-th aligned source document, f[k] = k-th aligned target document, e[k,i] = i-th term in e[k], f[k,j] = j-th term in f[k], a[i,j,k] = probability of alignment from f[k,j] to e[k,i], t(f|e) = probability of alignment from term e to term f.

4 Term Alignment Initialization

We retrieve term alignment candidates by pairing all possible combinations of extracted monolingual source terms and target terms across the aligned document pairs. Before each cycle of EM, we assign an initial term alignment score, t(f|e) to each of these term pair candidates. Basically, we initialize the term alignment score t(f|e) based on document alignment score (D), lexical similarity (L), named entity similarity (N), context similarity (C), temporal similarity (T), and related term similarity (R). The similarity calculations of the corpus-driven features (D, C, T, R) are derived directly from the corpus and require limited lexical resource. The non-corpus-driven features (L, N) make use of a small word based bilingual dictionary to measure their lexical relevancy. That makes our model not resource-demanding and it shows that our model can work under limited resource condition.

All the above features contribute to the term alignment score t(f|e) independently, and we formulate their cumulative contributions as the following:

$$t(f|e) = \left[\sum_{(E,F): e \in E, f \in F} D(F|E) \right] \times L(f|e) \times N(f|e) \times C(f|e) \times T(f|e) \times R(f|e) \quad (1)$$

where,
e = source term
f = target term
E = source document
F = target document
D = document alignment score
L = lexical similarity
N = named entity similarity
C = context similarity
T = temporal similarity
R = related term similarity

This formula allows us to extend the model with additional features without affecting the existing configuration.

4.1 Document Alignment Score (D)

As explained in the Section 3, the relaxation on the requirement of parallel corpora in the new EM model leads to the incorporation of document alignment score. To indicate the confidence level of document alignment, we credit every aligned term pair candidate formed across the aligned documents with the corresponding document alignment score. Although it is not necessary, document alignment score is first normalized to the range of [0,1], with 1 indicates parallel alignment.

4.2 Lexical Similarity (L)

We design a simple lexical similarity measurement of two terms based on word translation. Term pairs that share more than 50% of word translation pairs will be credited with lexical similarity of L_0, where L_0 is configurable contribution weightage of lexical similarity. This provides us a primitive hint on term alignment without resorting to exhaustive dictionary lookup.

$$L(f|e) = \begin{cases} L_0, & if \quad T_W(f|e) \geq 0.5 \\ 1, & otherwise \end{cases} \quad (2)$$

where $L_0 > 1$ and $T_W(f|e)$ is word translation score.

4.3 Named Entity Similarity (N)

Named entity similarity is a measure of predefined category membership likelihood, such as person, location and organization. Term pairs that belong to the same NE categories will be credited with named entity similarity of N_0, where N_0 is a configurable weightage of named entity similarity. We use this similarity score to discover bilingual terms of same NE categories, yet not covered by bilingual dictionary.

$$N(f|e) = \begin{cases} N_0, if \quad NE \quad categories \quad match \\ 1, otherwise \end{cases} \quad (3)$$

where $N_0 > 1$.

4.4 Context Similarity (C)

We assume that terms with similar contexts are likely to have similar meaning. Thus, we make use of context similarity to measure semantic similarity. Here, only k nearest content words (verbs, nouns, adjectives and adverbs) before or after the terms within the sentence boundary are considered as its contexts. The following shows the calculation of context similarity of two terms based on cosine similarity between their context frequency vectors before scaling to the range of [1, C_0], where C_0 is a configurable contribution weightage of context similarity. As shown in the formula, the t(f'|e') accounts for the translation probability from the source context word to the target context word, hence the cosine similarity calculation is carried out in the target language domain.

$$C(f|e) = 1 + (C_0 - 1) \frac{\sum_{\substack{e' \in context(e) \\ f' \in context(f)}} freq(e') freq(f') t(f'|e')}{\sqrt{\sum_{e' \in context(e)} freq(e')^2} \sqrt{\sum_{f' \in context(f)} freq(f')^2}} \quad (4)$$

where $C_0 > 1$.

4.5 Temporal Similarity (T)

In temporal similarity, we make use of date information which is available in some corpus (e.g. news). We assume aligned terms are synchronous in time, this is especially true for comparable news corpora (Tao and Zai, 2005). We

use Discrete Fourier Transform (DFT) to transform the distribution function of a term in discrete time domain to a representative function in discrete frequency domain, which is usually known as "spectrum". We then calculate the power spectrum, which is defined as magnitude square of a spectrum. Power spectrum is sensitive to the relative spacing in time (or frequency component), yet invariant to the shifting in time, thus it is most suitably to be used for pattern matching of time distribution. The temporal similarity is calculated based on cosine similarity between the power spectrums of the two terms before scaling to the range of [1, T_0], where T_0 is a configurable contribution weightage of temporal similarity.

$$T(f \mid e) = (T_0 - 1)\cos sine\left(P_e(k), P_f(k)\right) + 1 \quad (5)$$

where $T_0 > 1$ and

$$\cos sine\left(u(k), v(k)\right) = \frac{\sum_k u(k)v(k)}{\sqrt{\sum_k u(k)^2}\sqrt{\sum_k v(k)^2}}$$

$$P_x(k) = \left| DFT\{DistributionFunction_x(n)\}\right|^2$$

$$= \left| \sum_{n=0}^{N-1} DistributionFunction_x(n) \times e^{-\frac{2\pi i}{N}kn} \right|^2$$

4.6 Related Term Similarity (R)

Related terms are terms that correlate statistically in the same documents and they can be found by using mutual information or t-test in the monolingual corpus. Basically, related term similarity is a measure of related term likelihood. Aligned terms are assumed to have similar related terms, hence related term similarity contributes to semantic similarity. The related term similarity is calculated based on weighted contribution from the related terms of the source term before scaling to the range of [1, R_0], where R_0 is a configurable contribution weightage of related terms similarity.

$$R(f \mid e) = (R_0 - 1)Rsimilarity(f \mid e) + 1 \quad (6)$$

where $R_0 > 1$ and

$$Rsimilarity(f \mid e) = \frac{\sum_{e' \in R(e)} vote(f \mid e')}{\sum_{f \in F}\sum_{e' \in R(e)} vote(f \mid e')}$$

$$vote(f \mid e') = \frac{\sum_{\substack{e'' \in R(e) \cap \\ [R(e') \cup \{e'\}]}} w(e'', f) \times MI(e, e'') \times vote(f \mid e'')}{\sum_{f \in F}\sum_{\substack{e'' \in R(e) \cap \\ [R(e') \cup \{e'\}]}} w(e'', f) \times MI(e, e'') \times vote(f \mid e'')}$$

$$w(e'', f) = \begin{cases} 1.5, & if \quad Tr(e'') \cap R(f) \neq \varnothing \\ 1, & otherwise \end{cases}$$

$$MI(e, e'') = \log\left(\frac{p(e, e'')}{p(e)p(e'')}\right)$$

vote(f|e') is initialized to 1 before it is computed iteratively until it converges. R(e) is the set of related term of e and Tr(e) is the set of translated term of e.

5 MI & TScore Rescoring

We design the MI & TScore rescoring process to enhance the alignment score t(f|e) of e-f term pairs that have significant co-occurrence frequencies in aligned document pairs, based on pointwise mutual information and TScore (or commonly known as t-test) of the terms. By using both measures concurrently, the association relationship of a term pair can be assumed with higher confidence. On top of that, the association of a term pair can also be suggested by a much higher TScore value alone. In this rescoring process, we scale up the alignment score t(f|e) of any term pair which is strongly associated by a constant factor. The following shows the mathematical expressions of what has been described, with M_0 as the configurable scaling factor.

Rescoring condition:

$$if \quad \{[TScore(e, f) \geq 2.5 \quad and \quad MI(e, f) \geq 0.6 \times \underset{\substack{(e', f'): freq(e') = freq(e) \\ or \quad freq(f') = freq(f)}}{Max} MI(e', f')] \quad (7)$$

$$or \quad TScore(e, f) \geq 5\} \quad then$$

$$T(f \mid e) = T(f \mid e) \times M_0$$

where $M_0 > 1$ and

$$TScore\ (e, f) = \frac{p(e, f) - p(e)p(f)}{\sqrt{\frac{p(e, f)}{2N}}}$$

$$N = NumberOfPair(e, f)$$

6 Experiment and Evaluation

We conduct the experiment on articles from three newspapers of different languages published by Singapore Press Holding (SPH), namely Straits Times[1] (English), ZaoBao[2] (Chinese) and Berita Harian[3] (Malay), in June 2006. There are 3187 English articles, 4316 Chinese articles and 1115 Malay articles. English is chosen to be the source language and the remaining two languages as target languages. To analyze the effect of the quality of comparable document in our term alignment model, we prepare two different input sets of document alignment, namely golden document alignment and automated document alignment for each source-target language pair. The former is retrieved by linguistic experts who are requested to read the contents of the articles in the source and the target languages, and then match the articles with similar contents (e.g. news coverage on same story), while the latter is generated using unsupervised method proposed by Vu et. al. (2009), mentioned in Section 2.

In both cases of document alignments, only monolingual noun terms extracted automatically by program (Vu et. al., 2008) will be used as basic semantic unit. There are 23,107 unique English noun terms, 31,944 unique Chinese noun terms and 8,938 unique Malay noun terms extracted in overall. In average, there are 17.3 noun term tokens extracted for each English document, 16.9 for Chinese document and 13.0 for Malay document. Also note that the term alignment reference list is constructed based on these extracted monolingual terms under the constraints of document alignment. In other words, the linguistic experts are requested to match the extracted terms across aligned document pairs (for both golden document alignment and automated document alignment sets respectively). The numbers of comparable document pairs and the corresponding unique term alignment reference pairs are shown in Table 2.

In the experiment, we will conduct the named entity recognition (NER) by using the developed system from the Stanford NLP Group, for English, and an in-house engine, for Chinese. Currently, there is no available NER engine for Malay.

Dictionary	E-C	C-E	E-M	M-E

Table 1. Statistics of dictionaries, where E = English, C = Chinese, M = Malay.

Corpus	GoldenDocAlign		AutomatedDocAlign	
	Doc Align	Term Align Ref	Doc Align	Term Align Ref
ST-ZB	90	313	899	777
ST-BH	42	113	475	358

Table 2. Statistics of comparable document alignment pairs and term alignment reference pairs.

For baseline, we make use of IBM model 1, modified in the same way which has been described in the section 3, except that we treat all comparable documents as parallel sentences, i.e. document alignment score is 1. Precision and recall are used to evaluate the performance of the system. To achieve high precision, high thresholds are used in the system and they are kept constant throughout the experiments for consistency. To evaluate the capability of discovering new bilingual terminology, we design a novelty metric, which is the ratio of the number of correct out-of-dictionary term alignment over the total number of correct term alignment.

$$Precision = \frac{C}{T} \qquad Recall = \frac{C}{G} \qquad Novelty = \frac{N}{C} \tag{8}$$

where,

C = total number of correct term alignment result.
T = total number of term alignment result.
G = total number of term alignment reference.
N = total number of correct term alignment result that are out-of-dictionary.

Table 3 shows the evaluation result of term alignment using EM algorithm with incremental feature setting. The particular order of setting is due to the implementation sequences and it is not expected to affect the result of analysis.

We observe that the precision, recall and novelty of the system are comparatively higher when the golden document alignment is used instead of the automated document alignment.

corpora	Setting	GoldenDocAlign			AutomatedDocAlign		
		Precision	Recall	Novelty	Precision	Recall	Novelty
ST-ZB	IBM 1	75.0%	1.92%	50.0%	22.2%	0.26%	50.0%
	(D)	75.0%	1.92%	50.0%	22.2%	0.26%	50.0%
	(D,L)	81.8%	2.88%	55.6%	33.3%	0.52%	25.0%
	(D,L,R)	81.8%	2.88%	55.6%	33.3%	0.52%	25.0%
	(D,L,R,M)	78.6%	3.51%	63.6%	35.7%	0.64%	40.0%
	(D,L,R,M,N)	88.2%	4.79%	53.3%	35.7%	0.64%	40.0%
	(D,L,R,M,N,C)	89.5%	5.43%	52.9%	33.3%	0.64%	40.0%
	(D,L,R,M,N,C,T)	89.5% (17/19)	5.43% (17/313)	52.9% (9/17)	37.5% (6/16)	0.77% (6/777)	16.7% (1/6)
ST-BH	IBM 1	33.3%	0.89%	0.00%	33.3%	0.78%	0.00%
	(D)	33.3%	0.89%	0.00%	33.3%	0.78%	0.00%
	(D,L)	75.0%	5.31%	50.0%	50.0%	1.94%	0.00%
	(D,L,R)	75.0%	5.31%	50.0%	50.0%	1.94%	0.00%
	(D,L,R,M)	75.0%	5.31%	50.0%	54.5%	2.33%	0.00%
	(D,L,R,M,N)	75.0%	5.31%	50.0%	54.5%	2.33%	0.00%
	(D,L,R,M,N,C)	83.3%	8.85%	60.0%	50.0%	1.94%	0.00%
	(D,L,R,M,N,C,T)	83.3% (10/12)	8.85% (10/113)	60.0% (6/10)	50.0% (5/10)	1.94% (5/258)	0.00% (0/5)

Table 3. Performance of term alignment using EM algorithm with incremental feature setting, where D = document alignment, L = lexical similarity, R = related term similarity, M = MI & TScore rescoring, N = named entity similarity, C = context similarity, T = temporal similarity.

This is expected since the golden document alignment provides document pairs with stronger semantic bonding. This also suggests that improving on the document alignment would further improve the term alignment result.

It is noteworthy observation that the implemented features improve the system precision and recall under various scenarios, although the degree of improvement varies from case to case. This shows the effectiveness of these features in the model.

On the other hand, the novelty of the system is around 40%+ and 50%+ for ST-ZB and ST-BH respectively (except for the automated document alignment in ST-BH scenarios). This suggests that the system can discover quite a large percentage of the correct bilingual terminologies that do not exist in the lexicon initially.

Compared with the baseline IBM model 1, there is an increase of 14.5% in precision, 3.51% in recall and 2.9% in novelty for ST-ZB, using the golden document alignment. For ST-BH, there is an even larger increase: 50% in precision, 7.96% in recall and 60% in novelty.

7 Conclusion

We have proposed an unsupervised EM-based hybrid model to extract bilingual terminology from comparable corpora through document alignment constraint. Our strategy is to make use of various information (corpus-driven and non-corpus-driven) to make initial guess on the semantic bonding of the term alignment candidates before subjecting them to document alignment constraint through EM algorithm. The hybrid model allows inclusion of additional features without reconfigurations on existing features, this make it practically attractive. Moreover, the proposed system can be easily deployed in any language with minimal configurations.

We have successfully conducted the experiments in English-Chinese and English-Malay comparable news corpora. The features employed in the model have shown incremental improvement in performance over the baseline method. In particular, the system shows improvement in the capability to discover new bilingual terminology from comparable corpora even with limited usage of dictionaries.

From the experiments, we have found that the quality of comparable bilingual documents is a

major limiting factor to achieve good performance. In future, we want to explore ways to improve on this.

Abstract

This paper introduces several extractive approaches for automatic image tagging, relying exclusively on information mined from texts. Through evaluations on two datasets, we show that our methods exceed competitive baselines by a large margin, and compare favorably with the state-of-the-art that uses both textual and image features.

1 Introduction

With continuously increasing amounts of images available on the Web and elsewhere, it is important to find methods to annotate and organize image databases in meaningful ways. Tagging images with words describing their content can contribute to faster and more effective image search and classification. In fact, a large number of applications, including the image search feature of current search engines (e.g., Yahoo!, Google) or the various sites providing picture storage services (e.g., Flickr, Picasa) rely exclusively on the tags associated with an image in order to search for relevant images for a given query.

However, the task of developing accurate and robust automatic image annotation models entails daunting challenges. First, the availability of large and correctly annotated image databases is crucial for the training and testing of new annotation models. Although a number of image databases have emerged to serve as evaluation benchmarks for different applications, including image annotation (Duygulu et al., 2002), content-based image retrieval (Li and Wang, 2008) and cross language information retrieval (Grubinger et al., 2006), such databases are almost exclusively created by manual labeling of keywords, requiring significant human effort and time. The content of these image databases is often restricted only to a few domains, such as medical and natural photo scenes (Grubinger et al., 2006), and specific objects like cars, airplanes, or buildings (Fergus et al., 2003). For obvious practical reasons, it is important to develop models trained and evaluated on more realistic and diverse image collections.

The second challenge concerns the extraction of useful image and text features for the construction of reliable annotation models. Most traditional approaches relied on the extraction of image colors and textures (Li and Wang, 2008), or the identification of similar image regions clustered as blobs (Duygulu et al., 2002) to derive correlations between image features and annotation keywords. In comparison, there are only a few efforts that leverage on the multitude of resources available for natural language processing to derive robust linguistic-based image annotation models. One of the earliest efforts involved the use of captions for face recognition in photographs through the construction of a specific lexicon that integrates linguistic and photographic information (Srihari and Burhans, 1994). More recently, several approaches have proposed the use of WordNet as a knowledge-base to improve content-based image annotation models, either by removing noisy keywords through semantic clustering (Jin et al., 2005) or by inducing a hierarchical classification of candidate labels (Srikanth et al., 2005).

In this paper, we explore the use of several natural language resources to construct image annotation models that are capable of automatically tagging images from unrestricted domains with good accuracy. Unlike traditional image annotation methodologies that generate tags using image-based features, we propose to extract them in a manner analogous to keyword extraction. Given a target image and its surrounding text, we extract those words and phrases that are most likely to represent meaningful tags. More importantly, we

Coling 2008: Poster Volume, pages 647–655,
Beijing, August 2010

are interested to investigate the potential of such linguistic-based models on image annotation accuracy and reliability. Our work is motivated by the need for annotation models that can be efficiently applied on a very large scale (e.g. harvesting images from the web), which are required in applications that cannot afford the complexity and time associated with current image processing techniques.

The paper makes the following contributions. We first propose a new evaluation framework for image tagging, which is based on an analogy drawn between the tasks of image labeling and lexical substitution. Next, we present three extractive approaches for the task of image annotation. The methods proposed are based only on the text surrounding an image, without the use of image features. Finally, by combining several orthogonal methods through machine learning, we show that it is possible to achieve a performance that is competitive to a state-of-the-art image annotation system that relies on visual and textual features, thus demonstrating the effectiveness of text-based extractive annotation models.

2 Related Work

Several online systems have sprung into existence to achieve annotation of real world images through human collaborative efforts (Flickr) and stimulating competition (von Ahn and Dabbish, 2004). Although a large number of image tags can be generated in short time, these approaches depend on the availability of human annotators and are far from being automatic. Similarly, research in the other direction via text-to-image synthesis (Li and Fei-Fei, 2008; Collins et al., 2008; Mihalcea and Leong, 2009) has also helped to harvest images, mostly for concrete words, by refining image search engines.

Most approaches to automatic image annotation have focused on the generation of image labels using annotation models trained with image features and human annotated keywords (Barnard and Forsyth, 2001; Jeon et al., 2003; Makadia et al., 2008; Wang et al., 2009). Instead of predicting specific words, these methods generally target the generation of semantic classes (e.g. vegetation, animal, building, places etc), which they can achieve with a reasonable amount of success. Recent work has also considered the generation of labels for real-world images (Li and Wang, 2008; Feng and Lapata, 2008). To our knowledge, we are unaware of any other work that performs extractive annotation for images from unrestricted domains through the exclusive use of textual features.

3 Dataset

As the methods we propose are extractive, standard image databases with no surrounding text such as Corel (Duygulu et al., 2002) are not suitable, nor are they representative for the challenges associated with raw data from unrestricted domains. We thus create our own dataset using images randomly extracted from the Web.

To avoid sparse searches, we use a list of the most frequent words in the British National Corpus as seed words, and query the web using the Google Image API. A webpage is randomly selected from the query results if it contains a single image in the specified size range (width and height of 275 to 1000 pixels[1]) and its text contains more than 10 words. Next, we use a Document Object Model (DOM) HTML parser[2] to extract the content of the webpage. Note that we do not perform manual filtering of our images except where they contain undesirable qualities (e.g. porn, corrupted or blank images).

In total, we collected 300 image-text pairs from the web. The average image size is 496 pixels width and 461 pixels height. The average text length is 278 tokens and the average document title length is 6 tokens. In total, there are 83,522 words and the total vocabulary is 8,409 words.

For each image, we also create a gold standard of manually assigned tags, by using the labels assigned by five human annotators. The image annotation is conducted via Amazon Mechanical Turk, which was shown in the past to produce reliable annotations (Snow et al., 2008). For increased annotation reliability, we only accept annotators with an approval rating of 98%.

Given an image, an annotator extracts from the associated text a minimum of five words or collocations.Annotators can choose words freely from the text, while collocation candidates are restricted to a fixed set obtained from the n-grams (n ≤ 7) in the text that also appear as article names or surface forms in Wikipedia. Moreover, when interpreting the image, the annotators are instructed to focus on both the denotational and conotational attributes present in the image[3].

Table 1: Two sample images. The number besides each label indicates the number of human annotators agreeing on that label. Note that the mode image has a tag (i.e."train") in the gold standard set most frequently selected by the annotators

4 A New Evaluation Framework : Image Tagging as Lexical Substitution

While evaluations of previous work in image annotation were often based on labels provided with the images, such as tags or image captions, in our dataset such annotations are either missing or unreliable. We rely instead on human-produced extractive annotations (as described in the previous section), and formulate a new evaluation framework based on the intuition that an image can be substituted with one or more tags that convey the same meaning as the image itself. Ideally, there is a single tag that "best" describes the image overall (i.e. the gold standard tag agreed by the majority of human annotators), but there are also multiple tags that describe the fine-grained concepts present in the image. Our evaluation framework is inspired by the lexical substitution task (McCarthy and Navigli, 2007), where a system attempts to generate a word (or a set of words) to replace a target word, such that the meaning of the sentence is preserved.

Given this analogy, the evaluation metrics used for lexical substitution can be adapted to the evaluation of image tagging. Specifically, we measure the precision and the recall of a tagging method using four subtasks: **best normal**: provides precision and recall for the top-ranked tag returned by a method; **best mode**: provides precision and recall only if the top-ranked tag by a method matches the tag in the gold standard that was most frequently selected by the annotators; **out of ten (oot) normal**: provides precision and recall for the top ten tags by the system; and **out of ten (oot) mode**: similar to best mode, but it considers the top ten tags returned by the system instead of one. Table 1 show examples of a normal and a mode image.

Formally, let us assume that $\mathtt{H}$ is the set of annotators, namely $\{\mathtt{h}_1, \mathtt{h}_2, \mathtt{h}_3, ...\}$, and $\mathtt{I}$, $\{\mathtt{i}_1, \mathtt{i}_2, \mathtt{i}_3, ...\}$ is the set of images for which each human annotator provide at least five tags. For each $\mathtt{i}_j$, we calculate $\mathtt{m}_j$, which is the most frequent tag for that image, if available. We also collect all $\mathtt{r}_j^k$, which is the set of tags for the image $\mathtt{i}_j$ from the annotator $\mathtt{h}_k$.

Let the set of those images where there is a tag agreed upon by the most annotators (i.e. the images with a mode) be denoted by $\mathtt{IM}$, such that $\mathtt{IM} \subseteq \mathtt{I}$. Also, let $\mathtt{A} \subseteq \mathtt{I}$ be the set of images for which the system provides more than one tag. Let the corresponding set for the images with modes be denoted by $\mathtt{AM}$, such that $\mathtt{AM} \subseteq \mathtt{IM}$. Let $\mathtt{a}_j \in \mathtt{A}$ be the set of system's extracted tags for the image $\mathtt{i}_j$.

Thus, for each image $\mathtt{i}_j$, we have the set of tags extracted by the system, and the set of tags from the human annotators. As the next step, the multiset union of the human tags is calculated, and the frequencies of the unique tags is noted. Therefore, for image $\mathtt{i}_j$, we calculate $\mathtt{R}_j$, which is $\sum \mathtt{r}_j^k$, and the individual unique tag in $\mathtt{R}_j$, say $\mathtt{res}$, will have a frequency associated with it, namely $\mathtt{freq}_{\mathtt{res}}$.

Given this setting, the precision (P) and recall (R) metrics we use are defined below.

be downloaded at
http://lit.csci.unt.edu/index.php/Downloads

Best measures:

$$P = \frac{\sum_{a_j:i_j \in A} \frac{\frac{\sum_{res \in a_j} freq_{res}}{|a_j|}}{|R_j|}}{|A|}$$

$$R = \frac{\sum_{a_j:i_j \in I} \frac{\frac{\sum_{res \in a_j} freq_{res}}{|a_j|}}{|R_j|}}{|I|}$$

$$modeP = \frac{\sum_{bestguess_j \in AM} (1if\_best\_guess = m_j)}{|AM|}$$

$$modeR = \frac{\sum_{bestguess_j \in IM} (1if\_best\_guess = m_j)}{|IM|}$$

Out of ten (oot) measures:

$$P = \frac{\sum_{a_j:i_j \in A} \frac{\sum_{res \in a_j} freq_{res}}{|R_j|}}{|A|}$$

$$R = \frac{\sum_{a_j:i_j \in I} \frac{\sum_{res \in a_j} freq_{res}}{|R_j|}}{|I|}$$

$$modeP = \frac{\sum_{a_j:i_j \in AM} (1if\_any\_guess \in a_j = m_j)}{|AM|}$$

$$modeR = \frac{\sum_{a_j:i_j \in IM} (1if\_any\_guess \in a_j = m_j)}{|IM|}$$

As a simplified example (with less tags), consider $\mathtt{i_j}$ showing a picture of a Chihuahua being labeled by five annotators with the following tags :

Annotator	Tags
1	dog,pet
2	chihuahua
3	animal,dog
4	dog,chihuahua
5	dog

In this case, $\mathtt{r}^1_\mathtt{j}$ = {dog,pet}, $\mathtt{r}^2_\mathtt{j}$ = {chihuahua}, $\mathtt{r}^3_\mathtt{j}$ = {animal,dog} and so on. The tag "dog" appears the most frequent among the five annotators, hence $\mathtt{m_j}$ = {dog}. $\mathtt{R_j}$={dog, dog, dog, dog, chihuahua, chihuahua, animal, pet}. The `res` with associated frequencies would be dog 4, chihuahua 2, animal 1, pet 1. If the system's proposed tag for $\mathtt{i_j}$ is {dog, animal}, then the numerator of P and R for best subtask would be $\frac{\frac{4+1}{2}}{8}$ = 0.313. Similarly, the numerator of P and R for oot subtask is $\frac{4+1}{8}$ = 0.625.

5 Extractive Image Annotation

The main idea underlying our work is that we can perform effective image annotation using information drawn from the associated text. Following (Feng and Lapata, 2008), we propose that an image can be annotated with keywords capturing the denotative (entities or objects depicted) and connotative (semantics or ideologies interpreted) attributes in the image. For instance, a picture showing a group of athletes and a ball may also be tagged with words like "soccer," or "sports activity." Specifically, we use a combination of knowledge sources to model the denotative quality of a word as its picturability, and the connotative attribute as its saliency. The idea of visualness and salience as textual features for discovering named entities in an image was first pursued by (Deschacht and Moens, 2007), using data from the news domain. In contrast, we are able to perform annotation of images from unrestricted domains using content words (nouns, verbs and adjectives). In the following, we first describe three unsupervised extractive approaches for image annotation, followed by a supervised method using a re-ranking hypothesis that combines all the methods.

5.1 Flickr Picturability

Featuring a repository of four billion images, Flickr (http://www.flickr.com) is one of the most comprehensive image resources on the web. As a photo management and sharing application, it provides users with the ability to tag, organize, and share their photos online. Interestingly, an inspection of Flickr tags for randomly selected images reveal that users tend to describe the denotational attributes of images, using concrete and picturable words such as cat, bug, car etc. This observation lends evidence to Flickr's suitability as a resource to model the picturability of words.

Given the text (T) of an image, we can use the $getRelatedTags$ API to retrieve the most frequent Flickr tags associated with a given word, and use them as corpus evidence to filter or promote words in the text. In the filtering phase we ignore any words that return an empty list of Flickr's related tags, based on the assumption that these words are not used in the Flickr tags repository. We also discard words with a length that is less than three characters (α=3). In the promotion phase, we reward any retrieved tags that appear as surface forms in the text. This reward is proportional to the term frequency of these tags in the

Algorithm 1 Flickr Picturability Algorithm

```

text. Additionally, we also include in the final label set any word that returns a non-empty related tags set with a discounted weight (β=0.5) of its term frequency, to the end of enriching our labels set while assuring more credit are given to the picturable words.

To extract multiword labels, we locate all n-grams formed exclusively from our extracted set of possible labels. The subsequent score for each of these n-grams is:

$$L[w_i..w_{i+k}] = (\sum_{j=i}^{j=i+k} L[wj])/k$$

By reverse sorting the associative array in L, we can retrieve the top K words to label the image. For illustration, let us consider the following text snippet.

> *On the Origin of Species, published by Charles Darwin in 1859, is considered to be the foundation of evolutionary biology.*

After removing stopwords, we consider the remaining words as candidate labels. For each of these candidates w_i (i.e. $origin$, $species$, $published$, $charles$, $darwin$, $foundation$, $evolutionary$, and $biology$), we query Flickr and obtain their related tag set R_i. $origin$, $published$, and $foundation$ return an empty set of related tags and hence are removed from our set of candidate labels, leaving $species$, $charles$, $darwin$, $evolutionary$, and $biology$ as possible annotation keywords with the initial score of 0.5. In the promotion phase, we score each w_i based on the number of votes it receives from the remaining w_j (Figure 1). Each vote represents an occurrence of the candidate tag w_i in the related tag set R_j of the candidate tag w_j. For example, $darwin$ appeared in the Flickr related tags for $charles$, $evolutionary$, and $biology$, hence it has a weight of 3.5. The final list of candidate labels are shown in Table 2.

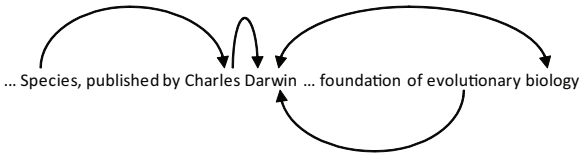

Figure 1: Flickr Picturability Labels

Label	$S(w_i)$
darwin	3.5
charles darwin	2.5
charles	1.5
biology	1.5
evolutionary biology	1.0
evolutionary	0.5
species	0.5

Table 2: Candidate labels obtained for a sample text using the Flickr model

5.2 Wikipedia Salience

We hypothesize that an image often describes the most important concepts in the associated text. Thus, the keywords selected from a text could be used as candidate labels for the image. We use a graph-based keyword extraction method similar to (Mihalcea and Tarau, 2004), enhanced with a semantic similarity measure. Starting with a text, we extract all the candidate labels and add them as vertices in the graph. A measure of word similarity is then used to draw weighted edges between the nodes. Using the PageRank algorithm, the words are assigned with a score indicating their salience within the given text.

To determine the similarity between words, we use a directed measure of similarity. Most word similarity metrics provide a single-valued score between a pair of words w_1 and w_2 to indicate their semantic similarity. Intuitively, this is not always the case, as w_1 may be represented by concepts that are entirely embedded in other concepts, represented by w_2. In psycholinguistics terms, uttering w_1 may bring to mind w_2, while the appearance of w_2 without any contextual clues may not associate with w_1. For example, $Obama$ brings to mind the concept of $president$, but $president$

may trigger other concepts such as $Washington$, $Lincoln$, $Ford$ etc., depending on the existing contextual clues. Thus, the degree of similarity of w_1 with respect to w_2 should be separated from that of w_2 with respect to w_1. Specifically, we use the following measure of similarity, based on the Explicit Semantic Analysis (ESA) vectors derived from Wikipedia (Gabrilovich and Markovitch, 2007):

$$DSim(w_i, w_j) = \frac{C_{ij}}{C_i} * Sim(w_i, w_j)$$

where C_{ij} is the count of articles in Wikipedia containing words w_i and w_j, C_i is the count of articles containing words w_i, and Sim(w_i, w_j) is the cosine similarity of the ESA vectors representing the input words.The *directional weight* (C_{ij}/C_i) amounts to the degree of association of w_i with respect to w_j. Using the directional inferential similarity scores as directed edges and distinct words as vertices, we obtain a graph for each text. The directed edges denotes the idea of "recommendation" where we say w_1 recommends w_2 if and only if there is a directed edge from w_1 to w_2, with the weight of the recommendation being the directional similarity score. Starting with this graph, we use the graph iteration algorithm from (Mihalcea and Tarau, 2004) to calculate a score for each vertex in the graph. The output is a sorted list of words in decreasing order of their ranks, which are used as candidate labels to annotate the image. This is achieved by using C_j instead of C_i for the denominator in the directional weight. As an example, consider the text snippet :

> *Microsoft Corporation is a multinational computer technology corporation that develops, manufactures, licenses, and supports a wide range of software products for computing devices*

after stopword removal, the list of nouns extracted is *Microsoft, computer, corporation, devices, products, technology, software*. Note that the top-ranked word must infer some or all of the words in the text. In this case, the word *Microsoft* infers the terms *computer*, *technology* and *software*.

To calculate the semantic relatedness between two collocations, we use a simplified version of the text-to-text relatedness technique proposed by and (Mihalcea et al., 2006) that incorporate the directional inferential similarity as an underlying semantic metric.

5.3 Topical Modeling

Intuitively, every text is written with a topic in mind, and the associated image serves as an illustration of the text meaning. In this paper, we investigate the effect of topical modeling on image annotation accuracy directly. We use the Pachinko Allocation Model (PAM) (Li and McCallum, 2006) to model the topics in a text, where keywords forming the dominant topic are assumed as our set of annotation keywords. Compared with previous topic modeling approaches, such as Latent Dirichlet allocation (LDA) or its improved variant Correlated Topic Model (CTM) (Blei and Lafferty, 2007), PAM captures correlations between all the topic pairs using a directed acyclic graph (DAG). It also supports finer-grained topic modeling, and has state-of-the-art performance on the tasks of document classification and topical keyword coherence. Given a text, we use the PAM model to infer a list of *super-topics* and *sub-topics* together with words weighted according to the likelihood that they belong to each of these topics. For each text, we retrieve the top words belonging to the dominant super-topic and sub-topic. We use 50 super-topics and 100 sub-topics as operating parameters for PAM, since these values were found to provide good results in previous work on topic modeling. Default values are used for other parameters in the model.

5.4 Supervised Learning

The three tagging methods target different aspects of what constitutes a good label for an image. We use them as features in a machine learning framework, and introduce a final rank attribute S(t_j), which is a linear combination of the reciprocals of the rank of each tag as given by each method,

$$S(t_j) = \sum_{m \in methods} \lambda_m \frac{1}{r^m_{t_j}}$$

where $r^m_{t_j}$ is the rank for tag t_j given by method m. The weight of each method λ_m is estimated from the training set using information gain values. Since our predicted variable (*mode* precision or recall) is continuous, we use the Support Vector Algorithm (nu-SVR) implementation of SVM (Chang and Lin, 2001) to perform regression analysis on the weights for each method via a radial basis function kernel. A ten-fold cross-validation is applied on the entire dataset of 300 images.

	Best				out-of-ten (oot)			
	Normal		Mode		Normal		Mode

Table 3: Results obtained on the Web dataset

6 Experiments and Evaluations

We evaluate the performance of each of the three tagging methods separately, followed by an evaluation of the combined method. Each system produces a ranked list of K words or collocations as tags assigned to a given image. A system can discretionary generate less (but not more) than K tags, depending on its confidence level.

For comparison, we implement three baselines: *tf*idf*, *Doc Title* and *Random*. For *tf*idf*, we use the British National Corpus to calculate the *idf* scores, while the frequency of a term is calculated from the entire text associated with an image. The *Doc Title* baseline is similar, except that the term frequency is calculated based on the title of the document. The *Random* baseline randomly selects words from a co-occurrence window of size K before and after an image as its annotation. Following other tagging methods, we apply a pre-processing stage, where we part-of-speech tag the text (to retain only nouns), followed by stemming. We also determine an upper bound, which is calculated as follows. For each image, the labels assigned by each of the five annotators are in turn evaluated against a gold standard consisting of the annotations of the other four annotators. The best performing annotator is then recorded. This process is repeated for each of the 300 images, and the average precision and recall are calculated. This represents an upper bound, as it is the best performance that a human can achieve on this dataset. Table 3 shows our experimental results.

Among the individual methods, the method implementing Flickr picturability has the highest individual score for *best* and *oot* modes, yielding a precision and recall of 78.57% and 92.86% respectively. The Wikipedia Saliency method also scores the highest (jointly with Flickr) in the *oot* mode, but for the *best* mode achieves a score only marginally better than the random baseline. A plausible explanation is that it tends to favor "all-inferring" over-specific labels, while the most frequently selected tags in mode pictures are typically more "picturable" than being specific (e.g. "train" for the mode picture in Table 1). The topic modeling method has mixed results: its scores for *oot* normal and mode are somewhat competitive with *tf*idf*, but it scores consistently lower than the DocTitle in the *best* subtask, possibly due to the absence of a more sophisticated reranking algorithm tailored for the image annotation task other than the intrinsic ranking mechanism in PAM. It is worth noting that the combined supervised system provides the overall best results (6.87%) on the *best* normal, and achieves a perfect precision and recall (100%) for *oot* mode, which means perfect agreement with the human tagging.

7 Comparison with Related Work

We also compare our work against (Feng and Lapata, 2008) as it allows for a direct comparison with models using both image and textual features under a standard evaluation framework. We obtained the BBC dataset used in their experiments, which consists of 3121 training and 240 testing images. In this dataset, images are implicitly tagged with captions by the author of the corresponding BBC article. The evaluations are run against these captions.

In their experiments, Feng and Lapata created four annotation models. The first two (tf*idf and Document Title) are the same as used in our baseline experiments. The third model (Lavrenko03) is an application of the continuous relevance model in (Jeon et al., 2003), trained with the BBC image features and captions. Finally, the forth (ExtModel) is an extension of the relevance model using additional information in auxiliary texts. Briefly, the model assumes a multiple Bernoulli distribution for words in a caption, and generates tags for a test image using a weighted combination of the accompanying document, caption and image features learned during training.

	Top 10			Top 15			Top 20		
Models	P	R	F1	P	R	F1	P	R	F1
*tf*idf*	4.37	7.09	5.41	3.57	8.12	4.86	2.65	8.89	4.00
DocTitle	9.22	7.03	7.20	9.22	7.03	7.20	9.22	7.03	7.20
Lavrenko03	9.05	16.01	11.81	7.73	17.87	10.71	6.55	19.38	9.79
ExtModel	14.72	27.95	19.82	11.62	32.99	17.18	9.72	36.77	15.39
Flickr picturability	12.13	22.82	15.84	9.52	26.82	14.05	8.23	29.80	12.90
Wikipedia Salience	11.63	21.89	15.18	9.28	26.20	13.70	7.81	29.41	12.35
Topic Modeling	11.42	21.49	14.91	9.28	26.20	13.70	7.86	29.57	12.42
Combined (SVM)	13.38	25.17	17.47	11.08	31.29	16.37	9.50	35.76	15.01

Table 4: Results obtained on the BBC dataset used in (Feng and Lapata, 2008)

The experimental setup is similar to the earlier section, but a few modifications are made for a fair and direct comparison. First, we extend our models coverage to include content words (i.e. nouns, verbs, adjectives) determined using the Tree Tagger (Schmid, 1994). Second, no collocations are used. Third, we adopt the evaluation framework used by Feng and Lapata to extract the top 10, 15 and 20 tags. Note that in our methods, the extraction of tags for a test image is only done on the document surrounding the image, after excluding the caption. As the number of negative examples (words not present in the caption) greatly outnumber the positive instances, we employ an undersampling method (Kubat and Matwin, 1997) to balance the dataset for training.

The results are shown in Table 4. Interestingly, all our unsupervised extraction-based models perform consistently above the supervised Lavrenko03 model, indicating that textual features are more informative than captions and image features taken together. Comparing with models using significantly less document information (tf*idf and Doc title), our models gain even greater advantage. Note that the title of any BBC article does not exceed 10 words, hence comparison is only meaningful given the top 10 tags retrieved.

Feng and Lapata used LDA to perform reranking of final candidates in their ExtModel. However, when used as a model alone, the PAM topic model achieved promising scores in all the categories, performing best for top 10 keywords (F1 of 14.91%). Flickr picturability stands out as the best performing unsupervised method, scoring the highest precision (12.13%, top 10), recall (29.80%, top 20) and F1 (15.84%, top 10).

Overall, this comparative evaluation yields some important insights. First, our combined model using SVM is statistically better ($p<0.1$ for top 10, 15, 20) than the Laverenko03 model, but not statistically different from the ExtModel. This demonstrates the effectiveness of textual-based models over traditional models trained with image features and captions. While it is intuitively clear that image features help in improving tagging performance, we show that mining only the text surrounding an image, where it exists, can yield a performance that is comparable to a state-of-the-art system that uses both textual and visual features. Moreover, an increase in complexity of a model by using more features may hinder its applicability to large datasets, but not necessarily improving annotation performance (Makadia et al., 2008). On this, text-based annotation models can provide a desirable compromise. For instance, our unsupervised models implementing Flickr picturability and Wikipedia Salience are able to extract annotations from a BBC article (average 133.85 tokens) in approximately 1 second and 20 seconds respectively.

8 Conclusions and Future Work

In this paper, we introduced several text-based extractive approaches for automatic image annotation and showed that they compare favorably with the state-of-the-art in image annotation using both text and image features. We believe our work has practical applications in mining and annotating images over the Web, where texts are naturally associated with images, and scalability is important. Our next direction seeks to derive robust annotation models using additional ontological knowledge-bases. We would also like to advance the the state-of-the-art by augmenting current textual models with image features.

Unsupervised Discriminative Language Model Training for Machine Translation using Simulated Confusion Sets

Zhifei Li and **Ziyuan Wang** and **Sanjeev Khudanpur** and **Jason Eisner**

zhifei.work@gmail.com,{zwang40, khudanpur, eisner}@jhu.edu

Abstract

An *unsupervised* discriminative training procedure is proposed for estimating a language model (LM) for machine translation (MT). An English-to-English synchronous context-free grammar is derived from a baseline MT system to capture *translation alternatives*: pairs of words, phrases or other sentence fragments that potentially compete to be the translation of the same source-language fragment. Using this grammar, a set of impostor sentences is then created for each English sentence to *simulate* confusions that would arise if the system were to process an (unavailable) input whose correct English translation is that sentence. An LM is then trained to discriminate between the original sentences and the impostors. The procedure is applied to the IWSLT Chinese-to-English translation task, and promising improvements on a state-of-the-art MT system are demonstrated.

1 Discriminative Language Modeling

A language model (LM) constitutes a crucial component in many tasks such as machine translation (MT), speech recognition, information retrieval, handwriting recognition, etc. It assigns a priori probabilities to word sequences. In general, we expect a low probability for an ungrammatical or implausible word sequence. The dominant LM used in such systems is the so-called n-gram model, which is typically derived from a large corpus of target language text via maximum likelihood estimation, mitigated by some smoothing or regularization. Due to the Markovian assumptions implicit in n-gram models, however, richer linguistic and semantic dependencies are not well captured. Rosenfeld (1996) and Khudanpur and Wu (2000) address such shortcoming by using maximum entropy models with long-span features, while still working with a *locally* normalized left-to-right LM. The whole-sentence maximum entropy LM of Rosenfeld et al. (2001) proposes a *globally* normalized log-linear LM incorporating several sentence-wide features.

The n-gram as well as the whole-sentence model are *generative* or descriptive models of text. However, in a task like Chinese-to-English MT, the de facto role of the LM is to *discriminate* among the alternative English translations being contemplated by the MT system for a particular Chinese input sentence. We call the set of such alternative translations a *confusion set*. Since a confusion set is typically a minuscule subset of the set of all possible word sequences, it is arguably better to train the LM parameters so as to make the *best candidate* in the confusion set more likely than its competitors, as done by Roark et al. (2004) for speech recognition and by Li and Khudanpur (2008) for MT. Note that identifying the best candidate requires *supervised* training data—bilingual text in case of MT—which is expensive in many domains (e.g. weblog or newsgroup) and for most language pairs (e.g. Urdu-English).

We propose a novel discriminative LM in this paper: a globally normalized log-linear LM that can be trained in an *efficient* and *unsupervised* manner, using only monolingual (English) text.

The main idea is to exploit (translation) uncertainties inherent in an MT system to derive an English-to-English confusion grammar (CG), illustrated in this paper for a Hiero system (Chiang, 2007). From the *bilingual* synchronous context-free grammar (SCFG) used in Hiero, we extract a *monolingual* SCFG, with rules of the kind, $X \rightarrow \langle \text{strong tea}, \text{powerful tea} \rangle$ or

Coling 2008: Poster Volume, pages 656–664,
Beijing, August 2010

$X \rightarrow \langle \text{in } X_1, \text{in the } X_1 \rangle$. Thus our CG is also an SCFG that generates pairs of English sentences that differ from each other in ways that alternative English hypothesis considered during translation would differ from each other. This CG is then used to "translate" each sentence in the LM training corpus into what we call its *confusion set* — a set of other "sentences" with which that sentence would likely be confused by the MT system, were it to be the target translation of a source-language sentence. Sentences in the training corpus, each paired with its confusion set, are then used to train a discriminative LM to prefer the training sentences over the alternatives in their confusion sets.

Since the monolingual CG and the bilingual Hiero grammar are both SCFGs, the confusion sets are isomorphic with translation hypergraphs that are used by supervised discriminative training. The confusion sets thus *simulate* the supervised case, with a key exception: lack of any (Chinese) source-language information. Therefore, only target-side "language model" probabilities may be estimated from confusion sets.

We carry out this discriminative training procedure, and empirically demonstrate promising improvements in translation quality.

2 Discriminative LM Training

2.1 Whole-sentence Maximum Entropy LM

We aim to train a globally normalized log-linear language model $p_\theta(y)$ of the form

$$p_\theta(y) \quad = \quad \mathrm{Z}^{-1}\, e^{f(y)\cdot\theta} \tag{1}$$

where y is an English sentence, $f(y)$ is a vector of arbitrary features of y, θ is the (weight) vector of model parameters, and $\mathrm{Z} \stackrel{\text{def}}{=} \sum_{y'} e^{f(y')\cdot\theta}$ is a normalization constant. Given a set of English training sentences $\{y_i\}$, the parameters θ may be chosen to maximize likelihood, as

$$\theta^* \quad = \quad \arg\max_\theta \prod_i p_\theta(y_i). \tag{2}$$

This is the so called whole-sentence maximum entropy (WSME) language model[1] proposed by Rosenfeld et al. (2001). Training the model of (2) requires computing Z, a sum over all possible word sequences y' with any length, which is computationally intractable. Rosenfeld et al. (2001) approximate Z by random sampling.

[1]Note the contrast with the maximum entropy n-gram LM (Rosenfeld, 1996; Khudanpur and Wu, 2000), where the normalization is performed for each n-gram history.

2.2 Supervised Discriminative LM Training

In addition to the computational disadvantage, (2) also has a modeling limitation. In particular, in a task like MT, the primary role of the LM is to discriminate among alternative translations of a *given* source-language sentence. This set of alternatives is typically a minuscule subset of all possible target-language word sequences. Therefore, a better way to train the global log-linear LM, given bilingual text $\{(x_i, y_i)\}$, is to generate the *real* confusion set $\mathcal{N}(x_i)$ for each input sentence x_i using a specific MT system, and to adjust θ to discriminate between the reference translation y_i and $y' \in \mathcal{N}(x_i)$ (Roark et al., 2004; Li and Khudanpur, 2008).

For example, one may maximize the conditional likelihood of the bilingual training data as

$$\begin{aligned} \theta^* \quad &= \quad \arg\max_\theta \prod_i p_\theta(y_i \mid x_i) \\ &= \quad \arg\max_\theta \prod_i \frac{e^{f(x_i,y_i)\cdot\theta}}{\sum_{y'\in\mathcal{N}(x_i)} e^{f(x_i,y')\cdot\theta}}\,, \end{aligned} \tag{3}$$

which entails summing over *only* the candidate translations y' of the given input x_i. Furthermore, if the features $f(x_i, y)$ are depend on *only* the output y, i.e. on the English-side features of the bilingual text, the resulting discriminative model may be interpreted as a *language model*.

Finally, in a Hiero style MT system, if $f(x_i, y)$ depends on the target-side(s) of the bilingual rules used to construct y from x_i, we essentially have a *syntactic* LM.

2.3 Unsupervised Discriminative Training using Simulated Confusion Sets

While the supervised discriminative LM training has both computational and modeling advantages over the WSME LM, it relies on bilingual data, which is expensive to obtain for several domains and language pairs. For such cases, we propose a novel discriminative language model, which is

still a global log-linear LM with the modeling advantage and computational *efficiency* of (3) but requires only monolingual text $\{y_i\}$ for training θ. Specifically, we propose to modify (3) as

$$\theta^* = \arg\max_\theta \prod_i p_\theta(y_i \,|\, \mathcal{N}(y_i)) \quad (4)$$
$$= \arg\max_\theta \prod_i \frac{e^{f(y_i)\cdot\theta}}{\sum_{y' \in \mathcal{N}(y_i)} e^{f(y')\cdot\theta}},$$

where $\mathcal{N}(y_i)$ is a *simulated* confusion set for y_i obtained by applying a confusion grammar to y_i, as detailed in Section 3. Our hope is that $\mathcal{N}(y_i)$ resembles the actual confusion set $\mathcal{N}(x_i)$ that an MT system would generate if it were given the input sentence x_i.

Like (3), the maximum likelihood training of (4) does not entail the expensive computation of a global normalization constant Z, and is therefore very *efficient*. Unlike (3) however, where the input x_i for each output y_i is needed to create $\mathcal{N}(x_i)$, the model of (4) can be trained in an *unsupervised* manner with only $\{y_i\}$.

3 Unsupervised Discriminative Training of the Language Model for MT

The following is thus the proposed procedure for unsupervised discriminative training of the LM.

1. Extract a *confusion grammar* (CG) from the baseline MT system.
2. "Translate" each English sentence in the LM training corpus, using the CG as an English-to-English translation model, to generate a *simulated* confusion set.
3. Train a discriminative language model on the simulated confusion sets, using the corresponding original English sentences as the training references.

The trained model may then be used for actual MT decoding. We next describe each step in detail.

3.1 Extracting a Confusion Grammar

We assume a synchronous context free grammar (SCFG) formalism for the confusion grammar (CG). While the SCFG used by the MT system is bilingual, the CG we extract will be *monolingual*, with both the source and target sides being English. Some example CG rules are:

$$\begin{aligned} X &\rightarrow \langle \text{ strong tea , powerful tea } \rangle, \\ X &\rightarrow \langle X_0 \text{ at beijing , beijing 's } X_0 \rangle, \\ X &\rightarrow \langle X_0 \text{ of } X_1 \text{ , } X_0 \text{ of the } X_1 \rangle, \\ X &\rightarrow \langle X_0 \text{ 's } X_1 \text{ , } X_1 \text{ of } X_0 \rangle. \end{aligned}$$

Like a regular SCFG, a CG contains rules with different "arities" and reordering of the nonterminals (as shown in the last example) capturing the confusions that the MT system encounters when choosing word *senses*, *reordering patterns*, etc.

3.1.1 Extracting a Confusion Grammar from the Bilingual Grammar

The confusion grammar is derived from the MT system's bilingual grammar. In Hiero, the bilingual rules are of the form $X \rightarrow \langle c, e \rangle$, where both c and e may contain (a matched number of) nonterminal symbols. For every c which appears on the source-side of two different Hiero rules $X \rightarrow \langle c, e_1 \rangle$ and $X \rightarrow \langle c, e_2 \rangle$, we extract two CG rules, $X \rightarrow \langle e_1, e_2 \rangle$ and $X \rightarrow \langle e_2, e_1 \rangle$, to capture the confusion the MT system would face were it to encounter c in its input. For each Hiero rule $X \rightarrow \langle c, e \rangle$, we also extract $X \rightarrow \langle e, e \rangle$, the *identity* rule. Therefore, if a pattern c appears with $|E|$ different translation options, we extract $|E|^2$ different CG rules from c. In our current work, the rules of the CG are unweighted.

3.1.2 Test-set Specific Confusion Grammars

If the bilingual grammar contains all the rules that are extractable from the bilingual training corpus, the resulting confusion grammar is likely to be huge. As a way of reducing computation, the bilingual grammar can be restricted to a specific test set, and only rules used by the MT system for translating the test set used for extracting the CG.[2]

To economize further, one may extract a CG from the translation *hypergraphs* that are generated for the test-set. Recall that a *node* in a hypergraph corresponds to a specific source (Chinese) span, and the node has many incident *hyperedges*, each associated with a different bilin-

[2]Test-set specific CGs are of course only practical for offline applications.

gual rule. Therefore, all the bilingual rules associated with the incoming hyperedges of a given node translate the same Chinese string. At each hypergraph node, we extract CG rules to represent the competing English sides as described above. Note that even though different rules associated with a node may have different "arity," we extract CG rules only from pairs of bilingual rules that have the same arity.

A CG extracted from only the bilingual rule pairs incident on the same node in the test hypergraphs is, of course, much smaller than a CG extracted from the entire bilingual grammar. It is also more suitable for our task, since the test hypergraphs have already benefited from a baseline n-gram LM and pruning, removing all confusions that are easily resolved (rightly or wrongly) by other system components.

3.2 Generating Simulated Confusion Sets

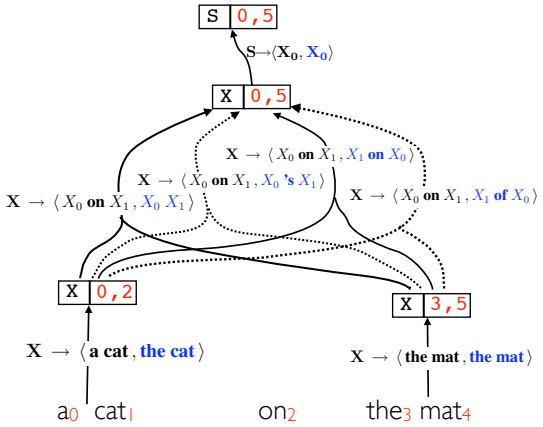
For each English sentence y in the training corpus, we use the extracted CG to produce a simulated confusion set $\mathcal{N}(y)$. This is done like a regular MT decoding pass, because we can treat the CG as a Hiero style "translation" grammar[3] for an English-to-English translation system.

Since the CG is an SCFG, the confusion set $\mathcal{N}(y)$ generated for a sentence y is a *hypergraph*, encoding not only the alternative sentences y' but also the hierarchical derivation tree for each y' from y (e.g., which phrase in y has been replaced with what in y'). As usual, many different derivation trees d may correspond to the same string/sentence y' due to spurious ambiguity. We use $\mathrm{D}(y)$ to denote the set of derivations d, which is a hypergraph representation of $\mathcal{N}(y)$.

Figure 1 presents an example confusion hypergraph for the English sentence y ="*a cat on the mat*," containing four alternative hypotheses:

$$\begin{array}{lcl} X & \rightarrow & \langle \text{a cat} \,,\, \text{the cat} \rangle \\ X & \rightarrow & \langle \text{the mat} \,,\, \text{the mat} \rangle \\ X & \rightarrow & \langle X_0 \text{ on } X_1 \,,\, X_0 \; X_1 \rangle \\ X & \rightarrow & \langle X_0 \text{ on } X_1 \,,\, X_0 \text{ 's } X_1 \rangle \\ X & \rightarrow & \langle X_0 \text{ on } X_1 \,,\, X_1 \text{ on } X_0 \rangle \\ X & \rightarrow & \langle X_0 \text{ on } X_1 \,,\, X_1 \text{ of } X_0 \rangle \\ S & \rightarrow & \langle X_0 \,,\, X_0 \rangle \end{array}$$

(a) An example confusion grammar.



(b) An example hypergraph generated by the confusion grammar of (a) for the input sentence "*a cat on the mat*."

Figure 1: **Example confusion grammar and simulated confusion hypergraph.** Given an input sentence $y =$ "*a cat on the mat*," the confusion grammar of (a) generates a hypergraph $\mathrm{D}(y)$ shown in (b), which represents the confusion set $\mathcal{N}(y)$ containing four alternative sentences y'.

$\mathcal{N}(y) = \{$ "*the cat the mat*," "*the cat 's the mat*," "*the mat of the cat*," "*the mat on the cat*"$\}$.

Notice that each competitor $y' \in \mathcal{N}(y)$ can be regarded as the result of a "round-trip" translation $y \rightarrow x \rightarrow y'$, in which we reconstruct a possible Chinese source sentence x that our Hiero bilingual grammar could translate into both y and y'.[4] We will train our LM to prefer y, which was actually observed. Our CG-based round-trip forces $x \rightarrow y'$ to use the *same* hierarchical segmentation of x as $y \rightarrow x$ did. This constraint leads to efficient training but artificially reduces the diversity

[3] To make sure that we produce at least one derivation tree for each y, we need to add to the CG the following two glue rules, as done in Hiero (Chiang, 2007).

$$\begin{array}{lcl} S & \rightarrow & \langle X_0 \,,\, X_0 \rangle \,, \\ S & \rightarrow & \langle S_0 \; X_1 \,,\, S_0 \; X_1 \rangle \,. \end{array}$$

We also add an out of vocabulary rule $X \rightarrow \langle word, \text{oov} \rangle$ for each *word* in y and set the cost of this rule to a high value so that the OOV rule will get used only when the CG does not know how to "translate" the *word*.

[4] This is because of the way we construct our CG from the Hiero grammar. However, the identity and glue rules in our CG allow almost any portion of y to be preserved untranslated through the entire $y \rightarrow x \rightarrow y'$ process. Much of y will necessarily be preserved in the situation where the CG is extracted from a small test set and hence has few non-identity rules. See (Li, 2010) for further discussion.

of $\mathcal{N}(y)$. In other recent work (Li et al., 2010), we have taken the round-trip view more seriously, by imputing *likely* source sentences x and translating them back to *separate*, *weighted* confusion forests $\mathcal{N}(y)$, *without* any same-segmentation constraint.

3.3 Confusion-based Discriminative Training

With the training sentences y_i and their simulated confusion sets $\mathcal{N}(y_i)$ — represented as hypergraphs $\mathrm{D}(y_i)$) — we can perform the discriminative training using any of a number of procedures such as MERT (Och, 2003) or MIRA as used by Chiang et al. (2009). In our paper, we use hypergraph-based minimum risk (Li and Eisner, 2009),

$$\begin{aligned}\theta^* &= \arg\min_\theta \sum_i \mathrm{Risk}_\theta(y_i) \qquad (5)\\ &= \arg\min_\theta \sum_i \sum_{d\in \mathrm{D}(y_i)} \mathrm{L}(\mathrm{Y}(d), y_i) p_\theta(d \,|\, \mathrm{D}(y_i)),\end{aligned}$$

where $\mathrm{L}(y', y_i)$ is the loss (e.g negated BLEU) incurred by producing y' when the true answer is y_i, $\mathrm{Y}(d)$ is the English *yield* of a derivation d, and $p_\theta(d \,|\, \mathrm{D}(y_i))$ is defined as,

$$p_\theta(d \,|\, \mathrm{D}(y_i)) = \frac{e^{f(d)\cdot\theta}}{\sum_{d\in \mathrm{D}(y_i)} e^{f(d)\cdot\theta}}, \qquad (6)$$

where $f(d)$ is a feature vector over d. We will specify the features in Section 5, but in general they should be defined such that the training will be efficient and the actual MT decoding can use them conveniently.

The objective of (5) is differentiable and thus we can optimize θ by a gradient-based method. The risk and its gradient on a hypergraph can be computed by using a second-order expectation semiring (Li and Eisner, 2009).

3.3.1 Iterative Training

In practice, the full confusion set $\mathcal{N}(y)$ defined by a confusion grammar may be too large and we have to perform pruning when training our model. But the pruning itself may depend on the model that we aim to train. How do we solve this circular dependency problem? We adopt the following procedure. Given an initial model θ, we generate a hypergraph (with pruning) for each y, and train an optimal θ^* of (5) on these hypergraphs. Then, we use the optimal θ^* to *regenerate* a hypergraph for each y, and do the training again. This iterates until convergence. This procedure is quite similar to the k-best MERT (Och, 2003) where the training involves a few iterations, and each iteration uses a new k-best list generated using the latest model.

3.4 Applying the Discriminative LM

First, we measure the goodness of our language model in a simulated task. We generate simulated confusion sets $\mathcal{N}(y)$ for some held out English sentences y, and test how well $p_\theta(d \,|\, \mathrm{D}(y))$ can recover y from $\mathcal{N}(y)$. This is merely a proof of concept, and may be useful in deciding which features $f(d)$ to employ for discriminative training.

The intended use of our model is, of course, for actual MT decoding (e.g., translating Chinese to English). Specifically, we can add the discriminative model into an MT pipeline as a feature, and tune its weight relative to other models in the MT system, including the baseline n-gram LM.

4 Related and Similar Work

The detailed relation between the proposed procedure and other language modeling techniques has been discussed in Sections 1 and 2. Here, we review two other methods that are related to our method in a broader context.

4.1 Unsupervised Training of Global Log-linear Models

Our method is similar to the contrastive estimation (CE) of Smith and Eisner (2005) and its successors (Poon et al., 2009). In particular, our confusion grammar is like a *neighborhood function* in CE. Also, our goal is to improve both efficiency and accuracy, just as CE does. However, there are two important differences. First, the neighborhood function in CE is manually created based on human insights about the particular task, while our neighborhood function, generated by the CG, is automatically *learnt* (e.g., from the bilingual grammar) and specific to the MT system being used. Therefore, our neighborhood function is more likely to be informative and adaptive to the task. Secondly, when tuning θ, CE uses the maximum likelihood training, but we use the minimum

risk training of (5). Since our training uses a task-specific loss function, it is likely to perform better than maximum likelihood training.

4.2 Paraphrasing Models

Our method is also related to methods for training paraphrasing models (Quirk et al., 2004; Bannard and Callison-Burch, 2005; Callison-Burch et al., 2006; Madnani et al., 2007). Specifically, the form of our *confusion grammar* is similar to that of the *paraphrase model* they use, and the ways of extracting the grammar/model are also similar as both employ a second language (e.g., Chinese in our case) as a *pivot*. However, while a "translation" rule in a paraphrase model is expected to contain a pair of phrases that are good alternatives for each other, a confusion rule in our CG is based on an MT system processing unseen test data and contains pairs of phrases that are typically bad (and only rarely good) alternatives for each other.

The motivation and goal are also different. For example, the goal of Bannard and Callison-Burch (2005) is to extract paraphrases with the help of parallel corpora. Callison-Burch et al. (2006) aim to improve MT quality by adding paraphrases in the translation table, while Madnani et al. (2007) aim to improve the minimum error rate training by adding the automatically generated paraphrases into the English reference sets. In contrast, our motivation is to train a *discriminative* language model to improve MT (by using the confusion grammar to decide what alternatives the model should learn to discriminate).

5 Experimental Results

We have applied the confusion-based discriminative language model (CDLM) to the IWSLT 2005 Chinese-to-English text translation task[5] (Eck and Hori, 2005). We see promising improvements over an n-gram LM for a solid **Joshua**-based baseline system (Li et al., 2009).

5.1 Data Partitions for Training & Testing

Four kinds of data are used for CDLM training:

[5]This is a relatively small task compared to, say, the NIST MT tasks. We worked on it for a proof-of-concept. Having been successful, we are now investigating larger MT tasks.

	Data Usage	# sentences	
		ZH	EN
Set1	TM & LM training	40k	40k
Set2	Min-risk training	1006	1006×16
Set3	CDLM training	—	1006×16
Set4	Test	506	506×16

Table 1: **Data sets used.** Set1 contains translation-equivalent Chinese-English sentence pairs, while for each Chinese sentence in Set2 and Set4, there are 16 English translations. Set3 happens to be the English side of Set2 due to lack of additional in-domain English text, but this is not noteworthy; Set3 could be any in-domain target-language text corpus.

Set1 a bilingual training set on which 10 individual MT system components are trained,

Set2 a small bilingual, in-domain set for tuning relative weights of the system components,

Set3 an in-domain monolingual target-language corpus for CDLM training, and

Set4 a test set on which improvements in MT performance is measured.

We partition the IWSLT data into four such subsets as listed in Table 1.

5.2 Baseline MT System

Our baseline translation model components are estimated from 40k pairs of utterances from the travel domain, called Set1 in Table 1. We use a *5-gram* language model with modified Kneser-Ney smoothing (Chen and Goodman, 1998), trained on the English side of Set1, as our baseline LM.

The baseline MT system comprises 10 component models (or "features") that are standard in Hiero (Chiang, 2007), namely the baseline language model (BLM) feature, three baseline translation model features, one word-insertion penalty (WP) feature, and five *arity* features — three to count how many rules with an arity of zero/one/two are used in a derivation, and two to count how many times the unary and binary glue rules are used in a derivation. The relative weights of these 10 features are tuned via hypergraph-based minimum risk training (Li and Eisner, 2009) on the *bilingual* data Set2.

The resulting MT system gives a BLEU score of 48.5% on Set4, which is arguably a solid baseline.

5.3 Unsupervised Training of the CDLM

We extract a test-set specific CG from the hypergraphs obtained by decoding Set2 and Set4, as described in Section 3.1.2. The number of rules in the bilingual grammar and the CG are about 167k and 1583k respectively. The CG is used as the "translation" model to generate confusion hypergraphs for sentences in Set3.

Two CDLMs, corresponding to different feature sets $f(d)$ in equation (6), were trained.

Only n-gram LM Features: We consider a CDLM with only two features $f(d)$: a baseline LM feature (BLM) that equals the 5-gram probability of $\mathrm{Y}(d)$ and a word penalty feature (WP) equal to the length of $\mathrm{Y}(d)$.

Target-side Rule Bigram Features[6]: For each CG rule used in d, we extract counts of bigrams that appear on the target-side of the CG rule. For example, if the confusion rule $X \rightarrow \langle\, X_0 \text{ of } X_1 \,,\, X_0 \text{ of the } X_1 \,\rangle$ is used in d, the bigram features in $f(d)$ whose counts are incremented are: "*X of*," "*of the*" and "*the X*."[7] Note that the indices on the nonterminals in the rule have been removed. To avoid very rare features, we only consider the 250 most freqent terminal symbol (English words) in the English of Set1 and map all other terminal symbols into a single class. Finally, we replace the identities of words with their dominant POS tags. These restrictions result in 525 target-side rule bigram (TsRB) features $f(d)$ in the model of (6).

For each choice of the feature vector $f(d)$, be it 2- or 527-dimensional, we use the training procedure of Section 3.3.1 to iteratively minimize the objective of (5) and get the CDLM parameter θ^*.

Note that each English sentence in Set3 has 15 other paraphrases. We generate a separate confusion hypergraph $\mathrm{D}(y)$ for each English sentence y, but for each such hypergraph we use both y and its 15 paraphrases as "reference translations" when computing the risk $\mathrm{L}(\mathrm{Y}(d), \{y\})$ in (5).[8]

[6]Note that these features are novel in MT.

[7]With these target-side rule-based features, our LM is essentially a *syntactic* LM, not just an LM on English strings.

[8]We take unfair advantage of this unusual dataset to combat an unrelated complication—a seemingly problematic instability in the minimum risk training procedure.

As an illustration of this problem, we note that in supervised tuning of the baseline MT system ($|f(d)|$=10) with 500 sentences from Set2, the BLEU score on Set4 varies from 38.6% to 44.2% to 47.8% if we use 1, 4 and 16 reference translations during the supervised training respectively. We choose a system tuned on 16 references on Set2 as our baseline. In order not to let the unsupervised CDLM training suffer from this unrelated limitation of the tuning procedure, we give it too the benefit of being able to compute risk on Set3 using y plus its 15 paraphrases.

We wish to emphasize that this trait of Set3 having 15 paraphrases for each sentence is otherwise unnecessary, and *does not* detract much from the main claim of this paper.

5.4 Results on Monolingual Simulation

We first probe how our novel CDLM performs as a language model itself. One usually uses the perplexity of the LM on some unseen text to measure its goodness. But since we did not optimize the CDLM for likelihood, we instead examine how it performs in discriminating between a good English sentence and sentences with which the MT system may confuse that sentence. The test is performed as follows. For each test English sentence y of Set4, the confusion grammar defines a full confusion set $\mathcal{N}(y)$ via a hypergraph $\mathrm{D}(y)$. We use a LM to pick the most likely y^* from $\mathcal{N}(y)$, and then compute its BLEU score by using y and its 15 paraphrase sentences as references. The higher the BLEU, the better is the LM in picking out a good translation from $\mathcal{N}(y)$.

Table 2 shows the results[9] under a regular n-gram LM and the two CDLMs described in Section 5.3.

The baseline LM (BLM) entails no weight optimization a la (5) on Set3. The CDLM with the BLM and word pentaly (WP) features improves over the baseline LM. Compared to either of them, the CDLM with the target-side rule bigram features (TsRB) performs dramatically better.

5.5 Results on MT Test Data

We now examine how our CDLM performs during actual MT decoding. To incorporate the CDLM into MT decoding, we add the log-probability (6) of a derivation d under the CDLM as an additional

[9]Note that the scores in Table 2 are very low compared to scores for actual translation from Chinese shown in Table 3. This is mainly because in this monolingual simulation, the LM is the only model used to rank the $y' \in \mathcal{N}(y)$. Said differently, y^* is being chosen in Table 2 entirely for its fluency with no consideration whatsoever for its adequacy.

LM used for rescoring	Features used BLM	WP	TsRB	BLEU on Set4
Baseline LM	✓			12.8
CDLM	✓	✓		14.2
CDLM	✓	✓	✓	25.3

Table 2: **BLEU scores in monolingual simulations.** Rescoring the *confusion sets* of English sentences created using the CG shows that the CDLM with TsRB features recovers hypotheses much closer to the sentence that generated the confusion set than does the baseline n-gram LM.

Model used for rescoring	Features used 10 models	TsRB	BLEU on Set4
Joshua	✓		48.5
+ CDLM	✓	✓	49.5

Table 3: **BLEU scores on the test set.** The baseline MT system has ten models/features, and the proposed system has one *additional* model, the CDLM. Note that for the CDLM, only the TsRB features are used during MT decoding.

feature, on top of the 10 features already present in baseline MT system (see Section 5.2). We then (re)tune relative weights for these 11 features on the *bilingual* data Set2 of Table 1.

Note that the MT system also uses the BLM and WP features whose weights are now retuned on Set2. Therefore, when integrating a CDLM into MT decoding, it is mathematically equivalent to use only the TsRB features of the CDLM, with the corresponding weights as estimated alongside its "own" BLM and WP features during unsupervised discriminative training on Set3.

Table 3 reports the results. A BLEU score improvement of 1% is seen, reinforcing the claim that the unsupervised CDLM helps select better translations from among the system's alternatives.

5.6 Goodness of Simulated Confusion Sets

The confusion set $\mathcal{N}(y)$ generated by applying the CG to an English sentence y aims to simulate the real confusion set that would be generated by the MT system if the system's input was the Chinese sentence whose English translation is y. We investigate, in closing, how much the simulated confusion set resembles to the real one. Since we know the actual input-output pairs (x_i, y_i) for Set4, we generate two confusion sets: the simulated set $\mathcal{N}(y_i)$ and the real one $\mathcal{N}(x_i)$.

One way to measure the goodness of $\mathcal{N}(y_i)$ as a proxy for $\mathcal{N}(x_i)$, is to extract the n-gram types witnessed in the two sets, and compute the ratio of the number of n-grams in the intersection to the number in their union. Another is to measure the precision and recall of $\mathcal{N}(y_i)$ relative to $\mathcal{N}(x_i)$.

n-gram	Precision	Recall
unigram	36.5%	48.2%
bigram	10.1%	12.8%
trigram	3.7%	4.6%
4-gram	2.0%	2.4%

Table 4: **n-gram precision and recall of simulated confusion sets** relative to the true confusions when translating Chinese sentences. The n-grams are collected from k-best strings in both cases, with $k = 100$. The precision and recall change little when varying k.

Table 4 presents such precision and recall figures. For convenience, the n-grams are collected from the 100-best strings, instead of the hypergraph $\mathrm{D}(y_i)$ and $\mathrm{D}(x_i)$. Observe that the simulated confusion set does a reasonably good job on the real unigram confusions but the simulation needs improving for higher order n-grams.

6 Conclusions

We proposed a novel procedure to discriminatively train a globally normalized log-linear language model for MT, in an efficient and unsupervised manner. Our method relies on the construction of a confusion grammar, an English-to-English SCFG that captures translation alternatives that an MT system may face when choosing a translation for a given input. For each English training sentence, we use this confusion grammar to generate a simulated confusion set, from which we train a discriminative language model that will prefer the original English sentence over sentences in the confusion set. Our experiments show that the novel CDLM picks better alternatives than a regular n-gram LM from simulated confusion sets, and improves performance in a real Chinese-to-English translation task.

Abstract

This paper presents a novel feature-based semantic role labeling (SRL) method which uses both constituent and dependency syntactic views. Comparing to the traditional SRL method relying on only one syntactic view, the method has a much richer set of syntactic features. First we select several important constituent-based and dependency-based features from existing studies as basic features. Then, we propose a statistical method to select discriminative combined features which are composed by the basic features. SRL is achieved by using the SVM classifier with both the basic features and the combined features. Experimental results on Chinese Proposition Bank (CPB) show that the method outperforms the traditional constituent-based or dependency-based SRL methods.

1 Introduction

Semantic role labeling (SRL) is a major method in current semantic analysis which is important to NLP applications. The SRL task is to identify semantic roles (or arguments) of each predicate and then label them with their functional tags, such as 'Arg0' and 'ArgM' in PropBank (Palmer et al., 2005), or 'Agent' and 'Patient' in FrameNet (Baker et al., 1998).

The significance of syntactic analysis in SRL has been proven by (Gildea and Palmer, 2002; Punyakanok et al., 2005), and syntactic parsing has been applied by almost all current studies. In terms of syntactic representations, the SRL approaches are mainly divided into three categories: constituent-based, chunk-based and dependency-based. Constituent-based SRL has been studied intensively with satisfactory results. Chunk-based SRL has been found to be less effective than the constituent-based by (Punyakanok et al., 2005). In recent years, the dependency-based SRL has been greatly promoted by the CoNLL shared tasks on semantic parsing (Hajic et al., 2009). However, there is not much research on combined use of different syntactic views (Pradhan et al., 2005), on the feature level of SRL.

This paper introduces a novel method for Chinese SRL utilizing both constituent-based and dependency-based features. The method takes constituent as the basic unit of argument and adopts the labeling of PropBank. It follows the prevalent feature-based SRL methods to first turn predicate-argument pairs into flat structures by well-defined linguistic features, and then uses machine learning methods to predict the semantic labels. The method also involves two classification phases: semantic role identification (SRI) and semantic role classification (SRC). In addition, a heuristic-based pruning preprocessing (Xue and Palmer, 2004) is used to filter out a lot of apparently inappropriate constituents at the beginning.

Coling 2008: Poster Volume, pages 665–673,
Beijing, August 2010

And it has been widely reported that, in feature-based SRL, the performance can be improved by adding several combined features each of which is composed by two single features (Xue and Palmer, 2004; Toutanova et al., 2005; Zhao et al., 2009). Thus, in this work, we exploit combined use of both constituent-based and dependency-based features in addition to using features of singular types of syntactic view. We propose a statistical method to select effective combined features using both constituent-based and dependency-based features to make full use of two syntactic views.

2 Related Work

In recent years, many advances have been made on SRL using singular syntactic view, such as constituent (Gildea and Jurafsky, 2002; Xue and Palmer, 2004; Surdeanu et al., 2007), dependency (Hacioglu, 2004; Johansson and Nugues, 2008; Zhao et al., 2009), and CCG (Chen and Rambow, 2003; Boxwell et al, 2009). However, there are few studies on the use of multiple syntactic views. We briefly review the relevant studies of SRL using multiple syntactic views as follows.

Pradhan et al. (2005) built three semantic role labelers using constituent, dependency and chunk syntactic views, and then heuristically combined them at the output level. The method was further improved in Pradhan et al. (2008) which trains two semantic role labelers for constituents and dependency separately, and then uses the output of the two systems as additional features in another labeler using chunk parsing. The result shows an improvement to each labeler alone. A possible reason for the improvement is that the errors caused by different syntactic parsers are compensated. Yet, the features of different syntactic views can hardly complement each other in labeling. And the complexity of using multiple syntactic parsers is extremely high. Hacioglu (2004) proposed a SRL method to combine constituent and dependency syntactic views where the dependency parses are ob-tained through automatic mapping of constitu-ent parses. It uses the constituent parses to get candidates and then, the dependency parses to label them.

Boxwell et al. (2009) proposed a SRL method using features of three syntactic views: CCG, CFG and dependency. It primarily uses CCG-based features associated with 4 CFG-based and 2 dependency-based features. The combination of these syntactic views leads to a substantial performance improvement. Nguyen et al. (2009) proposed a composite kernel based on both constituent and dependency syntactic views and achieved a significant improvement in a relation extraction application.

3 Design Principle and Basic Features

Compared to related work, the proposed method integrates the constituent and dependency views in a collaborative manner. First, we define a basic feature set containing features from constituent and dependency syntactic views. Then, to make better use of two syntactic views, we introduce a statistical method to select effective combined features from the basic feature set. Finally we use both the basic features and the combined features to identify and label arguments. One of the drawbacks of the related work is the considerable complexity caused by multiple syntactic parsing processes. In our method, the cost of syntactic parsing will increase only slightly as we derive dependency parsing from constituent parsing using a constituent-to-dependency converter instead of using an additional dependency parser.

In our method, the feature set used for SRL consists of two parts: the basic feature set and the combined feature set built upon the basic feature set. The basic feature set can be further divided into constituent-based features and dependency-based features. Constituent features focus on hierarchical relations between multi-word constituents whereas dependency features focus on dependencies between individual words, as shown in Figure 1. Take the predicate '提高' (increased) as an example, in Figure 1(a), the NP constituent '中国的地位' (China's position) is labeled as 'Arg0'. The argument and the predicate are connected by the path of node types: 'NP-IP-VP-VP'. But in Figure 1(b), the individual word '地位' (position) is labeled as 'Arg0'. And the connection between the argument and the predicate is only one edge with the relation 'nsubj', which is more explicit than the path in the constituent structure. So the two syntactic views can complement each other on different linguistic units.

3.1 Constituent-Based Features

As a prevalent syntactic feature set for SRL, constituent-based features have been extensively studied by many researchers. In this work, we simply take 26 constituent-based features tested by existing studies, and add 8 new features define by us. Firstly, the 26 constituent-based features used by others are:

- The seven "standard" features: *predicate* (c1), *path* (c2), *phrase type* (c3), *position* (c4), *voice* (c5), *head word* (c6) and *predicate subcategorization* (c7) features proposed by (Gildea and Jurafsky, 2002).
- *Syntactic frame* (c8) feature from (Xue and Palmer, 2004).
- *Head word POS* (c9), *partial path* (c10), *first/last word in constituent* (c11/c12), *first/last POS in constituent* (c13/c14), *left/right sibling constituent* (c15/c16), *left/right sibling head* (c17/c18), *left/right sibling POS* (c19/c20), *constituent tree distance* (c21) and *temporal cue words* (c22) features from (Pradhan et al., 2004).
- *Predicate POS* (c23), *argument's parent constituent* (c24), *argument's parent constituent head* (c25) and *argument's parent constituent POS* (c26) inspired by (Pradhan et al., 2004).

Secondly, the 8 new features that we define are (we take the 'Arg0' node in Figure 1(a) as the example to illustrate them):

- *Locational cue words* (c27): a binary feature indicating whether the constituent contains location cue words, similar to the *temporal cue words* (c22). This feature is defined to distinguish the arguments with the 'ArgM-LOC' type from others.
- *POS pattern of argument's children* (c28): the left-to-right chain of the POS tags of the argument's children, e.g. 'NR-DEG-NN'.
- *Phrase type pattern of argument's children* (c29): the left-to-right chain of the phrase type labels of the argument's children, similar with the *POS pattern of argument's children* (c28), e.g. 'DNP-NP'.
- *Type of LCA and left child* (c30): The phrase type of the Lowest Common Ancestor (LCA) combined with its left child, e.g. 'IP-NP'.
- *Type of LCA and right child* (c31): The phrase type of the LCA combined with its right child, e.g. 'IP-VP'.

Three features: *bag of words of path* (c32), *bag of words of POS pattern* (c33) and *bag of words of type pattern* (c34), for generalizing three sparse features: *path* (c2), *POS pattern of argument's children* (c28) and *phrase type pattern of argument's children* (c29) by the bag-of-words representation.

3.2 Dependency-Based Features

The dependency parse can effectively represent the head-dependent relationship between words, yet, it lacks constituent information. If we want to label constituents using dependency-based features, we should firstly map each constituent to one or more appropriate words in the dependency tree. In this paper, we use the head word of a constituent to represent the constituent in the dependency parses.

The selection method of dependency-based features is similar to the method of constituent-based features. The 35 selected dependency-based features include:

- *Predicate/Argument relation type* (d1/d2), *relation path* (d3), *POS pattern of predicate's children* (d4) and *relation pattern of predicate's children* (d5) features from (Hacioglu, 2004).
- *Child relation set* (d6), *child POS set* (d7), *predicate/argument parent word* (d8/d9), *predicate/argument parent POS* (d10/d11), *left/right word* (d12/d13), *left/right POS* (d14/d15), *left/right relation* (d16/d17), *left/right sibling word* (d18/d19), *left/right sibling POS* (d20/d21) and *left/right sibling relation* (d22/d23) features as described in (Johansson and Nugues, 2008).
- *Dep-exists* (d24) and *dep-type* (d25) features from (Boxwell et al., 2009).
- *POS path* (d26), *POS path length* (d27), *REL path length* (d28) from (Che et al., 2008).
- *High/low support verb* (d29/d30), *high/low support noun* (d31/d32) features from (Zhao et al., 2009).
- *LCA's word/POS/relation* (d33/d34/d35) inspired by (Toutanova et al., 2005).

To maintain the consistency between two syntactic views, the dependency parses are generated by a constituent-to-dependency converter (Marneffe et al., 2006), which is suitable for semantic analysis as it retrieves the semantic head rather than the general syntactic head, using a set of modified Bikel's head rules.

4 Selection of Combined Features

The combined features, each of which consists of two different basic features, have proven to be positive for SRL. Several combined features have been widely used in SRL, such as '*predicate+head word*' and '*position+voice*'. But to our knowledge, there is no prior report about the selection method of combined features for SRL. The common entropy-based criteria are invalid here because the combined features always take lots of distinct values. And the greedy method is too complicated to be practical due to the large number of combinations.

In this paper, we define two statistical criteria to efficiently estimate the classification performance of each combined feature on the corpus. Inspired by Fisher Linear Discriminant Analysis (FLDA) (Fisher, 1938) in which the separation of two classes is defined as the ratio of the variance between the classes to the variance within the classes, namely larger ratio can lead to better separation between two classes, and the discriminant plane can be achieved by maximizing the separation. Therefore, in this paper, we adopt the ratio of inter-class distance to intra-class distance to measure to what extent a combined feature can partition the data.

Initially, the feature set contains only the N basic features. We construct one combined feature f_{ab} at each iteration by combining two basic features f_a and f_b, where $a,b \in [1,N]$ and $a \neq b$. We push f_{ab} into the feature set and take it as the $N+1$ *th* feature. Then, all the training instances are represented by feature vectors using the new feature set, and we then quantize the feature vectors of positive and negative data orderly to keep their intrinsic statistical difference. If the training dataset is denoted as $D:\{D_{pos}, D_{neg}\}$, then the separation criterion, namely the ratio of inter-class to intra-class distance for feature f_i can be given as

$$g(f_i) = \frac{InterDist_{f_i}(D_{pos}, D_{neg})}{IntraDist_{f_i}(D_{pos}, D_{neg})} \quad (1)$$

where the inter-class and the intra-class distance between D_{pos} and D_{neg} for feature f_i are specified by (2) and (3), respectively.

$$InterDist_{f_i}(D_{pos}, D_{neg}) = \left(Mean_{f_i}(D_{pos}) - Mean_{f_i}(D_{neg})\right)^2 \quad (2)$$

$$IntraDist_{f_i}(D_{pos}, D_{neg}) = S^2_{f_i}(D_{pos}) + S^2_{f_i}(D_{neg}) \quad (3)$$

$Mean_{f_i}(D)$ in (2) and $S_{f_i}(D)$ in (3) represents the sample mean and the corresponding sample standard deviation of feature f_i in dataset D as given in (4) and (5).

$$Mean_{f_i}(D) = \frac{\sum_{x \in D} x(i)}{|D|}, i \in [1, N+1] \quad (4)$$

$$S_{f_i}(D) = \sqrt{\frac{\sum_{x \in D}\left(Mean_{f_i}(D) - x(i)\right)^2}{N}}, i \in [1, N+1] \quad (5)$$

Essentially, the inter-class distance reflects the distance between the center of positive dataset and the center of negative dataset, and the intra-class distance indicates the intensity of all instances relative to the corresponding center. Therefore, larger ratio will lead to a better partition for a feature, as has been pointed out by FLDA. In order to compare the ratio between different combined features, we further standardize the value of $g(f_i)$ by computing its *z*-score $Z(f_i)$ which indicates how many standard deviations between a sample and its mean, as given in (6).

$$Z(f_i) = \frac{g(f_i) - \overline{g(f_i)}}{S_G} \quad (6)$$

where $\overline{g(f_i)}$ represents the sample mean as given in (7), and S_G represents the sample standard deviation of the sequence $g(f_i)$ where i ranges from *1* to *N+1* as given in (8).

$$\overline{g(f_i)} = \frac{\sum_{i=1}^{N+1} g(f_i)}{N+1}, i \in [1, N+1] \quad (7)$$

$$S_G = \sqrt{\frac{\sum_{i=1}^{N+1}(g(f_i) - \overline{g(f_i)})^2}{N}}, i \in [1, N+1] \quad (8)$$

After figuring out the $Z(f_a)$ and $Z(f_b)$ for the basic feature f_a and f_b, and $Z(f_{ab})$ for the combined feature f_{ab} by (6), we define the other criterion, namely the improvement $I(f_{ab})$ of the combined feature, as the smaller difference between the *z*-score of the combined

feature and its two corresponding basic features as given in (9).

$$I(f_{ab}) = Z(f_{ab}) - \mathrm{Max}\left(Z(f_a),\ Z(f_b)\right) \qquad (9)$$

Finally, the combined feature with a negative $I(f_{ab})$ value is eliminated. Then, we will rank the combined features in terms of their *z*-score, and use the top *N* of them for later classification. The selection method based on the two criteria can effectively filter out combined features whose means have no significant difference between positive and negative data, and hence retain the potentially useful combined features for the separation. Meanwhile, it has a relatively fast speed when dealing with a large number of features in comparison to the greedy method due to its simplicity.

5 Performance Evaluation

5.1 Experimental Setting

In our experiments, we adopt the three-step strategy proposed by (Xue and Palmer, 2004). First, argument candidates are generated from the input constituent parse tree using the prevalent heuristic-based pruning algorithm in (Xue and Palmer, 2004). Then, each predicate-argument pair is converted to a flat feature structure by which the similarity between two instances can be easily measured. Finally we employ the Support Vector Machines (SVM) classifier to identify and classify the arguments. It is noteworthy that we use the same basic features, but different combined features for the identification and classification of arguments. We present the result comparison between using gold-standard parsing and automatic parsing, and also offer an analysis of the contribution of the combined features.

To evaluate the proposed method and compare it with others, we use the most commonly used corpus in Chinese SRL, Chinese Proposition Bank (CPB) version 1.0, as the dataset. The CPB corpus contains 760 documents, 10,364 sentences, 37,183 target predicates and 88,134 arguments. In this paper, we focus on six main types of semantic roles: Arg0, Arg1, Arg2, ArgM-ADV, ArgM-LOC and ArgM-TMP. The number of semantic roles of the six types accounted for 95% of all the semantic roles in CPB. For SRC, we use the one-versus-all approach, in which six SVMs will be trained to separate each semantic type from the remaining types. We divide the corpus into three parts: the first 99 documents (chtb_001.fid to chtb_099.fid) serve as the test data, the last 32 documents (chtb_900.fid to chtb_931.fid) serve as the development data and the left 629 documents (chtb_100.fid to chtb_899.fid) serve as the training data.

We use the SVM-Light Toolkit version 6.02 (Joachims, 1999) for the implementation of SVM, and use the Stanford Parser version 1.6 (Levy and Manning, 2003) as the constituent parser and the constituent-to-dependency converter. In classifications, we employ the linear kernel for SVM and set the regularization parameter to the default value which is the reciprocal of the average Euclidean norm of training data. The performance metrics are: accuracy (A), precision (P), recall (R) and *F*-score (F).

5.2 Combined Feature Selection

First, we select the combined features for classifications of SRI and SRC using the method described in Section 4 on the training data with gold-standard parse trees. Due to the limit of this paper, we only list the top-10 combined features for SRI and SRC for the 6 different types, as shown in Table 1 in which each combined feature is expressed by the IDs of its two basic features with a plus sign between them.

Rank	SRI	ARG0	ARG1	ARG2	ADV	LOC	TMP
1	c1+c6	c1+c6	c1+c6	c1+c6	c1+c6	c5+c27	c1+c6
2	c1+d3	c32+c30	c30+d31	c1+d1	c30+d27	c9+d17	c22+c27
3	d25+d14	c7+c6	c30+d32	c1+c7	c30+d28	c9+d13	c7+c6
4	c4+d25	c1+c2	c5+c30	c7+c6	c1+c11	c9+c2	d26+d27
5	d25+d22	c1+c12	c30+d24	c1+c5	c24+d33	c23+c27	d26+d28
6	d25+d20	c23+c6	c30+c21	c1+c23	c30+d25	c9+c20	c23+d26
7	d25+d21	c1+c3	c5+c4	c23+c6	c24+d9	c14+c32	c5+d26
8	d25+d18	c10+d35	c1+c10	c1+c3	c27+c2	c14+c10	d26+d31
9	d25+d19	c10+d1	c30+d10	c5+c6	c22+c2	c9+c26	d26+d32
10	d25+d35	c10+d28	c4+c6	c1+d5	c24+d13	c14+c2	c23+c6

Table 1. Top-10 combined features for SRI and SRC ranked by *z*-score

Table 1 shows that the commonly used combined features, such as '*predicate+head word*' (c1+c6) and '*position+voice*' (c4+c5) proposed by (Xue and Palmer, 2004) are also included. In particular, the '*predicate+head word*' feature takes first place in all semantic

categories except LOC, in which the combination of the new feature '*locational cue words*' (c27) and the '*voice* (c5)' feature performs the best. The results also show that the most frequently occurred basic features in the combined set are '*predicate*' (c1), '*head word*' (c6), '*type of LCA and left child*' (c30), '*dep-type*' (d25) and '*POS path*' (d26). These basic features should be more discriminative when combined with others. Additionally, we find some other latent effective combined features, such as '*predicate subcategorization+head word*' (c7+c6), '*predicate POS+head word*' (c23+c6) and '*predicate+phrase type*' (c1+c3), whose performance will be further validated and analyzed later in this section. It is obvious that the obtained combined features for SRI and SRC are different, and the obtained combined features for each type are also different as our selection method is based on positive and negative data which are completely different for each argument type. In SRI phase, we will use the combined features for all the six semantic types (after removing duplicates).

Then, we evaluate the performance of SRL based on the top-*N* combined features. The preliminary evaluation on the development set suggests that the performance becomes stable when *N* exceeds 20. Therefore, we vary the value of *N* to 5, 10 and 20 in the experiments to evaluate the performance of combined features. Corresponding to the three different values of *N*, we finally obtained 28, 60 and 114 combined features for the SRL, respectively.

5.3 SRL Using Gold Parses

To illustrate each component of the method, we constructed 6 SRL systems using 6 different feature sets: 'Constituent Only' (CO) – uses the constituent-based features, as presented in Section 3.1; 'Dependency Only' (DO) – uses the dependency-based features, as presented in Section 3.2; 'CD' – uses both the constituent-based features and the dependency-based features, but no combined features; 'CD+Top5' – obtained by adding the top-5 combined features to the 'CD' system; and similarly for the 'CD+Top10' and the 'CD+Top20' systems. And 'CO' serves as the baseline in our experiments.

First, we evaluate the performance of SRI using the held-out test set with gold-standard constituent parse trees. The corresponding dependency parse trees are automatically generated by the constituent-to-dependency converter included in the Stanford Parser. The testing results of the six systems on the SRI phase are shown in Table 2.

System	A (%)	P (%)	R (%)	F (%)
CO	97.87	97.04	97.30	97.17
DO	92.76	92.90	84.19	88.33
CD	97.98	97.44	97.25	97.34
CD+Top5	98.12	97.56	97.58	97.57
CD+Top10	98.15	97.61	97.62	97.61
CD+Top20	98.18	97.68	97.64	97.66

Table 2. Results of SRI using gold parses

It can be seen from Table 2 that 'CD' and 'CD+Top20' give only slightly improvement over 'CO' by less than 1% point. In other words, feature combinations do not seem to be very effective for SRI. Then we label all recognized constituents in the SRI phase with one of the six semantic role types. Table 3 displays the *F*-score of each semantic type and the overall SRC on the test set with gold-standard parses.

System	Arg0	Arg1	Arg2	ADV	LOC	TMP	ALL
CO	92.40	90.57	59.98	96.25	86.80	98.14	91.23
DO	90.70	88.22	56.95	94.54	81.23	97.37	89.14
CD	92.85	91.29	63.35	96.55	87.55	98.32	91.86
CD+Top5	93.96	92.79	73.48	97.13	88.63	98.31	93.22*[1]
CD+Top10	94.15	93.23	74.18	97.42	87.17	98.57	93.41*
CD+Top20	94.10	93.19	75.13	97.23	88.05	98.48	93.46*

Table 3. Results of SRC using gold parses

Table 3 shows that the proposed method performs much better in SRC. It improves the constituent-based method by more than 2% in SRC. The effectiveness of combined features can also be clearly seen because the overall *F*-scores of the three systems using combined features all exceed 93%, significant greater than the systems using singular features. The improvement is noticeable for all semantic role types except the 'TMP' type. It means that the dependency parses cannot provide additional information to the labeling of this type. The results of Table 2 and Table 3 together show

[1] The F-score value with an asterisk (*) indicates that there is a statistically significant difference between this system and the baseline ('CO') using the chi-square test ($p<0.05$).

that our method using combined features can effectively improve the performance of SRL on the SRC phases, when using gold parses.

5.4 SRL Using Automatic Parses

To measure the performance of the algorithm in practical conditions, we replicate the above experiments using Stanford Parser on the raw texts of the test set, without segmentation or POS tagging. The dependency parses are also generated from the automatic constituent parses, as described in Section 5.3. The results are shown in Table 4.

System	A (%)	P (%)	R (%)	F (%)
CO	71.54	68.72	70.62	69.66
DO	68.86	65.06	60.68	62.79
CD	73.53	70.63	72.75	71.67*
CD+Top5	73.62	70.69	72.98	71.82*
CD+Top10	73.65	70.71	73.08	71.88*
CD+Top20	73.67	70.70	73.16	71.91*

Table 4. Results of SRI using automatic parses

Table 4 shows that the proposed method is also effective when using automatic parses despite the dramatic decrease in *F*-scores in comparison to using gold-standard parses. The decline is mainly caused by the heuristic-based pruning strategy in which a number of real arguments are pruned when using the constituent parses with errors. Further analysis shows that, in SRI using gold parses, the ratio of incorrectly pruned arguments to the total is less than 2%, but the ratio jumps to 17% when using automatic parses. Next, on the basis of the SRI results, we test the performance of SRC using the automatic parses, as shown in Table 5.

System	Arg0	Arg1	Arg2	ADV	LOC	TMP	ALL
CO	89.20	88.90	54.47	93.93	81.80	94.38	88.24
DO	88.79	89.32	50.21	91.27	78.26	93.86	87.63
CD	89.75	89.87	57.71	95.28	84.22	94.71	89.16*
CD+Top5	90.75	90.97	65.64	95.53	84.45	94.45	90.16*
CD+Top10	90.96	91.37	67.25	95.31	84.49	94.61	90.45*
CD+Top20	90.94	91.29	67.42	95.22	84.39	94.65	90.42*

Table 5. Results of SRC using auto parses

Table 5 shows only a slight decline in comparison with the result of using gold-standard parses, and it maintains the same trend of performance for each semantic role in the Table 3, which proves the validity of the proposed method when using automatic parses. Table 6 shows the *F*-score of the overall SRL on both the gold-standard and the automatic parse data.

System	Gold Parse (F%)	Auto Parse (F%)
CO	89.29	63.13
DO	82.69	60.34
CD	90.01	65.56*
CD+Top5	91.47*	66.37*
CD+Top10	91.68*	66.61*
CD+Top20	91.76*	66.61*

Table 6. Results of overall SRL

Table 6 shows that the *F*-score of the 'CD+Top20' surpasses that of the 'CO' system by more than 2% on the gold parses, and more than 3% on the automatic parse. In other words, the method using constituent and dependency syntactic views performs even more effective for the automatic parses. The last three rows of Table 6 shows that the top-10 combined features perform better than the top-5 features by adding 32 more features, but the top-20 combined features obtain similar results to the top-10 features by adding 54 more features. It suggests that only several salient combined features can actually improve the performance.

5.5 Combined Feature Performance

To evaluate the performance of each combined feature to identify the salient combined features for SRL, we rank the 60 combined features used by the 'CD+Top10' system on the test data with gold-standard parses, according to the *F*-score improvement achieved by each combined feature. Here we list the top 20 of them which are shown in Table 7.

Rank	Feature	Δ F(%)	Rank	Feature	Δ F(%)
1	c1+c6	0.611	11	c10+d1	0.413
2	c1+c10	0.593	12	c5+d26	0.404
3	c4+c6	0.557	13	c24+d9	0.395
4	c9+c20	0.503	14	d25+d35	0.395
5	c23+c6	0.494	15	c30+d24	0.377
6	c1+c3	0.458	16	c9+c26	0.377
7	c9+d13	0.449	17	c10+d28	0.368
8	c14+c10	0.431	18	c30+d29	0.365
9	c1+c5	0.422	19	c30+d30	0.361
10	c24+d33	0.413	20	c7+c6	0.361

Table 7. Top-20 combined features

As can be seen from Table 7, a half of combined features are composed by constituent

features only, and the other half contain at least one dependency-based feature. This indicates that dependency features can be helpful to construct combined features for SRL. Through analyzing the performance of each combined features, we have obtained some new and effective combined features which were not recognized before, such as '*predicate+partial path*' (c1+c10), '*position+head word*' (c4+c6), '*Head word POS+right sibling POS*' (c9+c20). Observation from these combined features suggests that not all combined features are composed by two significant basic features. Some not significant ones, such as '*partial path*' (c10) and '*Head word POS*' (c9) can also produce salient combined features.

Furthermore, we find that the relative order of the combined features in Table 7 is not exactly consistent with their orders in Table 1. The inconsistency indicates that the estimation criteria used for combined features selection is not perfect. In estimation, the effect of combined features is evaluated simply based on the distance between the positive and the negative dataset by considering the efficiency. But in practice, the effects of them are determined through one-by-one classification.

5.6 Comparison to Other Work

Finally, we compare the proposed method with other four representative Chinese SRL systems. First, the 'Xue[1]' system (Xue and Palmer, 2005) is a typical feature-based system using 9 basic features, 2 combined features and the Maximum Entropy (ME) classifier. Second, the 'Liu' system (Liu et al. 2007) which uses 19 basic features, 10 combined features and also the ME classifier. Third, the 'Che' (Che, 2008) system use a hybrid convolution tree kernel to directly measure the similarity between two constituent structures. Fourth, the 'Xue[2]' system described in (Xue, 2008), which is similar to 'Xue[1]' on basic framework, but using a new feature set. The 'Xue[2]' system evaluates the SRL of the verbal predicates and the nominalized predicates separately, and offers no consolidated evaluation in (Xue, 2008). So in the comparison, we refer to its performance on the verbal predicates and the nominalized predicates as 'Xue[21]' and 'Xue[22]'.

All the four systems mentioned above use the constituent as the labeling unit and use the CPB corpus as the data set, the same as our method. And we use the same training and test data splits as in the 'Xue[1]' and 'Che' systems. Table 8 shows the comparison results in terms of *F*-score on both gold parses and auto parses.

System	Gold Parse (F%)	Auto Parse (F%)
Xue[22]	69.6	57.3
Xue[1]	91.3	61.3
Liu	91.31	—
Che	91.67	65.42
Ours	91.76	66.61
Xue[21]	92.0	66.8

Table 8. Comparison to other work

Table 8 shows that our method performs better than the 'Xue[1]', 'Liu' and 'Che' systems on both gold parses and automatic parses. It is only slightly worse than the 'Xue[21]', namely the verbal predicates part of the 'Xue[2]' system. But for the other part of the 'Xue[2]' system for the nominalized predicates, namely the 'Xue[22]', our method performs much better than it. The results further verify the validity of the method.

6 Conclusions

This paper presents a novel feature-based SRL approach for Chinese. Compared to the traditional feature-based methods, the method can effectively integrate the constituent and the dependency syntactic views at the feature level. The method provides an effective way to connect two syntactic views by a statistical selection method of combined features to substantially improve the feature-based SRL method. The complexity of the method will not increase significantly compared to the method using one syntactic view as we use a constituent-to-dependency conversion rather than additional dependency parsing. The effectiveness of the method has been proven by the experiments on CPB using SVM classifier with linear kernel.

Abstract

As one of the important tasks of SemEval Evaluation, Frame Semantic Structure Extraction based on the FrameNet has received much more attention in NLP field. This task is often divided into three sub-tasks: recognizing target words which are word expressions that evoke semantic frames, assigning the correct frame to them, namely, Frame Identification (FI), and for each target word, detecting and labeling the corresponding frame elements properly. Frame identification is the foundation of this task. Since the existence of links between frame semantics and syntactic features, we attempt to study FI on the basis of dependency syntax. Therefore, we adopt a tree-structured conditional random field (T-CRF) model to solve Chinese frame identification based on Dependency Parsing. 7 typical lexical units which belong to more than one frame in Chinese FrameNet were selected to be researched. 940 human annotated sentences serve as the training data, and evaluation on 128 test data achieved 81.46% precision. Compared with previous works, our result shows obvious improvement.

1 Introduction

In recent years, semantic research has roused great interest in NLP field. With the progress of many semantic lexicons, this research gradually becomes promising and exciting. As one of the tasks of SemEval Evaluation, Frame Semantic Structure Extraction based on the FrameNet grows to be highlighted for special attention.

Given a sentence, the task of Frame Semantic Structure Extraction consists of the following three parts: recognizing the word expressions (target words) that evoke semantic frames; discriminating the word sense (frame) of each evoking expression; for each target word, labeling its syntactic dependents with regard to which roles in that frame they fill (Baker et al., 2006). Among of these three components, frame identification is the fundamental and key problem. However, current research of this task in Chinese is only focused on semantic role labeling based on the given target words and their corresponding frames (Xue, 2008). We insist that whether target words can be assigned correct frames in context is a crucial problem demanding prompt solution in this task.

Chinese FrameNet (CFN) (You and Liu, 2005), developed by Shanxi University, is an ongoing effort of building a semantic lexicon for Chinese based on the theory of Frame Semantics (Fillmore, 1982), referencing the FrameNet(Baker et al., 1998) and supported by corpus evidence. The CFN project currently contains more than 2100 lexical units, more than 300 semantic frames, and has exemplified more than 21600 annotated sentences. The ultimate goal of this project is to generate information about the articulation of the semantic and syntactic requirements of Chinese lexical items and presents this information in a variety of web-based reports and represents the lexical semantics of all the sentences in a Chinese text.

Coling 2008: Poster Volume, pages 674–682,
Beijing, August 2010

According to statistics, there are 332 lexical units belonging to more than one frame in the current CFN databases. For example, lexical unit “表示”can evoke the following three frames: “表达 (Expressing_publicly) ”, “陈述 (Statement) ” and “代表(representative) ”. In order to extract the semantic structure of a sentence containing ambiguous target words, the first step is to assign the correct frame to the target words in a given context.

This task is similar with the word sense disambiguation (WSD) task to a certain extent (Katrin Erk, 2005). WSD is to resolve the inherent polysemia of words by determining the appropriate sense for each ambiguous word in a given text, while frame identification is assigning a correct frame for the ambiguous target word in the current sentence context. Nevertheless, essential difference exists between them. WSD prefers to disambiguation on static sense, whereas based on the frame semantics, frame identification lays particular emphasis on consistency between sentence scene and the dynamic scene described by the candidate frames.

Since the existence of links between frame semantics and syntactic features, we adopt a tree-structured conditional random field (T-CRF) model to solve Chinese frame identification based on Dependency Parsing. 7 typical lexical units which belong to more than one frame in CFN were selected to be researched. 940 human annotated sentences were collected for the training data, and 128 for test data.

The rest of this paper is organized as follows. Section 2 introduces some related work. Section 3 gives a simple system description. Section 4 describes Chinese frame identification using T-CRF model. Section 5 presents our experimental results and some analysis. Section 6 is the conclusions.

2 Related Work

With the development and improvement of FrameNet, the research based on this lexical resource is increasing gradually. Frame Semantic Structure Extraction based on FrameNet is such hot topics. One sub-tasks of this research is frame identification, which is the research problem in this paper.

At present, there are some but not much work on frame identification. Main works are as follows: CL Research participated in the SemEval-2007 task for Frame Semantic Structure Extraction. They integrated the use of FrameNet in the Text Parser component of the CL Research KMS. In particular, they created a FrameNet dictionary from the FrameNet databases with the CL Research DIMAP dictionary software and used this dictionary as a lexical resource. The current FrameNet DIMAP dictionary contains 7575 entries, with many entries having multiple senses. For each sense, the FrameNet part of speech, the definition, the frame name, the ID number, and the definition source (identified as FN or COD) are captured from the FrameNet files. When a lexical unit is recognized in processing the text, the first step is to retrieve the entry for that item in the dictionary and use the frame element realization patterns to disambiguate among the senses. A score is computed for each sense and the score with the highest sense was selected. They evaluated on three texts and the best result is 66.10% precision (Litkowski, 2007).

Adrian Bejan and Hathaway (2007) selected from the FN lexicon 556 target words that evoke at least two semantic frames and have at least five sentences annotated for each frame. And then they assembled a multi-class classifier using two types of models: SVM and Maximum Entropy for each ambiguous target word. They extracted features used in word sense disambiguation (Florain et al., 2002), lexical features of the target word, and NAMED ENTITY FLAGS associated with the root vertex in a syntactic parse tree. For the rest of the ambiguous target words that have less than five sentences annotated, they randomly chose a frame as being the correct frame in a given context. For FI sub-task, they obtained 76.71% accuracy compared to a baseline of 60.72% accuracy that always predicts the most annotated frame for each of the 556 target words.

Johansson and Nugues (2007) firstly used some filtering rules to detect target words, and for the target words left after the filtering, they trained a disambiguating SVM classifier on all ambiguous words listed in FrameNet. The classifier used the following features: target lemma, target word, sub categorization frame, the set of dependencies of the target, the set of words of the child vertexes, and the parent word of the target. Its accuracy was 84% on the ambiguous

words, compared to a first-sense baseline score of 74%.

The above researches focused on English based on FrameNet. To our knowledge, there exists no work for Chinese by far. Most methods mentioned above treat the frame identification as an independent classification problem for each ambiguous target word in a sentence. However, because of neglecting the relations between the candidate frames, the resulting frame assignment may be semantically inconsistent over the sentence.

3 System Description

Our system consists of three stages. The first is corpus construction of our experiments. We selected 7 typical lexical units from the current CFN lexicon which can evoke at least two semantic frames. They are "表示","想","有","叫","倒","下降","装载", respectively. For each of them, we collected sentences containing this word from Sogou Corpus and CCL Contemporary Chinese Corpus of Beijing University. Through a series of refining, 940 sentences annotated correct frame for each target word comprise a standard corpus as the training data. Another 128 sentences serve as the test data.

The second stage is dependency parsing. We used LTP of Information Retrieval Research Center, Harbin Institute of Technology (HIT-CIR) to POS tagging and dependency parsing the training and test sentences. For the obvious lexical and syntax errors in the outputs, manually corrected was conducted.

At last, Chinese frame identification task is regarded as a labeling task on the dependency tree structure. By using T-CRF, we can model this as the maximization of the probability of word sense (frame) trees, given the scores for vertexes and edges. In the training phase, appropriate features of vertex and edge are extracted, and the weight vectors are optimized over the training data.

Figure 1 gives an illustration of the system.

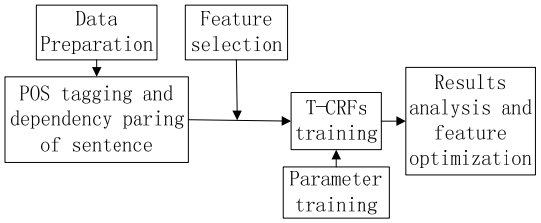

Figure 1. Framework of the system

4 Chinese Frame Identification

Given a sentence, frame identification is to determine an appropriate frame for each of target words by comparing consistency between sentence context and the dynamic scene described by their candidate frames. Currently, most researchers addressed this task as an independent classification problem for each target word in a sentence. Consequently, the resulting frame assignment for each target word may be semantically inconsistent over the sentence.

We regard Chinese frame identification problem as a labeling task on the dependency tree structure due to the links between syntactic features and frame semantics. Our empirical study shows that the frame of target word not only influenced by the adjacent words in position but also its governor and dependents words in syntactic structure. Therefore, we try to solve this problem based on dependency parsing. T-CRF model is a special CRF model, which is different from widely used linear-chain CRFs, in which the random variables are organized in a tree structure. As we can see, it should be feasible and reasonable to adopt a T-CRF model to frame identification after parsing the sentence.

In this section, we firstly introduce the linear-chain CRFs briefly, and then explain the T-CRF model for Chinese frame identification, especially the feature selection and parameter estimation.

4.1 Tree-Structured Conditional Random Field（T-CRF）

Conditional Random Fields (CRFs) are undirected graphical models (Lafferty et al, 2001). For the observation sequence $X = x_1 x_2 x_3 \cdots x_n$ and its corresponding label sequence $Y = y_1 y_2 y_3 \cdots y_n$, CRF defines the conditional probability as:

$$P(Y \mid X)$$
$$= \frac{1}{Z(X)} \{ \exp(\sum_i \sum_k \lambda_k f_k(y_{i-1}, y_i, X)) + \exp(\sum_i \sum_k \mu_k g_k(y_i, X)) \}$$

where X is the observation sequence, and y_i is the label at position i in label sequence Y. $f_k(\cdot)$ and $g_k(\cdot)$ are feature functions. λ_k and μ_k are the weight vectors. $Z(X)$ is the normalization factor. CRFs are state-of-the-art methods for sequence labeling problem in many NLP tasks.

Tree-Structured Conditional Random Field (Tang et al., 2006) is a particular case of CRFs, which can model dependencies across hierarchically laid-out information, such as dependency syntactic relations between words in a sentence.

The graphical structure of T-CRF is a tree, in which three main relations exist for a vertex: parent-child, child-parent and sibling vertexes. In our experiments, we only used parent-child edges and child-parent edges. The sibling-vertexes edges were ignored because of weak dependency syntactic relation between words in a sentence. So the probability distribution in our T-CRF model can be written as below.

$$p(y \mid x) = \frac{1}{Z(x)} \exp \sum_{v \in V} \{F + G + S\}$$
$$F = \sum_j \lambda_j f_j(v, y(v), x)$$
$$G = \sum_k \mu_k g_k(v, y(v), x, v', y(v'))$$
$$S = \sum_l \sigma_l s_l(v, y(v), x, v'', y(v''))$$

where F 、 G 、 S represent the feature functions of current vertex, feature functions of parent vertex of current vertex and feature functions of child vertexes of current vertex, respectively. v is a word corresponding to the vertex in the tree, v' is the parent vertex of v and v'' are the child vertexes of v.

In Chinese frame identification, the observation *x* in T-CRF corresponds to a word in the current sentence. The label *y* thus corresponds to the frame name for the word. In the experimental corpus, for the target word, y is annotated its correct frame name, while for the other words left, y is annotated tag "null". These target words are the 7 lexical units we selected and their frames come from the current CFN lexicon. At present, only the frame identification of target word was studied, the disambiguation of the other multi-senses words in the sentence was not being processed.

Although T-CRFs are relatively new models, they have already been applied to several NLP tasks, such as semantic role labeling, semantic annotation, word sense disambiguation, image modeling.(Cohn and Blunsom, 2005; Tang et al., 2006; Jun et al., 2009; Awasthi et al., 2007). All these works proved this model to be useful in modeling the semantic structure in a sentence or a text. Our study is the first application of T-CRFs to frame identification.

4.2 Feature Selection

In order to apply T-CRF model, it is necessary to represent the sentence with a hierarchical structure. We used LTP of HIT-CIR to POS tagging and dependency parsing the training and test sentences. To facilitate the description of feature selection based on the dependency tree structure, figure 2 gives the dependency output of an example.

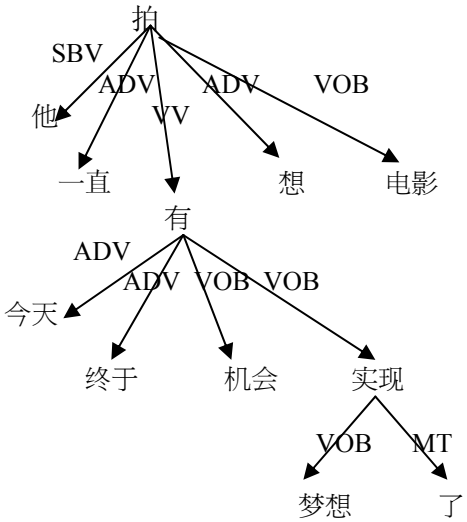

Figure 2. Example of a dependency parsed sentence.

This example sentence is:"他一直想拍电影，今天终于有机会实现梦想了". In English, it reads "He has been want to make films, and finally has the opportunity to realize his dream

today”. In the dependency tree structure, arrow points from the parent vertex to child vertex, the label on a arc is the type of dependency relation between the parent and the child vertex.

Feature selection is a core problem in sequence labeling model. In our experiments, 18 template settings were conducted to discover the best features for frame identification. During this process, we considered two main factors: firstly, the number of features should not be too large so as to avoid the over-fitting phenomenon; secondly, the selected features should be able to provide enough information conditioned on tolerated computation, for the purpose of improving the performance of system. With the increasing of the number of features and the cost of the system, if the performance of system can not be improved obviously, we stopped to add features and regard the parameter of current template as the best. At this moment, a good balance between the performance and cost of computation was achieved.

We experimented with two different types of feature settings. One we used was the very basic feature sets based on the words and Part of Speech (POS) and their bigram features. In order to see the effectiveness of dependency features, the other type of feature settings include more informative tree features. These features capture information about a vertex's parent, its children and the relation with its parent and children. These features are semantically and structurally very informative and we expect to improve our performance with them. The base and tree features we used are listed in table 1.

In these features, the setting of basic features is fundamental and meaningful because it can be used to compare T-CRF and linear chain CRF. For the tree features, given the i-th vertex in the observation x_i, $f(y_p, y_c)$ and $f(y_c, y_p)$ represent whether the current vertex has a parent-child dependency with a parent vertex and whether it has a parent-child dependency with a child vertex, respectively. In dependency grammars (Igor' A. Melchuk, 1988), every vertex has only one parent as its governor, and may have more than one child as its dependents. Words in a sentence through certain syntactic relations form the semantic structure of this sentence. Therefore, we argue that the words that have syntactic dependency relations with the target word are more important than the ones neighboring with it in position for frame identification. For this reason, we added the parent vertex and children vertexes into the tree features. With respective to the relation type, we used the annotation sets defined by HIT-CIR in LTP, which contain 24 kinds of dependency relation types. One thing should be concerned is that we don't consider all types of children vertexes. This is because that according to our empirical study, not all of the children have strong dependencies with the target word. On the contrary, more features would bring the noise and affect the efficiency seriously. Hence, we chose 4 types of children relation from the linguistic point of view. They are, "SBV(subject-verb)" representing "主谓关系", "VOB(verb-object)" representing "动宾关系", "ADV(adverbial)" representing "状中结构" and "ATT(attribute)" representing "定中关系". From the point of grammars and semantics, these four relations are more influenced on the words in a sentence. As we know, the subject, predicate and object constitute the semantic core of a sentence. The good news is that experimental results proved this hypothesis relatively correct.

Category	Features	
Base features	Word and bigram of word, POS and bigram of POS	
Tree features	$f(y_p, y_c)$	Parent vertex of current word
		The edge between current word and its parent
		The dependency relation type between current word and its parent
	$f(y_c, y_p)$	child vertex of current word
		The edge between current word and its child
		The dependency relation type between current word and its child

Table 1. Base Features & Tree Features

4.3 Parameter Estimation

The parameter estimation is to optimize the parameters $\theta = \{\lambda 1, \lambda 2, ...; \mu 1, \mu 2, ...\}$ from training data $D\{(x1, y1), (x2, y2), ...\}$ with empirical distribution $p(x, y)$. Nowadays, the commonly used method for parameter estimation is maximum likelihood function. That is $L_\theta = \arg\max \sum_i \log(p_\theta(y_i / x_i))$ given the observation sequences $\{x_1, x_2, ...\}$ and label sequences $\{y_1, y_2, ...\}$.

In this paper, the conventional L-BFGS method was used to estimate the optimal parameters $\theta = \{\lambda 1, \lambda 2, ...; \mu 1, \mu 2, ...\}$ (Jorge Nocedal and Stephen J. Wright. 1999).

5 Experiments

5.1 Data preparation

So far, there has no research on Chinese frame identification, thus it is unfeasible to do experiments based on readily available corpus. Accordingly, preparing a good and reasonable training and test data is our fundamental task.

At present, there are 332 lexical units that can evoke at least two frames in the CFN lexicon. In this paper, we selected 7 typical ambiguous lexical units to be researched. They are "表示","想","有","叫","倒","下降","装载". The selection principle is following: first of all, it is time-consuming to construct corpus for all of the 332 lexical units, so currently we just studied part of them to prove the validity of the method we proposed. Secondly, the frames evoked by these lexical units should be distinguished clearly by human annotators. For example, lexical unit "高兴" can evoke these three frames: "心理刺激(Experiencer_obj)", "情感体验 (Experiencer_subj)" and "情感反应 (Emotion_directed)". All these frames describe a tender feeling in psychology, so it is difficult to discriminate among them and thus hard to annotate sentences correctly. Thirdly, these 7 lexical units are high frequency words so it is easier to collect sentences and make the experiments more practical.

For each of 7 lexical units, we collected sentences containing this word from Sogou Corpus and Contemporary Chinese Corpus of Beijing University. After a preliminary screening, about 1000 sentences compose the original and coarse corpus.

Although these sentences were complete and relatively standard, some of them didn't meet the criterion of Chinese frame identification research. Such cases mainly include three aspects. For one thing, the correct frame of ambiguous target word is difficult to decide by human annotator. For the other, the meaning of target word can't correspond to any frame definition in current CFN version. For example, lexical unit "想" can express the meaning of opinion and wish which have the corresponding frames in CFN, while the meaning of thinking and memory did not. Lastly, some words couldn't evoke frames though their word forms are the same as lexical unit. We removed the sentences belonging to the above situations and got a refined corpus containing 940 sentences for training data and 128 for test data. And then, we used LTP to POS tagging and dependency parsing the training and test sentences.

5.2 Experimental Results and Analysis

For the linear-chain CRF, we defined the features based on the words, POS of words and their bigram features as the base features. For T-CRF, we used the base features and tree features. Six different types of template settings on these features are listed in table 2.

template	features
T1	Base features
T2	Add edge between current word and its parent on T1
T3	Add dependency type between current word and its parent on T2
T4	Add edge between current word and its four types children vertexes on T1
T5	Add dependency type between current word and its four types children vertexes on T4
T6	Add all these tree features on T1

Table 2. Template settings on different features

For each of these template settings, we experimented on different observation window size of 1, 2 and 3, which represents one word,

two words and three words previous and next to the current word respectively.

We use the $precision = \frac{n}{s}$ to evaluate our system, where n is the number of target words labeled correctly, and s is the total number of target words need to be labeled. In our 128 test sentences, there are 151 target words because there are some sentences containing more than one ambiguous target word. Experimental results on 18 templates are listed in table 3.

From the table 3, we can get four conclusions. Firstly, the best performance 81.46% in T-CRF model increases about 5% over the best performance 76.82% in CRF model. This suggests the dependencies on the tree structure can capture more important characteristics than those on the linear chains do. Secondly, when we added the edge feature between current word and its parent, the performance declined unexpectedly. This can be explained in linguistics: in a dependency parsed sentence, the clique of a governor and its dependents forms "a small world" which can express partial meaning of the sentence, while the parent of current vertex (except the root vertex which has no parent) can not influence much on it because its parent has its own clique, and current word is just a tiny fragment of the clique of its parent, on the contrary, the parent vertex feature will bring negative effect on the current word. For example, the target word "有" in figure 2 can illustrate this case clearly. Thirdly, when we added the children vertexes, the performance increased, that is because current word and its dependents together can form a semantic clique of the sentence. Lastly, when we added the dependency relation type on the features of parent-child edge and child-parent edge, the performance improved slightly because the relation type of edge is coarser than the edge between parent and child. There are only 24 kinds of dependency types but exist hundreds of edge combination possibilities between parent and child. Thus, this feature relived the data sparseness problem to a certain extent.

There are two main types of errors in the results: one is that the labeling frames of target words are not correct. For example, in the sentence "白洁异常强硬地表示，"不获全胜决不收兵"。" , the correct frame of "表示"should be "表达" instead of "陈述", because it described the attitude of "白洁" not declared a fact or a phenomena. However, this kind of deep semantics of sentence couldn't be capured by T-CRF model based on the dependency syntax. The other is that the labeling frames of some target words are tag "null". The reason is that some lexical units can't evoke a frame sometimes, so in the training data, these words are annotated "null".

5.3 Contrast Experiments

Qu (2008) argues that any words in a sentence has a certain attraction between each other and thus constitute the grammars and semantic structure of the sentence. Based on this cognition, he proposed a generalized collocation theory, which includes fixed collocation, loose collocation and Co-occurrence collocation. According to this theory, a context computing model RFR_SUM was presented to deal with the WSD task.

In essence, frame identification also belongs to context computing, so it should be reasonable to solve this problem with the generalized collocation theory. However, our current corpus is too insufficient to reflect all these three collocations in the statistical sense. Hence, we proposed a method named compatibility of lexical unit based on the Co-occurrence collocation to identify frame for ambiguous target word.

Window size	Precision					
	T1	T2	T3	T4	T5	T6
1	0.7682	0.7219	0.7351	0.8013	0.8146	0.7947
2	0.7682	0.7152	0.6887	0.7881	0.8146	0.7947
3	0.7417	0.6623	0.6689	0.7351	0.8013	0.7616

Table 3. Precisions of different templates based on three types of window size

The connotation of compatibility of lexical unit is as follows. In the CFN frame database, every frame defines a lexical units set, in which each of lexical unit can evoke this frame. When one of these lexical units serves as the target word in a sentence, we can use the compatibilities of other lexical units in this set with the sentence to reflect the consistency between this frame and current sentence. The compatibility of lexical unit with the sentence is computed by the Co-occurrence frequency of lexical unit and the notional words in the sentence in a large corpus. The calculation is as below.

Suppose l_i in the lexical units set $L = \{l_1, l_2, ...l_i, ..., l_m\}$ serves as the target word in the sentence S. The words in S except the functional words and l_i constitute a word set $W = \{w_1, w_2, ..., w_n\}$. And the compatibility of L with S is denoted as C.

$$C = \frac{c(l_1, W) + c(l_2, W) + ...c(l_m, W)}{m},$$

where m is the number of lexical units in L.

$$c(l_j, W) = \frac{f(l_j, w_1) + f(l_j, w_2) + ... + f(l_j, w_n)}{n},$$

where n is the number of words in W.

$$f(l_j, w_k) = \frac{count(l_j, w_k)}{sum},$$ where $count(l_j, w_k)$ represents the number of sentences, in which l_j and w_k occur together, and these sentences come from the corpus of Peking University People's Daily, January 1998. sum is the total number of sentences in the same People's Daily corpus.

In this way, the consistency between a frame and the current sentence is scored by the compatibility of L belonging to the candidate frame with this sentence, and the one with highest score is regarded as the correct frame. For our test data, 71.73% precision based on this method was obtained.

This model displayed a decline in precision of about 10% over the T-CRF. Analysis of the results found that the compatibility based on Co-occurrence collocation can only reflect a weak correlation between words, neglecting the position and syntactic structure information in a sentence.

In addition, we used the most-frequency-frame experiment as the baseline. In the corpus consisted of 940 training sentences and 128 test sentences, the frequency of each frame was counted for ranking. The result of this method obtained 61.23% precision, which proved that T-CRF model performed obvious improvement.

6 Conclusions

In this paper, we investigated the problem of Frame Identification in Chinese which is the first work on Chinese FrameNet. A tree-structured conditional random field (T-CRF) model was applied to this task based on the dependency syntactic structure. This model provides a way to incorporating the long-distance dependencies between target words and the syntactic related words with it. In our experiments, the syntactic dependency features were shown to work effectively for Frame Identification, with 71.73%, 76.82%, and 81.46% precision for compatibility of lexical unit, CRF and T-CRF, respectively.

Although a relatively good performance was achieved on the test data, the small-scale and simplicity of sentence structure in corpus cannot be ignored compared with the FrameNet corpus. However, the experimental results that we gained is still promising, suggesting that our model is comparatively appropriate to the Frame Identification task and still has a great potential for improvement. The next work will focus on the three aspects: firstly, build a larger corpus containing various sentence structures in Chinese; the other is that more semantic features will be tried to add in the T-CRF model, such as the frame elements and the semantic relations between frames, finally, we will try to identify frames of target words using other machine learning methods which has been proved high performance in this task.

Linguistic Cues for Distinguishing Literal and Non-Literal Usages

Linlin Li and **Caroline Sporleder**

{linlin, csporled}@coli.uni-saarland.de

Abstract

We investigate the effectiveness of different linguistic cues for distinguishing literal and non-literal usages of potentially idiomatic expressions. We focus specifically on features that generalize across different target expressions. While idioms on the whole are frequent, instances of each particular expression can be relatively infrequent and it will often not be feasible to extract and annotate a sufficient number of examples for each expression one might want to disambiguate. We experimented with a number of different features and found that features encoding lexical cohesion as well as some syntactic features can generalize well across idioms.

1 Introduction

Nonliteral expressions are a major challenge in NLP because they are (i) fairly frequent and (ii) often behave idiosyncratically. Apart from typically being semantically more or less opaque, they can also disobey grammatical constraints (e.g., *by and large*, *lie in wait*). Hence, idiomatic expressions are not only a problem for semantic analysis but can also have a negative effect on other NLP applications (Sag et al., 2001), such as parsing (Baldwin et al., 2004).

To process non-literal language correctly, NLP systems need to recognise such expressions automatically. While there has been a significant body of work on idiom (and more generally multiword expression) detection (see Section 2), until recently most approaches have focused on a *type-based classification*, dividing expressions into "idiomatic" or "not idiomatic" irrespective of their actual use in a discourse context. However, while some expressions, such as *by and large*, always have a non-compositional, idiomatic meaning, many other expressions, such as *break the ice* or *spill the beans*, can be used literally as well as idiomatically and for some expressions, such as *drop the ball*, the literal usage can even dominate in some domains. Consequently, those expressions have to be disambiguated in context (*token-based classification*).

We investigate how well models for distinguishing literal and non-literal use can be learned from annotated examples. We explore different types of features, such as the local and global context, syntactic properties of the local context, the form of the expression itself and properties relating to the cohesive structure of the discourse. We show that several feature types work well for this task. However, some features can generalize across specific idioms, for instance features which compute how well an idiom "fits" its surrounding context under a literal or non-literal interpretation. This property is an advantage because such features are not restricted to training data for a specific target expression but can also benefit from data for other idioms. This is important because, while idioms as a general linguistic class are relatively frequent, instances of each particular idiom are much more difficult to find in sufficient numbers. The situation is exacerbated by the fact the distributions of literal vs. non-literal usage tend to be highly skewed, with one usage (often the non-literal one) being much more frequent than the other. Finding sufficient examples of the minority class can then be difficult, even if instances are extracted from large corpora. Furthermore, for highly skewed distributions, many more majority class examples have to be annotated to obtain an acceptable number of minority class instances.

We show that it is possible to circumvent this problem by employing a generic feature space that

Coling 2008: Poster Volume, pages 683–691,
Beijing, August 2010

looks at the cohesive ties between the potential idiom and its surrounding discourse. Such features generalize well across different expressions and lead to acceptable performance even on expressions unseen in the training set.

2 Related Work

Until recently, most studies on idiom classification focus on type-based classification; sofar there are only comparably few studies on token-based classification. Among the earliest studies on token-based classification were the ones by Hashimoto et al. (2006) on Japanese and Katz and Giesbrecht (2006) on German. Hashimoto et al. (2006) present a rule-based system in which lexico-syntactic features of different idioms are hard-coded in a lexicon and then used to distinguish literal and non-literal usages. The features encode information about the passivisation, argument movement, and the ability of the target expression to be negated or modified. Katz and Giesbrecht (2006) compute meaning vectors for literal and non-literal examples in the training set and then classify test instances based on the closeness of their meaning vectors to those of the training examples. This approach was later extended by Diab and Krishna (2009), who take a larger context into account when computing the feature vectors (e.g., the whole paragraph) and who also include prepositions and determiners in addition to content words.

Cook et al. (2007) and Fazly et al. (2009) take a different approach, which crucially relies on the concept of *canonical form* (CForm). It is assumed that for each idiom there is a fixed form (or a small set of those) corresponding to the syntactic pattern(s) in which the idiom normally occurs (Riehemann, 2001).The canonical form allows for inflectional variation of the head verb but not for other variations (such as nominal inflection, choice of determiner etc.). It has been observed that if an expression is used idiomatically, it typically occurs in its canonical form (Riehemann, 2001). Cook et al. exploit this behaviour and propose an unsupervised method in which an expression is classified as idiomatic if it occurs in canonical form and literal otherwise. Canonical forms are determined automatically using a statistical, frequency-based measure.

Birke and Sarkar (2006) model literal vs. non-literal classification as a word sense disambiguation task and use a clustering algorithm which compares test instances to two seed sets (one with literal and one with non-literal expressions), assigning the label of the closest set.

Sporleder and Li (2009) propose another unsupervised method which detects the presence or absence of cohesive links between the component words of the idiom and the surrounding discourse. If such links can be found the expression is classified as literal otherwise as non-literal. Li and Sporleder (2009) later extended this work by combining the unsupervised classifier with a second-stage supervised classifier.

Hashimoto and Kawahara (2008) present a supervised approach to token-based idiom distinction for Japanese, in which they implement several features, such as features known from other word sense disambiguation tasks (e.g., collocations) and idiom-specific features taken from Hashimoto et al. (2006). Finally, Boukobza and Rappoport (2009) also experimented with a supervised classifier, which takes into account various surface features.

In the present work, we also investigate supervised models for token-based idiom detection. We are specifically interested in which types of features (e.g., local context, global context, syntactic properties) perform best on this task and more specifically which features generalize across idioms.

3 Data

We used the data set created by Sporleder and Li (2009), which consists of 13 English expressions (mainly V+PP or V+NP) that can be used both literally and idiomatically, such as *break the ice* or *play with fire*.[1] To create the data set all instances of the target expressions were extracted from the Gigaword corpus together with five paragraphs of context and then labelled manually as 'literal' or 'non-literal'. Overall the data set consists of just under 4,000 instances. For most ex-

[1] We excluded four expressions from the original data set because their number of literal examples was very small (< 2).

pressions the distribution is heavily skewed towards the idiomatic interpretation, however for some, like *drop the ball*, the literal reading is more frequent. The number of instances varies, ranging from 15 for *pull the trigger* to 903 for *drop the ball*. While the instances were extracted from a news corpus, none of them are domain-specific and all expressions also occur in the BNC, which is a balanced, multi-domain corpus.

To compute the features which we extract in the next section, all instances in our data sets were part-of-speech tagged by the MXPOST tagger (Ratnaparkhi, 1996), parsed with the MaltParser[2], and named entity tagged with the Stanford NE tagger (Finkel et al., 2005). The lemmatization was done by RASP (Briscoe and Carroll, 2006).

4 Indicators of Idiomatic and Literal Usage

In this study we are particularly interested in which linguistic indicators work well for the task of distinguishing literal and idiomatic language use. The few previous studies have mainly looked at the lexical context in which and expression occurs (Katz and Giesbrecht, 2006; Birke and Sarkar, 2006). However, other properties of the linguistic context might also be useful. We distinguish these features into different groups and discuss them in the following sections.

4.1 Global Lexical Context (glc)

That the lexical context might be a good indicator for the usage of an expression is obvious when one looks at examples as in (1) and (2), which suggest that literal and non-literal usages of a specific idiom co-occur with different sets of words. Nonliteral uses of *break the ice* (1), for instance, tend to occur with words like *discuss*, *bilateral* or *relations*, while literal usages (2) predictably occur with, among others, *frozen*, *cold* or *water*. What we are looking at here is the global lexical context of an expression, i.e., taking into account previous and following sentences. We are specifically looking for words which are either semantically related (in a wide sense) to the literal or the nonliteral sense of the target expression. The presence or absence of such words can be a good indicator of how the expression is used in a context.

(1) "Gujral will meet Sharif on Monday and **discuss bilateral relations**," the Press Trust of India added. The minister said Sharif and Gujral would be able to "break the ice" over Kashmir.

(2) Meanwhile in Germany, the **cold** penetrated Cologne cathedral, where worshippers had to break the ice on the **frozen** holy **water** in the font.

We implemented two sets of features which encode the global lexical context: *salient words* and *related words* as described in Li and Sporleder (2009). The former feature uses a variant of tf.idf to identify words that are particulary salient for different usages. The latter feature identifies words which are most strongly related to the component words of the idiom.

We notice that sometimes several idioms cooccur within the same instance. This is to say that nonliteral usages may be indicators of each other since authors may put them in a same context to convey a specific opinion (e.g., irony). Due to this, global lexical context features may also generalize across idioms to some extend.

4.2 Local Lexical Context (locCont)

In addition to the global context, the local lexical context, i.e., the words preceding and following the target expression, might also provide important information. One obvious local clue are words like *literally* or *metaphorically speaking*, which when preceding or following an expression might indicate its usage. Unfortunately, such clues are not only very rare (we only found a handful in nearly 4,000 annotated examples) but also not always reliable. For instance, it is not difficult to find examples like (3) and (4) where the word *literally* is used even though the idiom clearly has a non-literal meaning.

(3) In the documentary the producer **literally** spills the beans on the real deal behind the movie production.

(4) The new philosophy is blatantly permissive and **literally** passes the buck to the House's other committees.

[2] http://maltparser.org/index.html

However, there are other local cues. For example, we found that the word *just* before *get ones feet wet* tends to indicate non-literal usage as in (5). Non-literal usage can also be indicated by the occurrence of the prepositions *over* or *between* after *break the ice* as in (1) and (6). While such cues are not perfect they often make one usage more likely than the other. Unlike the semantically based global cues, many local clues are more rooted in syntax, i.e., local cues work because specific *constructions* tend to be more frequent for one or the other usage.

(5) The wiki includes a page of tasks suitable for those **just** getting their feet wet.

(6) Would the visit of the minister help break the ice **between** India and Pakistan?

Another type of local cues involves selectional preferences. For example, idiomatic usage is probable if the subject of *play with fire* is a country as in (7) or if *break the ice* is followed by a *with*-PP whose NP refers to a person (8).

(7) Dudayev repeated his frequent warnings that **Russia** was playing with fire.

(8) Edwards usually manages to break the ice with the taciturn **monarch**.

Based on those observations, we encode which words occur in a ten word window around the target expression, five pre-target words and five post-target words, as the locCont features.

4.3 Discourse Cohesion (dc)

We implemented two features, *related score* and *discourse connectivity*, which take into account the cohesive structure of an expression in its context as described by Li and Sporleder (2009). In addition, we also included the prediction of the cohesion graph proposed by Sporleder and Li (2009) as an additional feature. These features look at the lexical cohesion between an expression and the surrounding discourse, so they are more likely to generalize across different idioms.

4.4 Syntactic Structure (allSyn)

To capture syntactic effects, we encoded information of the **head node (heaSyn)** of the target expression in the dependency tree (e.g., *break* in the dependency tree in Figure 1). The syntactic features we encoded are the **parent node (parSyn)**, **sibling nodes (sibSyn)** and **children nodes (chiSyn)** of the head node. These nodes include the following type of syntactic information:

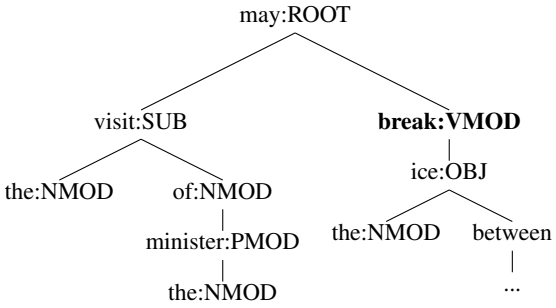

Figure 1: Dependency tree for a nonliteral example of *break the ice* (*The visit of the minister may break the ice between India and Pakistan.*)

Dependency Relation of the Verb Phrase The whole idiomatic expression used as an object of a preposition can be an indicative factor of idiomatic usage (see Example 9). This property is captured by the *heaSyn* feature.

(9) Ross headed back last week to Washington to brief president Bill Clinton on the Hebron talks after achieving a breakthrough **in** breaking the ice in the Hebron talks by arranging an Arafat-Netanyahu summit .

Modal Verbs usually appear in the parent position of the head verb (*parSyn*). Modals can be an indicator of idiomatic usage such as **may** in Figure 1. In contrast, the modal **had to** is indicative that the same phrase is used literally (Example 10).

(10) Dad **had to** break the ice on the chicken troughs.

Subjects can also provide clues about the usage of an expression, e.g., if selectional preferences are disobeyed. For instance, **visit** as a subject of the verb phrase *break the ice* is an indicator of idiomatic usage (see Figure 1). Subjects typically appear in the children position of the head verb (*chiSyn*), but sometimes may appear in the sibling position (*sibSyn*) as in Figure 1 .

Verb Subcat We also encode the arguments of the head verb of the target expression. These arguments can be, for example, additional PPs. This feature encodes syntactic constraints and attempts

to model selectional restrictions. The likelihood of subcategorisation frames may differ for the two usages of an expression, e.g., non-literal expressions often tend to have a shorter argument list. For instance, the subcat frame <PP-on, PP-for> intuitively seems more likely for literal usages of the expression *drop the ball* (see Example 11) than for non-literal ones, for which <PP-on> is more likely (12). To capture subcategorisation behaviour, we encode the children nodes of the head node (*chiSyn*).

(11) US defender Alexi Lalas twice went close to forcing an equaliser , first with a glancing equaliser from a Paul Caligiuri free kick and then from a Wynalda corner when Prunea dropped the ball **[on the ground]** only **[for Tibor Selyme to kick frantically clear]** .

(12) "Clinton dropped the ball **[on this]**," said John Parachini.

Modifiers of the verb can also be indicative of the usage of the target expression. For example, in 13, the fact that the phrase *get one's feet wet* is modified by the adverb *just* suggest that it is used idiomatically. Similar to verb subcat, modifiers are often appear in the children position (*chiSyn*).

(13) The wiki includes a page of tasks suitable for those **just** getting their feet wet.

Coordinated Verb Which verbs are coordinated with the target expression, if any, can also provide cues for the intended interpretation. For example, in (14), the fact that *break the ice* is coordinated with *fall* suggest that it is used literally. The coordinated verb can appear at the sibling position, children position, or some other position of the head verb depending on the parser. The Maltparser tends to put the coordinated verbs in the children position (*chiSyn*).

(14) They may break the ice and **fall** through.

4.5 Other Features

Named Entities (ne) can also indicate the usage of an expression. For instance, a country name in the subject position of the target expression *break the ice* is a strong indicator of this phrase being used idiomatically (see Example 7). Diab and Bhutada (2009) find that NE-features perform best. They used a commercial NE-tagger with 19 classes. We used the Stanford NE tagger (Finkel et al., 2005), and encoded three named entity classes ("person", "location", "organisation") in the feature vector.

Indicative Terms (iTerm) Some words such as *literally, proverbially* are also indicative of literal or idiomatic usages. We encoded the frequencies of those indicative terms as features.

Scare Quotes (quote) This feature encodes whether the idiom is marked off by scare quotes, which often indicates non-literal usage (15).

(15) Do consider "getting your feet wet" online, using some of the technology that is now available to us.

5 Experiments

In the previous section we discussed different linguistic cues for idiom usage. To determine which of these cues work best for the task and which ones generalize across different idioms, we carried out three experiments. In the first one (Section 5.1) we trained one model for each idiom (see Section 3) and tested the predictiveness of each feature type individually as well as all features together. In the second experiment (Section 5.2), we trained one generic model for all idioms and determined how the performance of this model differs from the idiom-specific models. Specifically we wanted to know whether the model would benefit from the additional training data available by combining information from several idioms. Finally (Section 5.3), we tested the generic model on *unseen* idioms to determine whether these could be classified based on generic properties even if training data for the target expressions had not been seen.

5.1 Idiom Specific Models

The first question we wanted to answer was how difficult token-based idiom classification is and which of the features we defined in the previous section work well for this task. We implemented a specific classifier for each of the idioms in the data set. We trained one model for all features in combination and one for each individual feature. Because the data set is not very big we decided to run these experiments in 10-fold stratified

cross-validation mode. We used the SVM classifier (SMO) from Weka.[3]

Table 1 shows the results. We report the precision (Prec.), recall (Rec.) and F-Score for the literal class, as well as the accuracy. Note that due to the imbalance in the data set, accuracy is not a very informative measure here; a classifier always predicting the majority class would already obtain a relatively high accuracy. The literal F-Score obtained for individual idioms varies from 38.10% for *bite one's tongue* to 96.10% for *bounce of the wall*. However, the data sets for the different idioms are relatively small and it is impossible to say whether performance differences on individual idioms are accidental, or due to differences in training set size or due to some inherent difficulty of the individual idiom. Thus we chose not to report the performance of our models on individual idioms but on the whole data set for which the numbers are much more reliable. The final performance confusion matrix is the sum over all individual idiom confusion matrices.

	Avg. literal			Avg.
feature	Prec.	Rec.	F-Score	Acc.
all	89.84	77.06	82.96	93.36
glc+dc	90.42	76.44	82.85	93.36
allSyn	76.30	86.13	80.92	91.48
heaSyn	76.64	85.77	80.95	91.53
parSyn	76.43	88.34	81.96	91.84
chiSyn	76.49	88.22	81.94	91.84
sibSyn	76.27	88.34	81.86	91.78
locCont	76.51	88.34	82.00	91.86
ne	76.49	88.22	81.94	91.84
iTerm	76.51	88.34	82.00	91.86
quote	76.51	88.34	82.00	91.86
Base_{maj}	76.71	88.34	82.00	91.86

Table 1: Performance of idiom-specific models (averaged over different idioms), 10-fold stratified cross-validation.

The Baseline (Base) is built based on predicting the majority class for each expression. This means predicting *literal* for the expressions which consist of more literal examples and *nonliteral* for the expressions consisting of more nonliteral examples. We notice the baseline gets a fairly high performance (Acc.=91.86%).

The results show that the expressions can be classified relatively reliably by the proposed features. The performance beats the majority baseline statistically significantly ($p = 0.01$, χ^2 test). We noticed that parSyn, chiSyn, locCont, iTerm and quote features are too sparse. These individual features cannot guide the classifier. As a result, the classifier only predicts the majority class which results in a performance similar to the baseline. Some of the syntactic features are less sparse and they get different results from the baseline classifier, however, the performances of these features are actually worse than the baseline. This may be due to the relatively small training size in each idiom specific model. When adding those features together with statistical-based features (glc+dc), the performance of the literal class can be improved slightly. However, we did not observe any performance increase on the accuracy.

5.2 Generic Models

Having verified that literal and idiomatic usages can be distinguished with some success by training expression-specific models, we carried out a second experiment in which we merged the data sets for different expressions and trained one generic model. We wanted to see whether a generic model, which has access to more training data, performs better and whether some features, e.g., the cohesion features profit more from this. The experiment was again run in 10-fold stratified cross-validation mode (using 10% from each idiom in the test set in each fold).

Table 2 shows the results. The baseline classifier always predict the majority class 'nonliteral'. Note that the result of this baseline is different from the majority baseline in the idiom specific model. In the idiom specific model, there are three expressions [4] for which the majority class is 'literal'.

Unsurprisingly, the F-Score and accuracy of the combined feature set drops a bit. However, the performance still statistically significantly beats the majority baseline classifier ($p << 0.01$, χ^2 test). Similar to previous observation, the

[4] I.e., *bounce off the wall*, *drop the ball*, *pull the trigger*

feature	Avg. literal Prec.	Rec.	F-Score	Avg. Acc.
all	89.59	65.77	73.22	89.90
glc+dc	82.53	60.86	70.06	89.08
allSyn	50.83	59.88	54.99	79.42
heaSyn	50.57	59.88	54.83	79.29
sibSyn	33.33	0.86	1.67	78.83
ne	62.45	20.00	30.30	80.69
iTerm	40.00	0.25	0.49	78.99
Base_{maj}	–	–	–	79.01

Table 2: Performance of the generic model (averaged over different idioms), 10-fold stratified cross-validation.

statistical-based features (glc+dc) work the best, while the syntactic features are also helpful. However, the local context, iTerm, quote features are very sparse and, as in the idiom-specific experiments, the performances of these features are similar to the majority baseline classifier. We excluded them from the Table 2.

The numbers show that the syntactic features help more in this model compared with the idiom-specific model. When including these features, literal F-Score increases by 3.16% while accuracy increases by 0.9%. It seems that the syntactic features benefit from the increased training set. This is evidence that these features can generalize across idioms. For instance, the phrase "The US" on the subject position may be not only indicative of the idiomatic usage of *break the ice*, but also of idiomatic usage of *drop the ball*.

We found that the indicative terms are rare in our corpus. This is the reason why the recall rate of the indicative terms is very low (0.25%). The indicative terms are not very predictive of literal or non-literal usage, since the precision rate is also relatively low (40%), which means those words can be used in both literal and nonliteral cases.

5.3 Unseen Idioms

In our final experiment, we tested whether a generic model can also be applied to completely new expressions, i.e., expressions for which no instances have been seen in the data set. Such a behaviour would be desireable for practical purposes as it is unrealistic to label training data for each idiom the model might possibly encounter in a text. To test whether the generic model does indeed generalize to unseen expressions, we test it on all instances of a given expression while training on the rest of the expressions in the dataset. That is, we used a modified cross-validation setting, in which each fold contains instances from one expression in the test set. Since our dataset contains 13 expressions, we run a 13-fold cross validation. The final confusion matrix is the sum over each confusion matrix in each round.

feature	Avg. literal Prec.	Rec.	F-Score	Avg. Acc.
all	96.70	81.65	88.54	95.41
glc+dc	96.93	77.00	85.83	94.48
allSyn	52.54	58.77	55.48	79.52
heaSyn	51.35	59.47	55.11	78.96
sibSyn	55.56	2.32	4.46	78.38
ne	61.89	19.05	29.13	79.87
iTerm	66.67	0.7	1.38	78.36
Base_{maj}	–	–	–	79.01

Table 3: Performance of the generic model on unseen idioms (cross validation, instances from each idiom are chosen as test set for each fold)

The results are shown in Table 3. Similar to the generic model, we found that the cohesion features and syntactic features do generalize across expressions. Statistical features (glc+dc) perform well in this experiment. When including more linguistically orientated features, the performance can be further increased by almost 1%. In line with former observations, the sparse features mentioned in the former two experiments also do not work for this experiments. We also excluded them from the table.

One interesting finding about this experiment of this model is that the F-Score is higher than for the "generic model". This is counter-intuitive, since in the generic model, each idiom in the testing set has examples in the training set, thus, we might expect the performance to be better due to the fact that instances from the same expression appearing in the training set are more informative compared with instances from different idioms. Further analysis revealed that there are some expressions for which it may actually be beneficial to

train on other expressions, as the evidence of some features may be misleading.

	literal F-S.		Acc.	
feature	Spe.	Gen.	Spe.	Gen.
all	86.85	**91.79**	80.67	**88.37**
glc+dc	86.75	**88.84**	80.67	**84.61**
allSyn	**85.71**	71.94	**75.28**	61.13
heaSyn	**85.79**	71.94	**75.39**	61.13

Table 4: Comparing the performance of the idiom *drop the ball* on the idiom specific model (Spe.) and generic model (Gen.)

Table 4 shows the comparison of the performance of *drop the ball* on the idiom specific model and the generic model on unseen idioms. It can be seen that the statistical features (glc+dc) work better for the model that is trained on the instances from other idioms than the model which is trained on the instances of the target expression itself. We found this is due to the fact that *drop the ball* is especially difficult to classify with the discourse cohesion features (dc). The literal cases are often found in a context containing words, such as **fault**, **mistake**, **fail**, and **miss**, which are used to describe a scenario in a baseball game,[5] while, on the other hand, those context words are also closely semantically related to the idiomatic reading of *drop the ball*. This means the classifier can be mislead by the cohesion features of the literal instances of this idiom in the training set, since they exhibit strong idiomatic cohesive links with the target expression. When excluding *drop the ball* from the training set, the cohesive links in the training data are less noisy. Thus, the performance increases. Unsurprisingly, the performance of syntactic features works better for the idiom specific model compared with the unseen idiom model.

6 Conclusion

Idioms on the whole are frequent but instances of each particular idiom can be relatively infrequent (even for common idioms like "spill the beans"). The classes can also be fairly imbalanced, with one class (typically the nonliteral interpretation) being much more frequent than the other. This causes problems for training data generation. For idiom specific classifiers, it is difficult to obtain large data sets even when extracting from large corpora and it is even more difficult to find sufficient examples of the minority class. In order to address this problem, we looked for features which can generalize across idioms.

We found that statistical features (glc+dc) work best for distinguishing literal and nonliteral readings. Certain linguistically motivated features can further boost the performance. However, those linguistic features are more likely to suffer from data sparseness, as a result, they often only predict the majority class if used on their own. We also found that some of the features that we designed generalize well across idioms. The cohesion features have the best generalization ability, while syntactic features can also generalize to some extent.

Abstract

The potential benefit of integrating contextual information for recommendation has received much research attention recently, especially with the ever-increasing interest in mobile-based recommendation services. However, context based recommendation research is limited due to the lack of standard evaluation data with contextual information and reliable technology for extracting such information. As a result, there are no widely accepted conclusions on how, when and whether context helps. Additionally, a system often suffers from the so called cold start problem due to the lack of data for training the initial context based recommendation model. This paper proposes a novel solution to address these problems with automated information extraction techniques. We also compare several approaches for utilizing context based on a new data set collected using the proposed solution. The experimental results demonstrate that 1) IE-based techniques can help create a large scale context data with decent quality from online reviews, at least for restaurant recommendations; 2) context helps recommender systems rank items, however, does not help predict user ratings; 3) simply using context to filter items hurts recommendation performance, while a new probabilistic latent relational model we proposed helps.

1 Introduction

In the information retrieval community, one major research focus is developing proactive retrieval agent that acts in anticipation of information needs of a user and recommends information to the user without requiring him/her to issue an explicit query. The most popular examples of such kind of proactive retrieval agent are recommender systems. Over the last several years, research in standard recommender systems has been improved significantly, largely due to the availability of large scale evaluation data sets such as Netflix. The current research focus goes beyond the standard user-item rating matrix. As researchers start to realize that the quality of recommendations depends on time, place and a range of other relevant users' context, how to integrate contextual information for recommendation is becoming an ever increasingly important topic in the research agenda (Adomavicius and Ricci, 2009).

One major challenge in context-aware recommendation research is the lack of large scale annotated data set. Ideally, a good research data set should contain contextual information besides users' explicit ratings on items. However, such kinds of data sets are not readily available for researchers. Previous research work in context based recommendation usually experiments on a small data set collected through user studies. Although undoubtedly useful, this approach is limited because 1) user studies are usually very expensive and their scales are small; 2) it is very hard for the research community to repeat such study; and 3) a personalized contextual system may not

Table 1: Examples of the restaurant reviews

succeed until a user has interacted with it for a long period of time to enable context based recommendation models well trained.

On the other hand, a large amount of review documents from web sites such as tripadvisor.com, yelp.com, cnet.com, amazon.com, are available with certain contextual information, such as time and companion, implicitly in the reviews (see Table 1 for examples). This offers us an opportunity to apply information extraction techniques for obtaining contextual information from the review texts. Together with users' explicit ratings on items, this might lead to a large research data set for context based recommendation and consequently address the cold start issue in the recommender systems. This paper describes the methods that extract the contextual information from online reviews and their impact on the recommendation quality at different accuracy levels of the extraction methods.

Another challenge is how to integrate contextual information into existing recommendation algorithms. Existing approaches can be classified into three major categories: pre-filtering, post-filtering and the modeling based approaches (Oku et al., 2007; Adomavicius and Tuzhilin, 2008). Pre-filtering approaches utilize contextual information to select data for that context, and then predict ratings using a traditional recommendation method on the selected data (Adomavicius et al., 2005). Post-filtering approaches first predict ratings on the whole data using traditional methods, then use the contextual information to adjust results. Both methods separate contextual information from the rating estimation process and leads to unsatisfying findings. For example, Adomavicious et al. (2005) found neither standard collaborative filtering nor contextual reduction-based methods dominate each other in all the cases. In the modeling based approaches, contextual information is used directly in the rating prediction process. For example, Oku et al. (2007) propose a context-aware SVM-based predictive model to classify restaurants into "positive" and "negative" classes, and contextual information is included as additional input features for the SVM classifier. However, treating recommendation as classification is not a common approach, and does not take advantage of the state of art collaborative filtering techniques. In this paper, we propose a new probabilistic model to integrate contextual information into the state of art factorization based collaborative filtering approach, and compare it with several baselines.

2 Mining Contextual Information from Textual Opinions

The context includes any information that can be used to characterize the situation of entities. Examples of context are: location, identity and state of people, companions, time, activities of the current user, the devices being used etc. (Lee et al., 2005). Without loss of generality, we looked into widely available restaurant review data. More specifically, we investigated four types of contextual information for a dining event, as they might affect users' dining decisions, and they have not been studied carefully before. The four types of contextual information are: *Companion* (whether a dining event involves multiple people), *Occasion* (for what occasions the event is), *Time* (what time during the day) and *Location* (in which city the event happens).

2.1 Text Mining Approaches

We developed a set of algorithms along with existing NLP tools (GATE (Cunningham et al., 2002) etc.) for this task. More detailed description of these algorithms is given below.

Time: we classified the meal time into the following types: "breakfast", "lunch", "dinner", "brunch", "morning tea", "afternoon tea". We

compiled a list of lexicons for these different types of meal times, and used a string matching method to find the explicit meal times from reviews. Here, the meal time with an expression, such as "6pm", was extracted using ANNIE's time named entity recognition module from the GATE toolkit. For example, if a user says, "When we went there, it was 10pm", we infer that it was for dinner.

Occasion: The ANNIE's time named entity recognition module recognizes certain special days from text. We augmented ANNIE's lookup function with a list of holidays in the United States from Wikipedia[1] as well as some other occasions, such as birthdays and anniversaries.

Location: Ideally, a location context would be a user's departure location to the selected restaurant. However, such information rarely exists in the review texts. Therefore, we used the location information from a user's profile to approximate.

Companion: Extracting a companion's information accurately from review data is more difficult. We utilized two methods to address the challenge:

Companion-Baseline: This is a string matching based approach. First, we automatically generated a lexicon of different kinds of companion words/phrases by using prepositional patterns, such as "with my (our) NN (NNS)". We extracted the noun or noun phrases from the prepositional phrases as the companion terms, which were then sorted by frequency of occurrence and manually verified. This led to a lexicon of 167 entries. Next, we grouped these entries into 6 main categories of companions: "family", "friend", "couple", "colleague", "food-buddy" and "pet". Finally, the review is tagged as one or more of the companion categories if it contains a corresponding word/phrase in that lexicon.

Companion-Classifier: In order to achieve better precision, we sampled and annotated 1000 sentences with companion terms from the corpus and built three classifiers: 1) a MaxEnt classifier with bag-of-words features, 2) a rule-based classifier, 3) a hybrid classifier. For the rule-based classifier, we looked into the structural aspects of the window where companion terms occurred, specifically, the adjacent verbs and prepositions associated with those terms. We collected high frequency structures including verbs, verb-proposition combinations, and verb-genitive combinations from the whole corpus, and then constructed a list of rules to decide whether a companion context exists based on these structures. For the hybrid classifier, we used the patterns identified by the rule-based classifier as features for the MaxEnt model (Ratnaparkhi, 1998). To train the classifier, we also included features such as POS tags of the verb and of the candidate companion term, the occurrence of a meal term (e.g. "lunch", "dinner"), the occurrence of pronouns (e.g. "we" or "us") and the genitive of the companion term. Based on the evaluation results (using 5-fold cross validation) shown in Table 2, the hybrid classifier is the best performing classifier and it is used for the subsequent experiments in the paper.

	Words	Rule	Hybrid
Precision	0.7181	0.7238	0.7379
Recall	0.8962	0.8947	0.9143
F-Score	0.7973	0.8003	0.8167

Table 2: Evaluation results for the bag-of-words-based classifier (Words), the rule-based classifier (Rule) and the hybrid classifier (Hybrid)

3 Recommendation based on Contextual Information

Next we consider how to integrate various contextual information into recommender systems. Assume there are N items and M users. Each user reviews a set of items in the system. The data set can be represented as a set of quadruplet $D = (y, i, j, \mathbf{c})$, where i is the index of user, j is the index of item, $\mathbf{c}$ is a vector describing the context of this rating data, and y is the rating value. Let $\mathbf{c} = (c_1, ..., c_k)$, where each component c_k represents a type of context, such as "dinner time" or "location=San Jose". The observed features (meta data) of user i and item j are represented as vectors $\mathbf{f}_i$ and $\mathbf{f}_j$ respectively, where each component in the vector represents a type of feature, such as "gender of the user" or "price range of the restaurant". In the rest of this paper, we in-

[1] http://en.wikipedia.org/wiki/List_of_holidays_by_country#United_States_of_America

tegrate context $\mathbf{c}$ into the user's observed features $\mathbf{f}_i$. This makes $\mathbf{f}_i$ a dynamic feature vector, which will change with different context. The goal is to predict ratings for candidate items given user i and context $\mathbf{c}$, and recommend the top items. We present two recommendation models for integrating contextual information in this section.

3.1 Boolean Model

The Boolean Model filters out items that do not match the context. The Boolean model itself returns an item set instead of a ranked list. We further rank the items by predicted rating values. We score items by the Boolean model as follows:

$$s(j) = \begin{cases} s_m(j) & \text{if item } j \text{ matches the context} \\ -\infty & \text{otherwise} \end{cases} \quad (1)$$

where $s_m(j)$ is the predicted rating computed using a rating prediction method m, such as a Collaborative Filtering model without using context.

3.2 Probabilistic Latent Relational Model

We propose a novel Probabilistic Latent Relational Model (PLRM) for integrating contextual information. In a context-aware recommender system, a user's interest for item is influenced by two factors: (1) the user's long-term preference, which can be learned from users' rating history; (2) the current context (how the item matches the current context). To capture the two factors simultaneously, we introduce a new probabilistic model by assuming the rating value $y_{i,j,\mathbf{c}}$ follows a Gaussian distribution with mean $u_{i,j,\mathbf{c}}$ and variance $1/\lambda^{(y)}$:

$$y_{i,j,\mathbf{c}} \sim \mathcal{N}(u_{i,j,\mathbf{c}}, 1/\lambda^{(y)}) \quad (2)$$

$$u_{i,j,\mathbf{c}} = \mathbf{u}_i^T A \mathbf{v}_j + (W_u \mathbf{f}_i)^T (W_v \mathbf{f}_j) \quad (3)$$

where $\mathbf{u}_i$ and $\mathbf{v}_j$ are the hidden representations of user i and item j to be learned from rating data, and W_u and W_v are feature transformation matrices for users and items respectively. In Equation (3), the first term $\mathbf{u}_i^T A \mathbf{v}_j$ is the estimation based on user' long term preferences, where $A = \{a\}$ is a matrix modeling the interaction between $\mathbf{u}_i$ and $\mathbf{v}_j$.[2] The second term $(W_u \mathbf{f}_i)^T (W_v \mathbf{f}_j)$ is the estimation based on current context and the observed features of users and items, since the context $\mathbf{c}$ is integrated into user's observed features $\mathbf{f}_i$.

$\{U, V, A, W\}$ are the parameters of the model to be estimated from the training data set D, where $W = \{W_u, W_v\} = \{w\}$, $U = \{\mathbf{u}_1, \mathbf{u}_2, ...\mathbf{u}_N\}$ and $V = \{\mathbf{v}_1, \mathbf{v}_2, ...\mathbf{v}_M\}$. We assume the prior distribution of the parameters follow the Gaussian distributions centered on 0. We use $1/\lambda^{(u)}$,$1/\lambda^{(v)}$, $1/\lambda^{(w)}$ and $1/\lambda^{(a)}$ to represent the variance of the corresponding Gaussian distributions. The effect of the prior distribution is similar to the ridge regression (norm-2 regularizer) commonly used in machine learning algorithms to control model complexity and avoid overfitting.

The proposed model is motivated by well performing recommendation models in the literature. It generalizes several existing models. If we set A to the identity matrix and W_u, W_v to zero matrices, the model presented in Equation (3) is equivalent to the well known norm-2 regularized singular value decomposition, which performs well on the Netflix competition(Salakhutdinov and Mnih, 2007). If we set A to zero matrix and W_u to identity matrix, the Model (3) becomes the bilinear model that works well on Yahoo news recommendation task (Chu and Park, 2009).

Based on the above model assumption, the joint likelihood of all random variables (U, V, A, W and D) in the system is:

$$P(U, V, A, W, D) = \prod_{(i,j,c,y) \in D} P(y_{i,j,c} | \mathbf{u}_i, \mathbf{v}_j, \mathbf{f}_i, \mathbf{f}_j, A, W_u, W_v) \prod_i P(\mathbf{u}_i) \prod_j P(\mathbf{v}_j) P(A) P(W_u) P(W_v) \quad (4)$$

3.3 Parameter Estimation

We use a modified EM algorithm for parameter estimation to find the posterior distribution of (U, V) and max a posterior (MAP) of (A, W). The estimation can be used to make the final pre-

[2]We introduce A matrix so that the model can also be used to model multiple different types of relationships/interactions jointly, where each type of relationship corresponds to a different A matrix. For the task in this paper, A is not required and can be set to the identity matrix for simplicity. However, we leave A as parameters to be estimated in the rest of this paper for generality.

dictions as follows:

$$\hat{y}_{i,j,c} = \int_{\mathbf{u}_i,\mathbf{v}_j} P(\mathbf{u}_i)P(\mathbf{v}_j)(\mathbf{u}_i^T A\mathbf{v}_j + (W_u\mathbf{f}_i)^T W_v\mathbf{f}_j)d\mathbf{u}_i d\mathbf{v}_j$$

E Step: the Variational Bayesian approach is used to estimate the posterior distributions of U and V. Assuming (A, W) are known, based on Equation 4, we have

$$P(U,V|A,W,D) \propto \prod_{(y,i,j,\mathbf{c})\in D} \mathcal{N}(\mathbf{u}_i^T A\mathbf{v}_j + (W_u\mathbf{f}_i)^T W_v\mathbf{f}_j, 1/\lambda^{(y)}) \times \prod_{i=1}^{M}\mathcal{N}(\mathbf{u}_i|\mathbf{0}, 1/\lambda^{(u)}I)\prod_{j=1}^{N}\mathcal{N}(\mathbf{v}_j|\mathbf{0}, 1/\lambda^{(v)}I)$$

Deriving the exact distribution and use it to predict y will result in intractable integrals. Thus we approximate the posterior with a variational distribution $Q(U,V) = \prod_{i=1}^{M} Q(\mathbf{u}_i)\prod_{j=1}^{N} Q(\mathbf{v}_j)$. $Q(\mathbf{u}_i)$ and $Q(\mathbf{v}_j)$ are restricted to Gaussian distributions so that predicting y using Bayesian inference with $Q(U,V)$ will be straightforward. $Q(U,V)$ can be estimated by minimizing the KL-divergence between it and $P(U,V|A,W,D)$. Since $Q(U,V)$ is factorized into individual $Q(\mathbf{u}_i)$ and $Q(\mathbf{v}_j)$, we can first focus on one $Q(\mathbf{u}_i)$ (or $Q(\mathbf{v}_j)$) at a time by fixing/ignoring other factors. For space considerations, we omit the derivation in this paper. The optimal $Q(\mathbf{u}_i)$ is $\mathcal{N}(\bar{\mathbf{u}}_\mathbf{i}, \mathbf{\Sigma_i})$, where $\bar{\mathbf{u}}_\mathbf{i} = \Sigma_i\mathbf{d}_i$,

$$\begin{aligned}\Sigma_i^{-1} &= \sum_{(y,i,j,\mathbf{c})\in D}\lambda^{(y)}A(\bar{\mathbf{v}}_\mathbf{j}\bar{\mathbf{v}}_\mathbf{j}^T + \Psi_j)A^T \\ &+ \lambda^{(u)}I \\ \mathbf{d}_i &= \sum_{(y,i,j,\mathbf{c})\in D}\lambda^{(y)}\tilde{y}A\bar{\mathbf{v}}_\mathbf{j}\end{aligned}$$

Similarly, the optimal $Q(\mathbf{v}_j)$ is $\mathcal{N}(\bar{\mathbf{v}}_\mathbf{j}, \mathbf{\Psi_j})$, where $\bar{\mathbf{v}}_\mathbf{j} = \Psi_j\mathbf{e}_j$,

$$\begin{aligned}\Psi_j^{-1} &= \sum_{(y,i,j,\mathbf{c})\in D}\lambda^{(y)}A^T(\bar{\mathbf{u}}_\mathbf{i}\bar{\mathbf{u}}_\mathbf{i}^T + \Sigma_i)A \\ &+ \lambda^{(v)}I \\ \mathbf{e}_j &= \sum_{(y,i,j,\mathbf{c})\in D}\lambda^{(y)}\tilde{y}A^T\bar{\mathbf{v}}_\mathbf{j}\end{aligned}$$

M Step: Based on the approximate posterior estimation $Q(U,V)$ derived in the E step, the maximum a posteriori estimation of $\{A, W\}$ can be found by maximizing the expected posterior likelihood $\{\hat{A}, \hat{W}\} = arg\max_{A,W} E_{Q(U,V)}(\log P(A,W,U,V|D))$. This can be done using the conjugate gradient descent method, and the gradient of A, W_u, W_v can be calculated as follows:

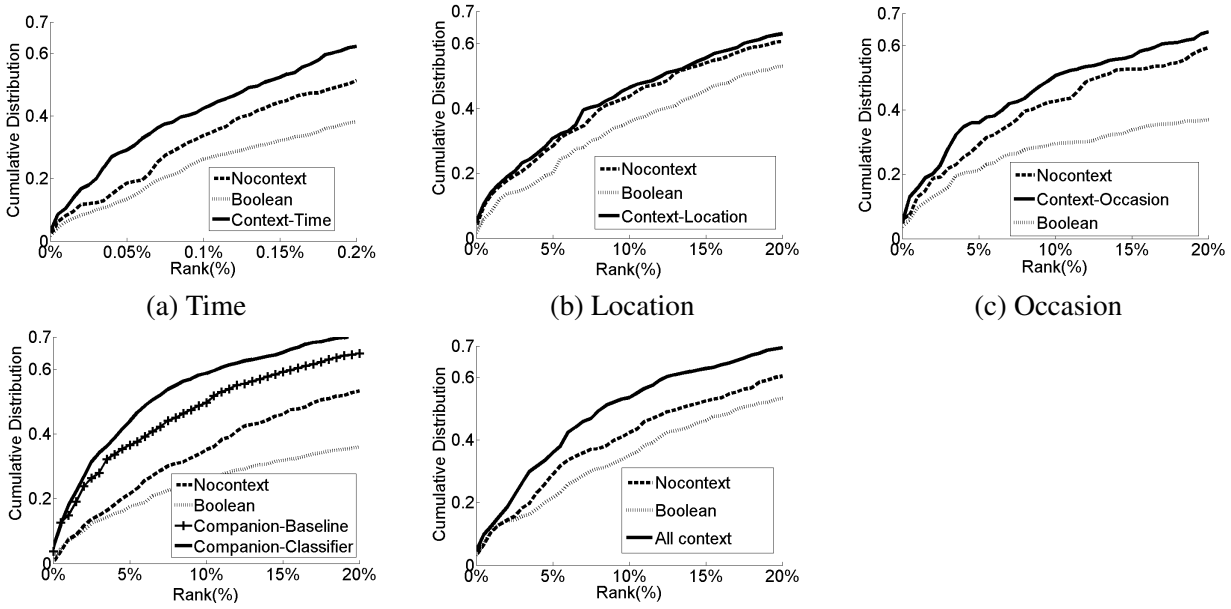
$$\begin{aligned}\frac{\partial\Phi}{\partial A} &= \sum_{(y,i,j,c)\in D}\lambda^{(y)}((\widehat{y}-y)\bar{\mathbf{u}}_\mathbf{i}\bar{\mathbf{v}}_\mathbf{j}^T \\ &+ \bar{\mathbf{u}}_\mathbf{i}\bar{\mathbf{u}}_\mathbf{i}^T A\Psi_j + \Sigma_i A\bar{\mathbf{v}}_\mathbf{j}\bar{\mathbf{v}}_\mathbf{j}^T + \Sigma_i A\Psi_j) \\ &+ \lambda^{(a)}A \\ \frac{\partial\Phi}{\partial W_u} &= \sum_{(y,i,j,\mathbf{c})\in D}\lambda^{(y)}(\widehat{y}-y)W_v\mathbf{f}_j\mathbf{f}_i^T \\ &+ \lambda^{(w)}W_u \\ \frac{\partial\Phi}{\partial W_v} &= \sum_{(y,i,j,\mathbf{c})\in D}\lambda^{(y)}(\widehat{y}-y)W_u\mathbf{f}_i\mathbf{f}_j^T \\ &+ \lambda^{(w)}W_v\end{aligned}$$

where $\Phi = E_{Q(U,V)}(\log P(A,W,U,V|D))$ and $\widehat{y} = \bar{\mathbf{u}}_\mathbf{i}^\mathbf{T}A\bar{\mathbf{v}}_\mathbf{j} + (W_u\mathbf{f}_i)^T W_v\mathbf{f}_j$.

4 Experimental Methodology

4.1 Data Collection

We collected an evaluation data set from a popular review web site where users review services/products and provide integer ratings from 1 to 5. The user profile and the description of items, such as user gender and the category of restaurants are also collected. The data set used in this paper includes the restaurants in Silicon Valley (Bay area) and the users who ever reviewed these restaurants. We extract context from the review texts. The four kinds of context considered in our paper are described in Section 2.1. For each type of context, we create a subset, in which all reviews contain the corresponding contextual information. Finally we construct four sub data sets and each data set is described by the corresponding context type: Time, Location, Occasion and Companion. We use "All" to represent the whole data set. Statistics about each data set are described in Table 3.



(a) Time (b) Location (c) Occasion

(d) Companion (e) All

Figure 1: Performance on the top-K recommendation task. The plots focus on the top 20% ranking region.

Dataset	#Ratings	#Users	#Items
All	756,031	82,892	12,533
Location	583,051	56,026	12,155
Time	229,321	49,748	10,561
Occasion	22,732	12,689	4,135
Companion	196,000	47,545	10,246

Table 3: Statistics of data

4.2 Experimental Setup

We design the experiments to answer the following questions: 1) Does including contextual information improve the recommendation performance? 2) How does the probabilistic latent relational modeling approach compare with pre-filtering or post-filtering approaches? 3) How does the extraction quality of the contextual information affect the recommendation performance?

To answer the first question, we compare the performance of the Probabilistic Latent Relational Model on a standard collaborative filtering setting where only rating information is considered, indicated by Nocontext. We also evaluate the performance of the Probabilistic Latent Relational Model when integrating contextual information, indicated by Context-X, where X represents the type of contextual information considered. To answer the second question, we compare the performance of Context-X with the pre-filtering Boolean Model, which first uses the context to select items and then ranks them using scores computed by Nocontext. To answer the third question, we compare the recommendation performance for different extraction precision. The performance on the following two recommendation tasks are reported in this paper:

Top-K Recommendation: We rank the items by the predicted rating values and retrieve the top K items. This task simulates the scenario where a real recommender system usually suggests a list of ranked K items to a user. To simulate the scenario that we only want to recommend the 5-star items to users, we treat 5-star rating data in testing data as relevant. Ideally, classic IR measures such as Precision and Recall are used to evaluate the recommendation algorithms. However, without complete relevance judgements, standard IR evaluation is almost infeasible. Thus we use a variation of the evaluation method proposed by Koren (Koren, 2008).

Rating Prediction: Given an active user i and a target item j, the system predicts the rating of user

	Training on Sub Data set			Training on the Whole Data set		
Testing Data	ItemAvg	Nocontext	Context	ItemAvg	Nocontext	Context
Time	1.1517	1.0067	1.0067	1.1052	0.9829	0.9822
Companion	1.2657	1.0891	1.0888	1.2012	1.0693	1.0695
Occasion	1.2803	1.1381	1.1355	1.2121	1.0586	1.0583
Location	1.1597	1.0209	1.0206	1.1597	1.0183	1.0183
All context	-	-	-	1.1640	1.0222	1.0219

Table 4: RMSE on the rating prediction task

	Time	CompanionBaseline	CompanionClassifier	Occasion
#Reviews	300	300	300	200
#Contexts	115	148	114	207
Precision	84.4%	62.2%	77.1%	-
Recall	80.2%	95.8%	91.7%	-
F-Score	82.2%	75.4%	83.8%	Accuracy 78.3%

Table 5: Performance of the context extraction module

i on item j. The prediction accuracy is measured by Root Mean Square Error (RMSE), which is commonly used in collaborative filtering research. This task simulates the scenario that we need to guess a user's rating about an item, given that the user has already purchased/selected the item.

For each data set (Time, Companion, Location, Occasion and All), we randomly sample 10% for testing, 80% for training and 10% for validation.

5 Experimental Results

5.1 Performance on Top-K Recommendation

Figure 1(a)-(e) shows the ranking performance on each data set. The x-axis is the rank and the y-axis is the portion of relevant products covered by this level of rank. The results across all data sets are consistent. With contextual information, PLRM Context-X outperforms Nocontext, whereas using context to pre-filter items (Boolean) does not help. It means that contextual information can help if used appropriately, however improperly utilizing context, such as simply using it as a boolean filter, may hurt the recommendation performance. Our proposed PLRM is an effective way to integrate contextual information.

5.2 Performance on Rating Prediction Task

Table 4 summaries the RMSE results of different approaches on the rating prediction task. The RMSE of simply using item's average rating value as the prediction is also reported as a reference since it is a commonly used approach by non personalized recommender systems. For each context, we can either train the model only on the subset that consists of rating data with related context, or train on a bigger data set by adding the rating data without related context. The results on both settings are reported here. Table 4 shows that utilizing context does not affect the prediction accuracy. We may wonder why the effects of adding context is so different on the rating task compared with the ranking task. One possible explanation is that the selection process of a user is influenced by context, while how the user rates an item after selecting it is less relevant to context. For example, when a user wants to have a breakfast, he may prefer a cafeteria rather than a formal restaurant. However, how the user rates this cafeteria is more based on user's experiences in the cafeteria, such as quality of services, food, price, environment, etc.

5.3 How does Text Mining Accuracy Affect Recommendation

To evaluate the extraction performance on "Companion", "Time" and "Occasion", we randomly sample some reviews and evaluate the perfor-

mance on the samples[3]. The results are shown in Table 5. Compared with other contexts, the extraction of companion context is more challenging and the string matching baseline algorithm produces significantly inferior results. However, by using a MaxEnt classifier with features selection, we can boost the precision of the companion context extraction to a level comparable to other contexts.

To further investigate the relationship between the quality of the extracted context and the performance of the recommender system, we compare the recommendation performance of Companion-Baseline and Companion-Classifier in Figure 1(d). It shows that improving the quality of the extraction task leads to a significant improvement on the recommender systems' top-K ranking task.

6 Conclusions

Reviews widely available online contain a large amount of contextual information. This paper proposes to leverage information extraction techniques to help recommender systems to train better context-aware recommendation models by mining reviews. We also introduce a probabilistic latent relation model for integrating the current context and the user's long term preferences. This model takes the advantages of traditional collaborative filtering approaches (CF). It also captures the interaction between contextual information and item characteristics. The experimental results demonstrate that context is an important factor that affects user choices. If properly used, contextual information helps ranking based recommendation systems, probably because context influences users' purchasing decisions. Besides, more accurate contextual information leads to better recommendation models. However, contextual information does not help the user rating prediction task significantly, probably because context doesn't matter much given the user has already chosen a restaurant.

As the first step towards using the information extraction techniques to help contextual recommendation, the techniques used in this paper are far from optimal. In the future, we will research more effective text mining techniques for contextual extraction(Mazur and Dale, 2008; McCallum et al., 2000; Lafferty et al., 2001) at the same time increasing the amount of annotated review data for better classifier performance through actively learning (Laws and Schütze, 2008). We also plan to work towards a better understanding of contextual information in recommender systems, and explore other types of contextual information in different types of recommendation tasks besides restaurant recommendations.

[3]We sample 300 reviews for "Time" and "Companion" evaluation. Due to the extremely low probability of occurrence of Occasion context, we futher sample 200 reviews containing Occasion-related expressions and only evaluate extraction accuracy on these samples

Abstract

Various strategies have been proposed to enhance web search through utilizing individual user information. However, considering the well acknowledged recurring queries and repetitive clicks among users, it is still an open issue whether using individual user information is a proper direction of efforts in improving the web search. In this paper, we first quantitatively demonstrate that individual user information is more beneficial than common user information. Then we statistically compare the benefit of individual and common user information through Kappa statistic. Finally, we calculate potential for personalization to present an overview of what queries can benefit more from individual user information. All these analyses are conducted on both English AOL log and Chinese Sogou log, and a bilingual perspective statistics consistently confirms our findings.

1 Introduction

Most of traditional search engines are designed to return identical result to the same query even for different users. However, it has been found that majority of queries are quite ambiguous (Cronen-Townsend et al., 2002) as well as too short (Silverstein et al., 1999) to describe the exact informational needs of users. Different users may have completely different information needs under the same query (Jansen et al., 2000). For example, when users issue a query "Java" to a search engine, their needs can be something ranging from a programming language to a kind of coffee.

In order to solve this problem, personalized search is proposed, which is a typical strategy of utilizing individual user information. Pitkow et al. (2002) describe personalized search as the contextual computing approach which focuses on understanding the information consumption patterns of each user, the various information foraging strategies and applications they employ, and the nature of the information itself. After that, personalized search has gradually developed into one of the hot topics in information retrieval. As for various personalization models proposed recently, Dou et al. (2007), however, reveal that they actually harms the results for certain queries while improving others. This result based on a large-scale experiment challenges not only the current personalization methods but also the motivation to improve web search by the personalized strategies.

In addition, the studies on query logs recorded by search engines consistently report the prevailing repeated query submissions by large number of users (Silverstein et al., 1999; Spink et al., 2001). It is reported that the 25 most frequent queries from the AltaVista cover 1.5% of the total query submissions, despite being only 0.00000016% of unique queries (Silverstein et al., 1999). As a result, the previous users' activities may serve as valuable information, and technologies focusing on common

Coling 2008: Poster Volume, pages 701–709,
Beijing, August 2010

user information, such as collaborative filtering (or recommendation) may be a better resolution to web search. Therefore, the justification of utilizing individual user information deserves further discussion.

To address this issue, this paper conducts a bilingual perspective of survey on two large-scale query logs publically available: the AOL in English and the Sogou[1] in Chinese. First we quantitatively investigate the evidences for exploiting common user information and individual user information in these two logs. After that we introduce Kappa statistic to measure the consistency of users' implicit relevance judgment inferred from clicks. It is tentatively revealed that using individual user information is what requires web search to face with after common user information is well exploited. Finally, we study the distribution of potential for personalization over the whole logs to generally disclose what kind of query deserves for individual user information.

The remainder of this paper is structured as follows. Section 2 introduces previous methods employing individual and common user information. In Section 3, we quantitatively compare the evidences for exploiting common user information and individual user information. In Section 4, we introduce Kappa statistic to measure the consistency of users' clicks on the same query and try to statistically present the development direction of current web search. Section 5 figures out utilizing individual user information as a research issue after well exploiting common user information. Section 6 presents the potential for personalization curve, trying to outline which kind of queries benefit the most from individual user information. Conclusions and future work are detailed in Section 7.

2 Related Work

With the rapid expansion of World Wide Web, it becomes more and more difficult to find relevant information through one-size-fits-all information retrieval service provided by classical search engines. Two kinds of user information are mainly used to enhance search engines: common user information and individual user information. We separately review the previous works focusing on using these two kinds of information.

Among various attempts to improve the performance of search engine, collaborative web search is the one to take advantage of the repetition of users' behaviors, which we call common user information. Since there is no unified definition on collaborative web search, in this paper, we believe that the collaborative web search assumes that community search activities can provide valuable search knowledge, and sharing this knowledge facilitates improving traditional search engine results (Smyth, 2007). An important technique of collaborative web search is Collaborative Filtering (CF, also known as collaborative recommendation), in which, items are recommended to an active user based on historical co-occurrence data between users and items (Herlocker et al., 1999). A number of researchers have explored algorithms for collaborative filtering and the algorithms can be categorized into two classes: memory-based CF and model-based CF. Memory-based CF methods apply a nearest-neighbor-like scheme to predict a user's ratings based on the ratings given by like-minded users (Yu et al., 2004). The model-based approaches expand memory-based CF to build a descriptive model of group-based user preferences and use the model to predict the ratings. Examples of model-based approaches include clustering models (Kohrs et al., 1999) and aspect models (J. Canny, 2002).

The other way to improve web search is personalized web search, focusing on learning the individual preferences instead of others' behaviors, which is called individual user information. Early works learn user profiles from the explicit description of users to filter search results (Chirita et al., 2005). However, most of users are not willing to provide explicit feedback on search results and describe their interests (Carroll et al., 1987). Therefore, recent researches on the personalized search focus on modeling user preference from different types of implicit data, such as query history (Speretta et al., 2005), browsing history (Sugiyama et al., 2004), clickthrough data (Sun et al., 2005), immediate search context (Shen et al., 2005) and other personal information (Teevan et al.,

[1] A famous Chinese search engine with a large number of Chinese web search users.

2005). So far, there is still no proper comparison between the two solutions. It is still an open question which kind of information is more effective to build the web search model.

Considering the difficulty in collecting private information, using individual user information seems less promising as the cost-effective solution to web search. To address this issue, some researches about the value of personalization have been conducted. Teevan et al. (2007) have done a ground breaking job to quantify the benefit for the search engines if search results were tailored to satisfy each user. The possible improvement by the personalized search, named potential for personalization, is measured by a gap between the relevance of individualized rankings and group ranking based on NDCG. However, it is less touched for the position of individual user information in contrast with common user information in large scale query log and how to balance the usage of common and individual information in information retrieval model.

This paper tentatively examines individual user information against common user information on two large-scale search engine logs in following aspects: the evidence from clicks on the same query, Kappa statistic for the whole queries, and overall distribution of queries in terms of number of submissions and Kappa value. The bilingual statistics consistently reveals the tendency of using individual user information as an equally important issue as (if not more than) using common user information) issue for researches on web search.

3 Quantitative Evidences for Using Common or Individual User Information

To quantitatively investigate the value of common user information and individual user information in query log, we discriminate the evidence for using the two different types of user information as follows:

(1) Evidence for using common user information: if there were multiple users who have exactly the same click sets on one query, we suppose those clicks sets, together with the query, as the evidence for exploiting common user information. It is clear that such queries are able to be better responded with other's search results. Note that common user information is hard to be clearly defined, in order to simplify the quantitative statistics we give a strict definition. Further analysis will be shown in following sections.

(2) Evidence for using individual user information: if a user's click set on a query was not the same as any other's, for that query, the search intent of the user who issue that query can be better inferred from his/her individual information than common user information. We suppose this kind of clicks, together with the related queries, as the evidence for exploiting individual user information.

Since users may have different search intents when they issue the same query, a query can be an evidence for using both common and individual user information. In our statistics, if a query has both duplicate click sets and unique click set, the query is not only counted by the first category but also the second category.

The statistics of the two categories are conducted in the query log of both English and Chinese search engines. We use a subset of AOL Query Log from March 1, 2006 to May 31, 2006 and Sogou Query Log from March 1, 2007 to March 31, 2007. The basic statistics of AOL and Sogou log are shown in Table 1. Notice that the queries in raw AOL and Sogou log without clicks are removed in this study.

Item	AOL	Sogou
#days	92	31
#users	6,614,960	7,488,754
#queries	7,840,348	8,019,229
#unique queries	4,811,649	4,580,836
#clicks	12,984,610	17,607,808

Table 1: Basic statistics of AOL & Sogou log

Table 2 summarizes the statistics of different evidence categories over AOL and Sogou log. Note that click set refers to the set of clicks related to a query submission instead of a unique query. As for evidence for using common and individual user information, there is no clear distinction in terms of number of records, number of users in two logs. However, in terms of unique query and distinct click set, one can't fail to find that evidence for using individual user information clearly exceeds

Log	The Condition		Number			
	Repeated queries	Click	Records	User	Unique Query	Distinct Click Set
AOL	3,745,088 (47.77% of total query submissions)	Same	2,438,284	277,416	382,267	461,460
		Different	2,563,245	343,846	542,593	1,349,892
Sogou	4,252,167 (53.02% of total query submissions)	Same	2,469,363	1,380,951	228,315	358,346
		Different	5,481,832	1,545,817	752,047	2,171,872

Table 2: Different click behaviors on repeated queries

that for using common user information, especially in Sogou log. Therefore, though making use of common and individual user information can address equally well for half users and half visits to the search engine, the fact that much more unique queries and click sets actually claims the significance of needing individual user information to personalize web results. And methods exploiting individual user information provide a much more challenging task in terms of problem space, though one may argue utilizing common user information is much easier to attack.

4 Kappa Statistics for Individual and Common user information

Section 3 has shown the evidence for using individual user information is prevailing than common user information in quantity for the unique queries in search engines. However, these counts deserve a further statistical characterization. In this section, we introduce Kappa statistic to depict the overall consistency of users' clicks in query logs.

4.1 Kappa

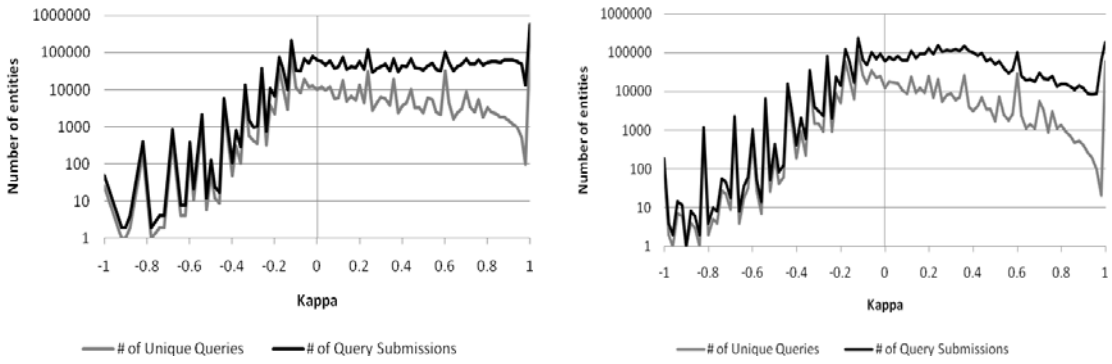
Kappa is a statistical measure introduced to access the agreement among different raters. There are two types of Kappa. One is Cohen's Kappa (Cohen, 1960), which measures only the degree of agreement between two raters. The other is Fleiss's Kappa (Fleiss, 1971), which generalizes Cohen's Kappa to measure agreement among more than two raters, denoted as:

$$\kappa = \frac{\overline{P} - \overline{P_e}}{1 - \overline{P_e}}$$

where, $\overline{P}$ is the probability that a randomly selected rater agree with another on a randomly selected subject. $\overline{P_e}$ is the expected probability of agreement if all raters made ratings by chance. If we use Kappa to measure the consistency of relevance judgment by different raters, $\overline{P}$ can be interpreted as the probability that two random selected raters consistently rate a random selected search result as relevant or non-relevant one. Similarly, $\overline{P_e}$ can also be construed as the expected probability of identical relevance judgment rated by different raters all by chance.

Teevan et al. (2008) used Fleiss's Kappa to measure the inter-rater reliability of different raters' explicit relevance judgments. We expand their work and employ Fleiss's Kappa to measure the consistency of implicit relevance judgments by users on the same query[2]. Here clicks are treated as a proxy for relevance: documents clicked by a user are judged as relevant and those not clicked as non-relevant (Teevan et al., 2008). As we all know that the result set of one query may change over time, so we select the longest time span to calculate Kappa value of a query, during which the result set of it preserves unchanged. From Kappa value of each query, we can statistically interpret to which extent users share consistent intent on the same query according to Table 3 (Landis and Koch, 1977). Though the interpretation in Table 3 is not accepted with no doubt, it can give us an intuition about what extent of agreement consistency is. In other words, Kappa is a measure with statistical sense. Meanwhile, Kappa values of queries with

[2] There may be more than two users who submitted the same query.



(a). AOL **(b). Sogou**

Figure 1: Number of unique queries and query submissions as a function of Kappa value.

κ	Interpretation
< 0	No agreement
0.0 – 0.20	Slight agreement
0.21 – 0.40	Fair agreement
0.41 – 0.60	Moderate agreement
0.61 – 0.80	Substantial agreement
0.81 – 1.00	Almost perfect agreement

Table 3: Kappa Interpretation

various sizes of click sets are also comparable. That is also the reason we choose Kappa to measure consistency.

4.2 Distribution of Kappa

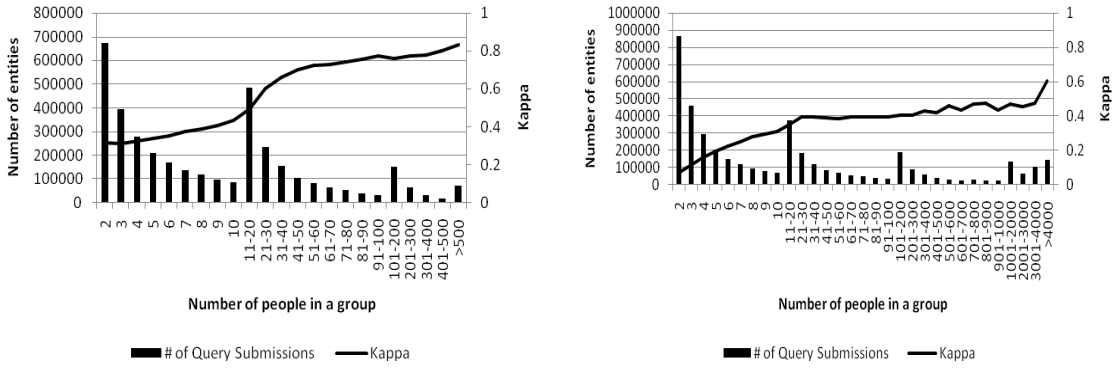
As introduced in Section 2, common user information is supposed to be the repetition of users' behaviors. We consider that the amount of repetition of users' clicks on one query is quantified by the consistency of its clicks. To statistically present the scale of repetition in current query log, we try to give an overview of consistency level of two commercial query logs.

Figure 1 plots distribution of Kappa value of the two logs in the coordinate with logarithmic Y-axis. About 34.5% unique queries (44.0% query submissions) in AOL log and only 13.9% unique queries (15.2% query submissions) in Sogou log have high Kappa values above 0.6. According to Table 3, click sets of these queries can be regarded as somewhat consistent. These queries can be roughly resolved by using common user information. On the other hand, for the rest of queries which constitute majority of the logs, users' click sets are rather diversified, which are hard to be satisfied by returning the same result list to them. As a whole, the queries in both AOL and Sogou can be characterized as less consistently in the clicks according to Kappa value, which is a statistical support for exploiting individual user information.

5 Individual or Common user information: A Tendency View

The above analyses quantitative analyses have shown that the repetition of search is not the statistically dominant factor, with the impression that employing individual user information is equally, if not more, important than common user information. This section tries to further reveal this issue so as to balance the position of individual user information and common user information from a research point.

Intuitively, a query can be characterized by the number of people issuing it, i.e. query frequency if we remove the resubmissions of one query by the same people. We try to depict the above mentioned query submissions and Kappa values as a function of number of people who issue the queries in Figure 2. In Figure 2, different numbers of users who issue the same query are shown on the x-axis, and the y-axis represents the number of different entities (left scale) and the average Kappa value (right scale) of the queries. We find that the number of queries becomes very small when the number of users in a group grows over 10, so we set a variant step length for them: with the length step of the group size falling between 2 and 10 set as 1, between 11 and 100 as 10, between 101 and 1000 as 100 and above 1000 as 1000.



(a). AOL **(b). Sogou**

Figure 2: Average Kappa value of queries as a function of number of people in a group who issue the same query (line) and the number of submissions of the queries issued by the same size of group (dark columns).

According to Figure 2(a), Kappa values of the queries in AOL log with more than 20 users are above 0.6, which indicates rather consistent clicks for them, accounting for about 29.4% of all query submissions. While for those queries visited by less than 20 users, the Kappa value declines gradually from 0.6 with the drop of users. For these queries occupying majority of query submissions, exploiting individual user information is supposed to be a better solution since the clicks on them are rather individualized.

According to Figure 2(b), though Kappa values of queries increase similarly with people submitting them in AOL, the overall consistency of the queries in Sogou log is much lower: with a Kappa value below 0.6 even for the queries visited by a large number of users. This fact indicates that Chinese users may be less consistent in their search intents, or partially reflects that the Chinese as a non-inflection language has more ambiguity, which can also be implied from Table 2. Therefore, individual user information may be more effective than common user information in Sogou log.

Summarized from Figure 2, it is sensible that common user information is appropriate for the queries in the right-most of X-axis. With most number of visiting people, such queries bear rather consistent clicks though covering only a small proportion of the distinct query set. Moving from the right to the left, we can find the majority of queries yield a less Kappa value, for which the individualized clicks require individual user information to meet the needs of each user. In this sense, how to exploit individual user information is predestined as the next issue of information retrieval if common user information was to be well utilized.

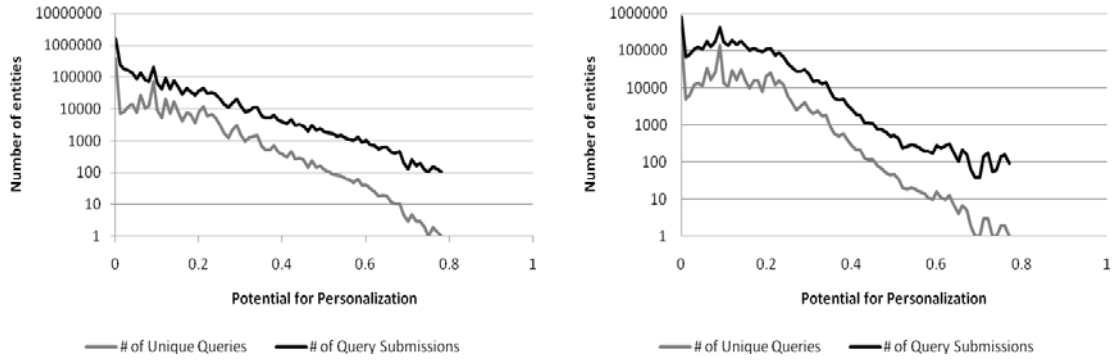
6 Queries for Personalization

Since using individual user information is a non-negligible issue in IR research, a subsequent issue is what queries can benefit in what extent from individual user information. In this section, we try to give an overview for this issue via a measure named potential for personalization.

6.1 Potential for Personalization

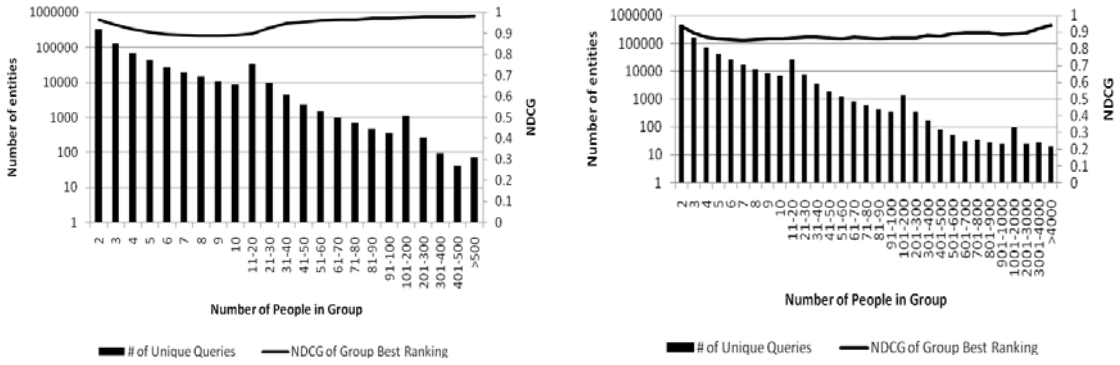
Potential for personalization proposed by Teevan et al. (2007) is used to measure the normalized Discounted Cumulative Gain (NDCG) improvement between the best ranking of the results to a group and individuals. NDCG is a well-known measure of the quality of a search result (Järvelin and Kekäläinen, 2000).

The best ranking of the results to a group is the ranking with highest NDCG based on relevance judgments of the users in the group. For the queries with explicit judgments, the best ranking can be generated as follows: results that all raters thought were relevant are ranked first, followed by those that most people thought were relevant but a few people thought were irrelevant, until the results most people though were irrelevant. In other word,



(a) AOL **(b) Sogou**

Figure 3: Number of unique queries and query submissions as a function of potential for personalization



(a) AOL **(b) Sogou**

Figure 4: The average NDCG of group best ranking as a function of number of people in group (solid line), combining with the distribution of the number of unique queries issued by the same size of group (dark columns)

the best ranking always tries to put the results that have the highest collective gain first to get the highest NDCG.

The previous work has shown that the implicit click-based potential for personalization is strongly related to variation in explicit judgments (J. Teevan et al., 2008). In this paper, we continue using click-based potential for personalization to measure the variation. Assuming the clicked results as relevant, we can calculate the potential for personalization of each query over the web search query log to present what kind of query can benefit more from personalization.

6.2 Potential for Personalization Distribution over Query Logs

Teevan et al. (2007) have depicted a potential for personalization curve based on explicit judgment to characterize the benefit that could be obtained by personalizing search results for each user. We continue using potential for personalization based on click-through to roughly reveal what kind of query can benefit more from personalization.

First we investigate the number of unique queries with different potential for personalization, which is shown in Figure 3. We find that there are about 53.9% unique queries in AOL log and 32.4% unique queries in Sogou log, whose potential for personalization is 0. For these queries, current web search is able to return perfect results to all users. However, for the rest of queries, even the best group ranking of results can't satisfy everyone who issues the query. So these queries should be better served by individual user information, covering

46.1% unique queries in AOL and 67.6% in Sogou.

Then, in order to further interpret what kind of query individual user information is needed most, we further relate potential for personalization to the number of users who submit the queries over AOL and Sogou query log as shown in Figure 4. For clarity's sake, we also set the same step length as in Figure 2.

According to Figure 4, the curve of potential for personalization is approximately U-shaped in both AOL log and Sogou Log. As the number of users in one group increases, performance of the best non-personalized rankings first declines, then flattens out and finally promotes[3]. Note that the left part of the curve is very similar to what Teevan et al. (2007) showed in their work.

Again in Figure 4, the queries which have the most potential for personalization are the ones which are issued by more than 6 and less than 20 users in AOL log. While in Sogou log, the queries issued by more than 6 and less than 4000 users have the most potential for personalization. Such different findings are probably caused by the content of query. There are many recommended queries in the homepage of Sogou search engine, most of which are informational query and clicked by a large number of users. Even when the size of group who issue the same query becomes very big, the query still has a wide variation of users' behaviors. So the consistency level of queries in Sogou log is much lower than the queries in AOL log at the same size of group.

7 Conclusion and Future Work

In this paper, we try to justify the position of individual user information comparing with common user information. It is shown that exploiting individual user information is a non-trivial issue challenging the IR community through the analysis of both English and Chinese large scale search logs.

We first classify the repetitive queries into 2 categories according to whether the corresponding clicks are unique among different users. We find that quantitatively the queries and clicks deserving for individual user information is much bigger than those deserving for common user information.

After that we use Kappa statistic to present that the overall consistency of query clicks recoded in search logs is pretty low, which statistically reveals that the repetition is not the dominant factor and individual user information is more desired to enhance most queries in current query log.

We also explore the distribution of Kappa values over different numbers of users in the group who issue the same query, concluding that how to utilize individual user information to improve the performance of web search engine is the next research issue confronted by the IR community when the repeated search of users are properly exploited.

Finally, potential for personalization is calculated over the two query logs to present an overview of what kind of queries that the optimal group-based retrieval model fails, which is supposed to benefit most from individual user information.

One possible enrichment to this work may come from the employment of content analysis based on text processing techniques. The different clicks, which are the basis of our examination, may have similar or even exact content in their web pages. Though the manual check for a small scale sampling from the Sogou log yields less than 1% probability for such case, the content based examination will be definitely more convincing than simple click counts. In addition, the queries for the two types of user information are not examined for their contents or the related information needs. Content analysis or linguistic view to these queries would be more informative. Both of these issues are to be addressed in our future work.

Abstract

Sentence-level aligned parallel texts are important resources for a number of natural language processing (NLP) tasks and applications such as statistical machine translation and cross-language information retrieval. With the rapid growth of online parallel texts, efficient and robust sentence alignment algorithms become increasingly important. In this paper, we propose a fast and robust sentence alignment algorithm, i.e., Fast-Champollion, which employs a combination of both length-based and lexicon-based algorithm. By optimizing the process of splitting the input bilingual texts into small fragments for alignment, Fast-Champollion, as our extensive experiments show, is 4.0 to 5.1 times as fast as the current baseline methods such as Champollion (Ma, 2006) on short texts and achieves about 39.4 times as fast on long texts, and Fast-Champollion is as robust as Champollion.

1 Introduction

Sentence level aligned parallel corpora are very important resources for NLP tasks including machine translation, cross-language information retrieval and so on. These tasks typically require support by large aligned corpora. In general, the more aligned text we have, the better result we achieve. Although there is a huge amount of bilingual text on the Internet, most of them are either only aligned at article level or even not aligned at all. Sentence alignment is a process mapping sentences in the source text to their corresponding units in the translated text. Manual sentence alignment operation is both expensive and time-consuming, and thus automated sentence alignment techniques are necessary. A sentence alignment algorithm for practical use should be (1) fast enough to process large corpora, (2) robust enough to tackle noise commonly present in the real data, and (3) effective enough to make as few mistakes as possible.

Various sentence alignment algorithms have been proposed, which generally fall into three types: length-based, lexicon-based, and the hybrid of the above two types. Length-based algorithms align sentences according to their length (measured by character or word). The first length-based algorithm was proposed in (Brown et al., 1991). This algorithm is fast and has a good performance if there is minimal noise (e.g., sentence or paragraph omission) in the input bilingual texts. As this algorithm does not use any lexical information, it is not robust. Lexicon-based algorithms are usually more robust than the length-based algorithm, because they use the lexical information from source and translation lexicons instead of solely sentence length to determine the translation relationship between sentences in the source text and the target text. However, lexicon-based algorithms are slower than length-based sentence alignment algorithms, because they require much more expensive computation. Typical lexicon-based algorithms include (Ma, 2006; Chen, 1993; Utsuro et al., 1994; Melamed, 1996). Sentence length and lexical information are also combined to achieve more efficient algorithms in two ways. One way is to use both sentence length and lex-

Coling 2008: Poster Volume, pages 710–718,
Beijing, August 2010

ical information together to determine whether two sentences should be directly aligned or not (Simard et al., 1993; Wu, 1994). The other way is to produce a rough alignment based on sentence length (and possibly some lexical information at the same time), and then build more precise alignment by using more effective lexicon-based algorithms (Moore, 2002; Varga et al., 2005). But both of the two ways suffer from high computational cost and are not fast enough for processing large corpora.

Lexical information is necessary for improving robustness of a sentence alignment algorithm, but use of lexical information will introduce higher computational cost and cause a lower speed. A common fact is that the shorter the text is, the less combination possibilities it would introduce and the less computational cost it would need. So if we can first split the input bilingual texts into small aligned fragments reliably with a reasonable amount of computational cost, and then further align these fragments one by one, we can speed up these algorithms remarkably. This is the main idea of our algorithm Fast-Champollion.

The rest of this paper is organized as follows: Section 2 presents formal definitions of sentence alignment problem, and briefly reviews the length-based sentence alignment algorithm and Champollion algorithm; Section 3 proposes the Fast-Champollion algorithm. Section 4 shows the experiment results; and Section 5 is the conclusion.

2 Definitions and Related Work

2.1 Definitions and Key Points

A **segment** is one or more consecutive sentence(s). A **fragment** consists of one segment of the source text (denoted by S) and one segment of the target text (denoted by T), and a fragment can be further divided into one or more beads. A **bead** represents a group of one or more sentences in the source text and the corresponding sentence(s) in the target text, denoted by $A_i = (S_{Ai}; T_{Ai}) = (S_{a_{i-1}+1}, S_{a_{i-1}+2}, \cdots, S_{a_i}; T_{b_{i-1}+1}, T_{b_{i-1}+2}, \cdots, T_{b_i})$, where S_i and T_j are the i$^{\text{th}}$ and j$^{\text{th}}$ sentence of S and T respectively.

In practice, we rarely encounter crossing alignment, e.g., sentences S_i and S_j of the source language are aligned to the sentences T_j and T_i of the target language respectively. But much more effort has to be taken for an algorithm to process crossing alignment well. So we do not consider crossing alignment here.

In addition, only a few type of beads are frequently observed in the real world. As it can save significantly in terms of computational cost and it would not do significant harm to algorithm without considering rare bead types, a common practice for designing sentence alignment algorithms is to only consider the frequently observed types of beads. Following this practice, we only consider beads of 1-to-0, 0-to-1, 1-to-1, 1-to-2, 2-to-1, 1-to-3, 3-to-1, 1-to-4, 4-to-1 and 2-to-2 types in our algorithm, where n-to-m means the bead consists of n sentence(s) of the source language and m sentence(s) of the target language.

2.2 Length-based Sentence Alignment Algorithm

Length-based sentence alignment algorithm was first proposed in (Brown et al., 1991). This algorithm captures the idea that long or short sentences tend to be translated into long or short sentences. A probability is produced for each bead based on the sentence length, and a dynamic programming algorithm is used to search for the alignment with the highest probability, which is treated as the best alignment.

This algorithm is fast and can produce good alignment when the input bilingual texts do not contain too much noise, but it is not robust, because it only uses the sentence length information. When there is too much noise in the input bilingual texts, sentence length information will be no longer reliable.

2.3 Champollion Aligner

Champollion aligner was proposed in (Ma, 2006). It borrows the idea of *tf-idf* value, which is widely used in information retrieval, to weight term[1] pair similarity. Greater weight is assigned to the less frequent translation term pairs, because these term

[1]Here terms are not limited to linguistic words, but also can be tokens like "QX6800"

pairs have much stronger evidence for two segments to be aligned. For any two segments, a similarity is assigned based on the term pair weight, sentence number and sentence length. And the dynamic programming algorithm is used to search for the alignment with the greatest total similarity. This alignment is treated as the best alignment.

Champollion aligner can produce good alignment even on noisy input as reported in (Ma, 2006). Its simplicity and robustness make it a good candidate for practical use. But this aligner is slow. Because its time complexity is $O(n^2)$ and it has to look up the dictionary multiple times in each step of the dynamic programming algorithm, which needs higher computational cost.

3 Fast-Champollion Algorithm

In this section we propose a new sentence alignment algorithm: Fast-Champollion. Its basis is splitting the input bilingual texts into small aligned fragments and then further aligning them one by one to reduce running time while maintaining Champollion-equivalent (or better) alignment quality; it takes the advantages of both length-based and lexicon-based algorithms to the maximum extent. The outline of the algorithm is that first the *length-based splitting module* is used to split the input bilingual texts into aligned fragments, and then the components of each of these fragments will be identified and aligned by a Champollion-based algorithm. The details are described in the following sections.

3.1 Length-based Splitting Module

Although length-based sentence alignment algorithm is not robust enough, it can produce rough alignment very fast with a certain number of reliably translated beads. Length-based splitting module is designed to select these reliably translated beads to be used for delimiting and splitting the input bilingual texts into fragments. These beads will be referred to as *anchor beads* in the remaining sections.

There are four steps in this module as described below in detail.

Step 1: decide whether to skip step 2-4 or not

When there is too much noise in the input bilingual texts, the percentage of reliably translated beads in the alignment produced by the length-based algorithm will be very low. In this case, we will skip step 2 through 4.

An evidence for such a situation is that the difference between the sentence numbers of the source and target language is too big. Suppose N_S and N_T are the number of sentences of the source and target language respectively. We specify $r = |N_S - N_T| / \min\{N_S, N_T\}$ as a measure of the difference, where min means minimum. If r is bigger than a threshold, we say the difference is too big. In our experiments, the threshold is set as 0.4 empirically.

Step 2: align the input texts using length-based algorithm

In this step, length-based sentence alignment algorithm is used to align the input bilingual texts. Brown, et al. (1991) models the process of sentence alignment as two steps. First, a bead is generated according to a fixed probability distribution over bead types, and then sentence length in the bead is generated according to this model: for the 0-to-1 and 1-to-0 type of beads, it is assumed that the sentence lengths are distributed according to a probability distribution estimated from the data. For other type of beads, the lengths of sentences of the source language are generated independently from the probability distribution for the 0-to-1 and 1-to-0 type of beads, and the total length of sentences of the target language is generated according to a probability distribution conditioned on the total length of sentences of the source language. For a bead $A_i = (S_{Ai}; T_{Ai})$, $l_{S_{Ai}}$ and $l_{T_{Ai}}$ are the total lengths of sentences in S_{Ai} and T_{Ai} respectively, which are measured by word[2]. Brown, et al. (1991) assumed this conditioned probability distribution is

$$Prob(l_{T_{Ai}}|l_{S_{Ai}}) = \alpha \exp\left(-\frac{(\lambda_i - \mu)^2}{2\sigma^2}\right),$$

where $\lambda_i = \log(l_{T_Ai}/l_{S_Ai})$ and α is a normalization factor. Moore (2002) assumed the condi-

[2]For Chinese, word segmentation should be done first to identify words.

tioned probability distribution is

$$Prob(l_{T_{Ai}}|l_{S_{Ai}}) = \frac{\exp(-l_{S_{Ai}}r)(l_{S_{Ai}}r)^{l_{T_{Ai}}}}{l_{T_{Ai}}!},$$

where r is the ratio of the mean length of sentences of the target language to the mean length of sentences of the source language. We tested the two models on our development corpus and the result shows that the first model performs better, so we choose the first one.

Step 3: determine the anchor beads

In this step, the reliably translated beads in the alignment produced by the length-based algorithm in Step 2 will be selected as anchor beads.

The length-based algorithm can generate a probability for each bead it produces. So a trivial way is to choose the beads with a probability above certain threshold as anchor beads. But as pointed out before, when there is too much noise, the alignment produced by the length-based algorithm is no longer reliable, and so is it with the probability. A fact is that if we select a non-translated bead as an anchor bead, we will split the input bilingual texts into wrong fragments and may cause many errors. So we have to make decision conservatively in this step and we decide to use lexical information instead of the probability to determine the anchor beads.

For a bead $A_i = (S_{Ai}; T_{Ai})$, the proportion of translation term-pairs is a good measure for determine whether this bead is reliably translated or not. In addition, use of *local information* will also be greatly helpful. To explain the use of "local information", let's define the fingerprint of a sentence first. Suppose we have a sequence of sentences $S_1, S_2, \cdots, S_m$, and $W(S_i)$is the set of distinct words in S_i, then the fingerprint of S_i is

$$f(S_i) = W(S_i) - W(S_{i-1}) - W(S_{i+1}),$$

and specially

$$f(S_1) = W(S_1) - W(S_2),$$

$$f(S_m) = W(S_m) - W(S_{m-1}).$$

The fingerprints of S_{Ai} and T_{Ai}, denoted by $f(S_{Ai})$ and $f(T_{Ai})$, are the unions of all the fingerprints of sentences in S_{Ai} and T_{Ai} respectively. As you can see, the fingerprint of a sentence is the set of words in the sentence that do not appear in the adjacent sentence(s), and thus can distinguish this sentence from its neighbors. So fingerprint is also a good measure. By combining these two measures together, we can select out more reliably translated beads.

For a word w, we use $d_D(w)$ to denote the set of all its translations in a bilingual dictionary D, and use $t_D(w)$ to denote the union of $\{w\}$ and $d_D(w)$, i.e., $t_D(w) = \{w\} \cup d_D(w)$. Given two sets of words A and B. We say a word w of A is translated by B if either one of its translations in the dictionary D or the word itself appears in B, i.e., $t_D(w) \cap B \neq \emptyset$. The set of all the words of A that are translated by B is:

$$h_D(A, B) = \{w \in A \; and \; t_D(w) \cap B \neq \emptyset\}.$$

Then the proportion of terms in A that are translated by B is

$$r_D(A, B) = \frac{|h_D(A, B)|}{|A|}.$$

We specify the proportion of translation term pairs in a bead, denoted as $ar_D(A_i)$, to be $\min\{r_D(W(S_{Ai}), W(T_{Ai})), r_D(W(T_{Ai}), W(S_{Ai}))\}$, where $W(S_{Ai})$ and $W(T_{Ai})$ are the sets of distinct words in S_{Ai} and T_{Ai} respectively. Also we specify the proportion of translation term-pairs in the fingerprint, denoted as $fr_D(A_i)$, to be $\min\{r_D(f(S_{Ai}), f(T_{Ai})), r_D(f(T_{Ai}), f(S_{Ai}))\}$. Given thresholds TH_{ar} and TH_{fr}, a bead is selected as an anchor bead when $ar_D(A_i)$ and $fr_D(A_i)$ are not smaller than TH_{ar} and TH_{fr} respectively. We will show that Fast-Champollion algorithm is not sensitive to TH_{ar} and TH_{fr} to some extent in Section 4.2.

Step 4: split the input bilingual texts

The anchor beads determined in Step 3 are used to split the input texts into fragments. The ending location of each anchor bead is regarded as a splitting point, resulting in two fragments.

3.2 Aligning Fragments with Champollion Aligner

The similarity function used by Champollion aligner is defined as follows. Given two (source

and target language) groups of sentences in a fragment, denoted by G_S=S_1, S_2,$\cdots$,S_m and G_T=T_1, T_2,$\cdots$,T_n, suppose there are k pairs of translated terms in G_S and G_T denoted by (ws_1, wt_1),(ws_2, wt_2),$\cdots$,(ws_k, wt_k), where ws_i is in G_S and wt_i is in G_T. For each pair of the translated terms (ws_i, wt_i), define $idtf(ws_i)$ to be

$$\frac{Total\ \#\ of\ terms\ in\ the\ whole\ document}{\#\ occurrences\ of\ ws_i\ in\ G_S},$$

and define

$$stf(ws_i, wt_i) = \min\{stf(ws_i), stf(wt_i)\},$$

where $stf(ws_i)$ and $stf(wt_i)$ are the frequency of ws_i and wt_i in G_S and G_T respectively. The similarity between G_S and G_T is defined as

$$\sum_{i=1}^{k} \log\left(idtf(ws_i) \times stf(ws_i, wt_i)\right) \times alignment\_penalty \times length\_penalty,$$

where $alignment\_penalty$ is 1 for 1-to-1 alignment type of beads and a number between 0 and 1 for other type of beads, $length\_penalty$ is a function of the total sentence lengths of G_S and G_T.

The reason for choosing Champollion aligner instead of other algorithms will be given in Section 4.2. And another question is how $idtf$ values should be calculated. $idtf$ is used to estimate how widely a term is used. An intuition is that $idtf$ will work better if the texts are longer, because if the texts are short, most words will have a low frequency and will seem to only appear locally. In Fast-Champollion, we calculate $idtf$ according to the whole document instead of each fragment. In this way, a better performance is achieved.

3.3 Parameter Estimation

A development corpus is used to estimate the parameters needed by Fast-Champollion.

For the length-based algorithm, there are five parameters that need to be estimated. The first one is the probability distribution over bead types. The ratio of different types of beads in the development corpus is used as the basis for the estimation. The second and third parameters are the probability distributions over the sentence length of the source language and the target language. These distributions are estimated as the distributions observed from the input bilingual texts. That is to say, these two distributions will not be the same for different bilingual input texts. The forth and fifth are μ and σ. They are estimated as the mean and variance of λ_i over the development corpus.

For Champollion aligner, $alignment\_penalty$ and $length\_penalty$ need to be determined. Because the Perl version of Champollion aligner[3] is well developed, we borrow the two definitions from it directly.

4 Experiments

4.1 Datasets and Evaluation Metrics

We have two English-Chinese parallel corpora, one for the development purpose and one for the testing purpose. Both of the two corpora are collected from the Internet and are manually aligned.

The development corpus has 2,004 beads. Given the space constraint, detailed information about the development corpus is omitted here.

The testing corpus contains 26 English-Chinese bilingual articles collected from the Internet, including news reports, novels, science articles, television documentary subtitles and the record of government meetings. There are 9,130 English sentences and 9,052 Chinese sentences in these articles[4]. The number of different type of beads in the golden standard answer is shown in Table 1.

Type	Number	Percentage(%)
1:1	7275	83.19
1:2 2:1	846	9.67
1:3 3:1	77	0.88
1:4 4:1	16	0.18
2:2	32	0.37
1:0 0:1	482	5.51
others	17	0.19

Table 1: Types of beads in the golden standard

Both the Fast-Champollion algorithm and the Champollion aligner need a bilingual dictionary and we supply the same bidirectional dictionary to

[3] http://champollion.sourceforge.net

[4] The definition of "sentence" is slightly different from the common sense here. We also treat semicolon and colon as the end of a sentence.

them in the following evaluations. This dictionary contains 45,439 pair of English-Chinese translation terms.

We use four commonly used measures for evaluating the performance of a sentence alignment algorithm, which are the *running time*,

$$\textit{Precision} = \frac{|GB \cap PB|}{|PB|},$$

$$\textit{Recall} = \frac{|GB \cap PB|}{|GB|},$$

and

$$\textit{F1-measure} = \frac{2 \times Precision \times Recall}{Precision + Recall},$$

where GB is the set of beads in the golden standard, and PB is the set of beads produced by the algorithm.

All the following experiments are taken on a PC with an Intel QX6800 CPU and 8GB memory.

4.2 Algorithm Design Issues

Why Choose Champollion?

We compared Champollion aligner with two other sentence alignment algorithms which also make use of lexical information. And the result is shown in Table 2. "Moore-1-to-1" and "Moore-all" are corresponding to the algorithm proposed in (Moore, 2002). The difference between them is how Recall is calculated. Moore's algorithm can only output 1-to-1 type of beads. For "Moore-1-to-1", we only consider beads of 1-to-1 type in the golden standard when calculating Recall, but all types of beads are considered for "Moore-all". The result suggests that ignoring the beads that are not of 1-to-1 type does have much negative effect on the overall performance of Moore's algorithm. Our goal is to design a general purpose sentence alignment algorithm that can process frequently observed types of beads. So Moore's algorithm is not a good choice. Hunalign refers to the hunalign algorithm proposed in (Varga et al., 2005). The resources provided to Champollion aligner and hunalign algorithm are the same in the test, but hunalign algorithm's performance is much lower. So hunalign algorithm is not a good choice either. Champollion algorithm is simple and has a high overall performance. So it is a better choice for us.

Aligner	Precision	Recall	F1-measure
Champollion	0.9456	0.9546	0.9501
Moore-1-to-1	0.9529	0.9436	0.9482
Moore-all	0.9529	0.7680	0.8505
Hunalign	0.8813	0.9037	0.8923

Table 2: The performance of different aligners on the development corpus

The Effect of TH_{ar} and TH_{fr}

TH_{ar} and TH_{fr} are two thresholds for selecting anchor beads in Step 3 of length-based splitting module. In order to investigate the effect of these two thresholds on the performance of Fast-Champollion, we run Fast-Champollion on the development corpus with different TH_{ar} and TH_{fr}. Both TH_{ar} and TH_{fr} vary from 0 to 1 with step 0.05. And the running time and F1-measure are shown in Figure 1 and Figure 2 respectively.

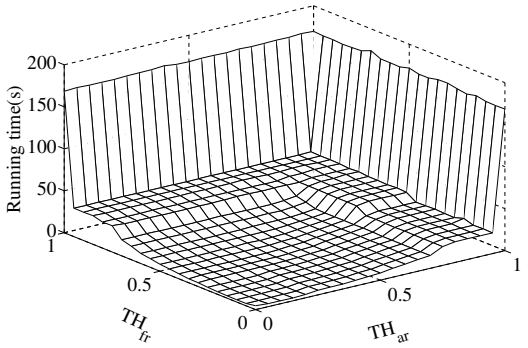

Figure 1: The running time corresponding to different TH_{ar} and TH_{fr}

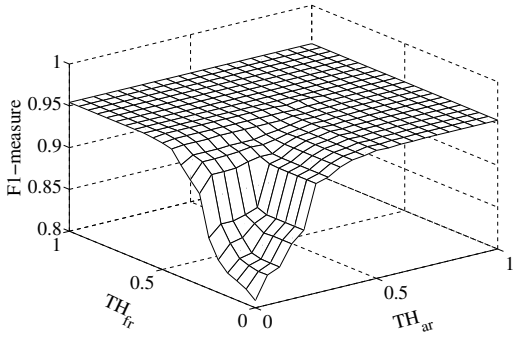

Figure 2: The F1-measure corresponding to different TH_{ar} and TH_{fr}

From Figure 1 and Figure 2, we see that for a large range of the possible values of TH_{ar} and TH_{fr}, the running time of Fast-Champollion increases slowly while F1-measure are nearly the same. In other words, Fast-Champollion are not sensitive to TH_{ar} and TH_{fr} to some extent. So making choice for the exact values of TH_{ar} and TH_{fr} becomes simple. And we use 0.5 for both of them in the following experiments.

4.3 Performance of Fast-Champollion

We use three baselines in the following evaluations. One is an implementation of the length-based algorithm in Java, one is a re-implemented Champollion aligner in Java according to the Perl version, and the last one is Fast-Champollion-Recal. Fast-Champollion-Recal is the same as Fast-Champollion except that it calculates $idtf$ values according to the fragments themselves independently instead of the whole document, and the Java versions of the length-based algorithm and Champollion aligner are used for evaluation.

Performance on Texts from the Internet

Table 3 shows the performance of Fast-Champollion and the baselines on the testing corpus. The result shows that Fast-Champollion achieves slightly better performance than Fast-Champollion-Recal. The running time of Champollion is about 2.6 times longer than Fast-Champollion with lower Precision, Recall and F1-measure. It should be pointed out that Fast-Champollion achieves better Precision, Recall and F1-measure than Champollion does because the splitting process may split the regions hard to align into different fragments and reduces the chance for making mistakes. Because of the noise in the corpus, the F1-measure of the length-based algorithm is low. This result suggests that Fast-Champollion is fast, robust and effective enough for aligning texts from the Internet.

Robustness of Fast-Champollion

In order to make a more precise investigation on the robustness of Fast-Champollion against noise, we made the following evaluation. First we manually removed all the 1-to-0 and 0-to-1 type of beads from the testing corpus to produce a clean corpus. This corpus contains 8,263 beads. Then we added 8263×n% 1-to-0 or 0-to-1 type of beads to this corpus at arbitrary positions to produce a series of noisy corpora, with n having the values of 5,10,...,100. Finally we ran Fast-Champollion algorithm and the baselines on these corpora respectively and the results are shown in Figure 3 and Figure 4, which indicate that for Fast-Champollion, when n increases 1, Precision drops 0.0021, Recall drops 0.0038 and F1-measure drops 0.0030 on average, which are very similar to those of Champollion, but Fast-Champollion is 4.0 to 5.1 times as fast as Champollion. This evaluation proves that Fast-Champollion is robust against noise and is a more reasonable choice for practical use.

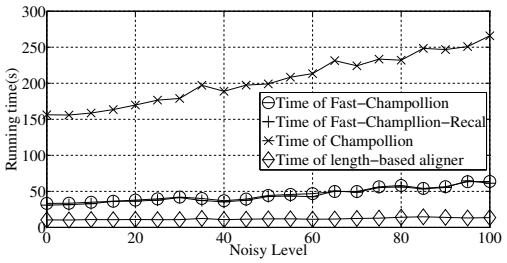

Figure 3: Running Time of Fast-Champollion, Fast-Champollion-Recal, Champollion and the length-based algorithm

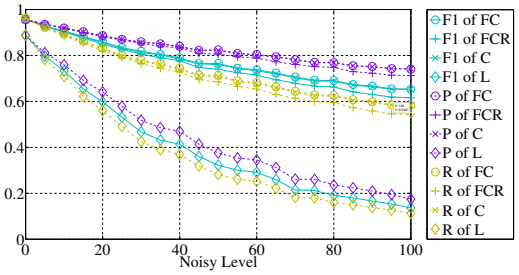

Figure 4: Precision (P), Recall (R) and F1-measure (F1) of Fast-Champollion (FC), Fast-Champollion-Recall (FCR), Champollion (C) and the length-base algorithm (L)

Performance on Long Texts

In order to test the scalability of Fast-Champollion algorithm, we evaluated it on long texts. We merged all the articles in the testing cor-

Aligner	Precision	Recall	F1-measure	Running time(s)
Fast-Champollion	0.9458	0.9408	0.9433	48.0
Fast-Champollion-Recal	0.9470	0.9373	0.9421	45.4
Champollion	0.9450	0.9385	0.9417	173.5
Length-based	0.8154	0.7878	0.8013	11.3

Table 3: Performance on texts from the Internet

Aligner	Precision	Recall	F1-measure	Running time(s)
Fast-Champollion	0.9457	0.9418	0.9437	51.5
Fast-Champollion-Recall	0.9456	0.9362	0.9409	50.7
Champollion	0.9464	0.9412	0.9438	2029.0
Length-based	0.8031	0.7729	0.7877	23.8

Table 4: Performance on long text

pus into a single long "article". Its length is comparable to that of the novel of Wuthering Heights. Table 4 shows the evaluation results on this long article. Fast-Champollion is about 39.4 times as fast as Champollion with slightly lower Precision, Recall and F1-measure, and is just about 1.2 times slower than the length-based algorithm, which has much lower Precision, Recall and F1-measure. So Fast-Champollion is also applicable for long text, and has a significantly higher speed.

4.4 Evaluation of the Length-based Splitting Module

The reason for Fast-Champollion can achieve relatively high speed is that the length-based splitting module can split the bilingual input texts into many small fragments reliably. We investigate the fragments produced by the length-based splitting module when aligning the long article used in Section 4.3. The length-based splitting module splits the long article at 1,993 places, and 1,972 segments are correct. The numbers of Chinese and English segments with no more than 30 Chinese and English sentences are shown in Figure 5. As there are only 27 and 29 segments with more than 30 sentences for Chinese and English respectively, we omit them in the figure. We can conclude that although the length-based splitting module is simple, it is efficient and reliable.

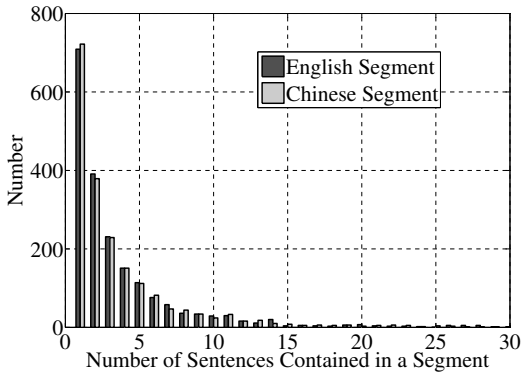

Figure 5: Numbers of Chinese/English segments with no more than 30 Chinese/English sentences

5 Conclusion and Future Work

In this paper we propose a new sentence alignment algorithm Fast-Champollion. It reduces the running time by first splitting the bilingual input texts into small aligned fragments and then further aligning them one by one. The evaluations show that Fast-Champollion is fast, robust and effective enough for practical use, especially for aligning large amount of bilingual texts or long bilingual texts.

Fast-Champollion needs a dictionary for aligning sentences, and shares the same problem of Champollion aligner as indicated in (Ma, 2006), that is the precision and recall will drop as the size of the dictionary decreases. So how to build bilingual dictionaries automatically is an important task for improving the performance of Fast-Champollion in practice, and is a critical problem for applying Fast-Champollion on language pairs without a ready to use dictionary.

Abstract

Tibetan word segmentation is essential for Tibetan information processing. People mainly use the basic machine matching method which is based on dictionary to segment Tibetan words at present, because there is no segmented Tibetan corpus which can be used for training in Tibetan word segmentation. But the method based on dictionary is not fit to Tibetan number identification. This paper studies the characteristics of Tibetan numbers, and then, proposes a method to identify Tibetan numbers based on classification of number components. The method first tags every number component according to the class it belongs to while segmenting, and then updates the tag series according to some predefined rules. At last adjacent number components are combined to form a Tibetan number if they meet a certain requirement. In the testing result from 7938K Tibetan corpus, the identification accuracy is 99.21%.

1 Introduction

As a phonetic writing script, Tibetan syllables are separated with syllable dots. But like Chinese, there is no separator between Tibetan words. Tibetan word segmentation is essential for Tibetan information processing. In recent years, many experts did much work on Tibetan word segmentation. CHEN Yuzhong (2003) proposed a method based on case auxiliary words and continuous features to segment Tibetan text. Based on this method, using reinstallation rules to identify Abbreviated Words, CAI Zhijie (2009) designed and implemented the Banzhida Tibetan word segmentation system. QI (2006) proposed a three level method to segment Tibetan text. Dolha (2007), Zhaxijia (2007), CAI Rangjia (2009) and TASHI (2009) researched the word categories and annotation scheme for Tibetan corpus and the parts-of-speech and tagging set standards. At present, there is no corpus for Tibetan word segmentation. However, models which are used in Chinese word segmentation, such as HMM, ME, CRF, have to be trained with segmented corpus. As a result, we can't use them in Tibetan word segmentation. So people mainly use machine matching method based on dictionary in Tibetan word segmentation. But machine matching can not be used to identify Tibetan numbers because we can not include all numbers in the dictionary.

In Tibetan text, numbers have 3 different representations. The first is Arabic numbers, such as "2010". The second is Tibetan alphabet numbers composed with Tibetan digital characters: ཀ(0), ཁ(1), ག(2), ང(3), ཅ(4), ཆ(5), ཇ(6), ཉ(7),

Coling 2008: Poster Volume, pages 719–724,
Beijing, August 2010

ཉ(8), ཊ(9), such as “༢༠༡༠”(2010). The third is Tibetan syllable numbers(“Tibetan numbers” in short) which are composed with Tibetan syllables, such as བཅོ་ལྔ(fifteen).The former two classes of numbers can be identified by combining adjacent number characters. However, this method is not fit to the third class, because some Tibetan syllables are used not only in numbers but also in other common words.

According to papers written by Dolha (2007), Zhaxijia (2007), CAI Rangjia (2009) and TASHI (2009), Tibetan numbers should be taken as single words in Tibetan word segmentation, however, we haven’t found any paper on the issue of the identification of Tibetan numbers in Tibetan word segmentation.

In this paper, we propose a method which is based on classification of number components to identify the third class of numbers.

2 Composition of Tibetan numbers

In Tibetan, we use the following syllables (words) to express the meanings of number one to nine: གཅིག གཉིས། གསུམ། བཞི། ལྔ། དྲུག བདུན། བརྒྱད། དགུ།, and the following different syllables for ten, hundred, thousand, ten thousand, million, ten million and so on: བཅུ། བརྒྱ། སྟོང་། ཁྲི། འབུམ། ས་ཡ། ཨ་བ། དུང་ཕྱུར།…..Generally, Tibetan syllable numbers are composed by these syllables, but some syllables have variants, and sometimes we have to use different conjunctions according to the context. The composition of Tibetan syllable numbers has the following rules.

1. Number 1-10 are expressed with the syllables mentioned above, but sometimes variants are used: ཆིག(1),ཉིས།(2),སུམ།(3).
2. Number “tens” (20, 30, 40 …) have the form of “(2-9)+བཅུ”. but in “20”, “30”, variants of “2” and “3” are used, while in “60”, “70”, “80”, variant of “ten”(ཅུ།) is used.
3. Number 11-19 have the form of “བཅུ(10)+(1-9)”, but in “13” and “15” variant of “10”(བཅོ།) is used.
4. Number 21-99, except “tens”, have the form of “(tens)+conjunction+(1-9)”. Different conjunctions are used according to different “tens”: རྩ། སོ། ཞེ། ང་། རེ། དོན། ཙྭ། ཙོ. Sometimes, this form is abbreviated to “conjunction+(1-9)”.
5. In number which is larger then 100, conjunction (དང་) may be used, just like “and” in the reading of English number “115”. Sometimes, (མེད་) is used to express the meaning of vacancy. For example, number “507” is “ལྔ་བརྒྱ་བཅུ་མེད་བདུན”: ལྔ་(five) བརྒྱ་(hundred)བཅུ་ (ten)མེད་(has no)བདུན (seven).
6. Composition of numbers larger than 1000 can be deduced.
7. Ordinal numeral has the form of “(cardinal numeral)+(པor་པོ)”.
8. Multiples have the form of “ལྷག+ (cardinal numeral)”.
9. Fractions have the form of “(cardinal numeral) +ཆ+ (cardinal numeral)”.
10. Decimals have the form of “(cardinal numeral) +དོ+(གངས་རྫོགorཚེག)+ (cardinal numeral)”. “གངས་རྫོད” or “ཚེག” means the decimal point.
11. Approximate numbers have the form of “(cardinal numeral)+(suffix)”. Suffix can be one of (ཙོ། ཙམ། ཡས་མས། ལྷག་ཙམ། གངས་ཀ་ཤས། ཐུག་ཀ་ཤས།…) according to the meaning to be expressed.
12. Some Tibetan numbers don’t obey the above rules. They have no form of number, but have meanings of number, such as “དང་པོ” (first).

3 Tibetan number identification

In this paper, we call all syllables mentioned in the previous section “number components” in general. For some of these number components, we can take it as a part of number when we meet one of them. For others, we can’t, because they can be used to express non-number meanings. So we have to check whether it is a part of a number according to the context when we meet a number component.

Tibetan number identification is a part of Tibetan word segmentation. In Tibetan word seg-

mentation system, Tibetan text is segmented into words by maximum matching method. In this procedure, every Tibetan number is segmented into number components. Then, identification module combines adjacent number components when they meet a certain predefined rules.

In this section, we first briefly introduce the whole procedure of Tibetan word segmentation, then the classification of number components and the tagging method to identify Tibetan number.

3.1 Flow of Tibetan word segmentation

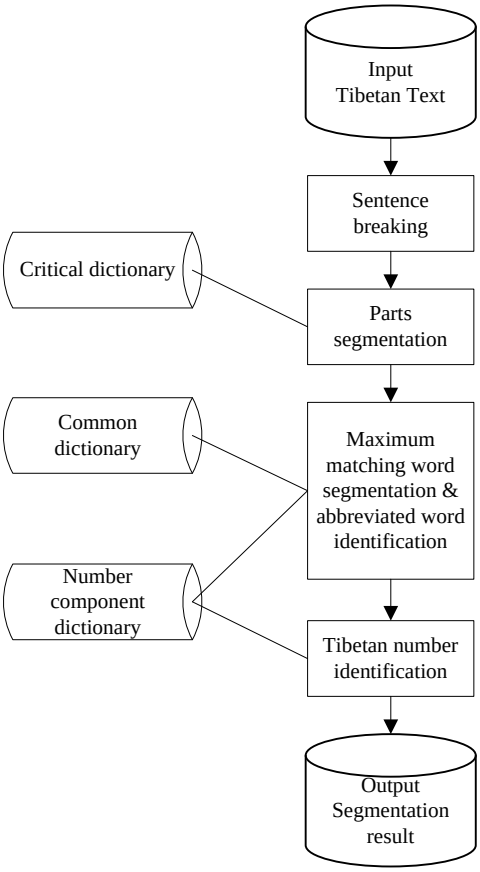

Figure 1. The flow chart of Tibetan word segmentation

As shown in Figure 1, for the input Tibetan text, we first segment it into sentences. Then we segment each sentence into parts with case-auxiliary words. In this procedure, a critical dictionary is used because case-auxiliary words can be a part of some Tibetan words (critical words). When we meet a critical word in Tibetan text, we should not segment it into shorter words. Next, we segment each part into words and identify the abbreviated word (CAI Zhijie, 2009) by maximum matching method with a common dictionary and the number components dictionary. At last, we identify Tibetan numbers and output word segmentation result.

In the procedure of segmenting a part into words, a Tibetan number is segmented into words; we must ensure every one of them is a number component. To do this, both common dictionary and number components dictionary are used. As we use maximum matching method, all Tibetan number words in the common dictionary should be obsolete.

Identification module tags each number component with a tag according to the class which it belongs to, then updates the tags and combines adjacent number components when they meet a certain predefined rules.

3.2 Classification of number components

We classify number components into the following five classes according to their functions and ambiguity.

Basic number: these number components are the basis of Tibetan numbers. Every one of them can be an independent number. If we meet it in context, we should take it as a part of a Tibetan number. Including: Tibetan number 1-9(གཅིག་གཉིས། གསུམ། བཞི། ལྔ། དྲུག་བདུན། བརྒྱད། དགུ།); ten, hundred, thousand, ten thousand, million, ten million and so on(བཅུ། བརྒྱ། སྟོང་། ཁྲི། འབུམ། སར་ཡ། ཉི་ག་དུད་ཕྱུར།…); and their variants.

Number prefix: when it is used as a part of Tibetan number, the next word must be a basic number, while the previous word may be or may not be a number component. Including: abbreviations of "(tens)+conjunction" (སོ། ཞེ། དཾ་རེ། དོན། ཐ། གོ); variants of 1, 2, 3(ཆིག ཉིས། སུམ); decimal point(གདངས་རྫུད་and ཚེག).

Number linker: when it is used as a part of Tibetan number, both the previous word and the next word must be number components. These include (དང་ ཚ མེད་). Conjunctions (སོ། ཞེ། དཾ་རེ། དོན། ཐ། གོ) belong to number prefix class, so we don't include them in this class. But Conjunction (ཙོ) doesn't belong to number prefix class, we include it in this class.

Number suffix: these number components are used to express the meaning of "total number", "approximate number", and "ordinal number" and so on. They follow basic number and should be taken as a part of Tibetan number word. Including: རྒྱ། ཙམ། ཡས་མས། ལྷག་ཙམ། གྲངས་ཀ་ཤས། ཐུག་ཀ་ཤས།…

Independent number: these number components have no form of number, but have meanings of number, such as "དང་པོ" (first).

The difference between "basic number" and "Independent number" is: a basic number can be a Tibetan number itself or a part of a Tibetan number, while an independent number is a Tibetan number itself, but it can't be a part of a Tibetan number.

3.3 Number identification

As shown in Figure 2, identification module tags each number component with a tag according to the class which it belongs to, then updates the tags and combines adjacent number components when they meet a certain predefined rules.

Figure 2. The flow of number identification

Class	Tag
Basic number	N **(**Number**)**
Number prefix	P **(**Prefix**)**
Number linker	L **(**Linker**)**
Number suffix	S**(**Suffix**)**
Independent number	I**(**Independent**)**
Other(non-number)	O **(**Other**)**

Table 1. Classes and their tags

We assign every class with a tag, as shown in Table 1. The tagging procedure screens every segmented part of Tibetan sentences, and tags every word with a tag according to the class which the word belongs to. If the word is not a number component, we tag it with "O" (Other).

As some number components can be used to express non-number meanings, (the cases exist in both number prefix class and number linker class), we have to check whether it is a part of a number according to the context. For number prefix, we take it as a part of number only if it is followed by a basic number, while for number linker, only if it follows a basic number and it is followed by another basic number. We define two rules to do this work.

Rule 1: update tag series "PN" to "NN".
Rule 2: update tag series "NLN" to "NNN".

The tags updating algorithm applies the rules to the current word series until no tag is updated. After tags updating, the tag of a number prefix ("P") is updated to "N" when it is a part of Tibetan number in the context, but the tag will still be "P" when it is not a part of Tibetan number. It is the same for number linkers.

Combination algorithm combines adjacent number components to form a Tibetan number word. It mainly combines continuous number components with tags "NN…N", and the following word is combined too if it has a tag "S". The tag of the number is updated to "N". All words with tag "N" or "I" are taken as Tibetan numbers after combination.

Then the segmentation result is output.

For example, for the following Tibetan sentence:

ལས་འཛོལ་མང་པོ་ཞིག་ནི་བརྒྱ་ཚ་གཅིག་གམ་ཐ་ན་བརྒྱ་ཚ་གྲངས་རྒྱུད་ལྷའི་ནང་ཁོངས་ཀྱི་ལྷ་ལག་གཅིག་ལ་སྟོན་མོར་ནས་བྱུང་འདུག (A considerable parts of accidents were due to the faults of 1% or even 0.5% of components.)

After parts segmentation and maximum matching word segmentation, it is segmented to:

ལས་འཛོལ/ མང་པོ/ ཞིག/ ནི/ བརྒྱ/ ཚ/ གཅིག/ གམ/ ཐ་ན/ བརྒྱ/ ཚ/ གྲངས་རྒྱུད/ ལྷ/ འི/ ནང་ཁོངས/ ཀྱི/ ལྷ་ལག་གཅིག/ ལ/ སྟོན་མོར/ ནས/ བྱུང/ འདུག/

After tagging:

ལས་འཛོལ/(O) མང་པོ/(O) ཞིག/(O) ནི/(O) བརྒྱ/(N) ཚ/(L) གཅིག/(N) གམ/(O) ཐ་ན/(O) བརྒྱ/(N) ཚ/(L) གྲངས་རྒྱུད/(P) ལྷ/(N) འི/(O) ནང་ཁོངས/(O) ཀྱི/(O) ལྷ་ལག་གཅིག/(O) ལ/(O) སྟོན་མོར/(O) ནས/(O) བྱུང/(O) འདུག/(O)

The corresponding tag series is:

OOOONLNOONLPNOOOOOOOOO

After the first run of tags updating, the tag series is changed to:

OOOONNNOONLNNOOOOOOOOO

After the second run of tags updating, the tag series is changed to:

OOOONNNOONNNNOOOOOOOOO

In the third run of tags updating, no tag is updated. Then, combination algorithm combines adjacent number components corresponding to the continuous "N" tags. The result is:

ལས་འཛིན་/ མང་པོ་/ ཞིག་/ ནི་/ བརྒྱ་ཚ་གཅིག་/ གམ་/ ཐ་ན་/ བརྒྱ་ཆག་ལས་ལྷུང་ལྷ་/ འི་/ ནང་ཁོངས་/ ཀྱི་/ ལྷུ་ལག་གཅིག་/ ལ་/ སྐྱོན་མོར་/ ནས་/ ཟྱང་/ འདུག/

The corresponding tag series is:

OOOONOONOOOOOOOOO

It has two "N" tags, which means two Tibetan numbers are identified.

4 Experiment

Corpus	Byte	Sentence	BNS	TNS
Corpus 1	1624K	13957	2590	1667
Corpus 2	1334K	11441	1748	1076
Corpus 3	1408K	11923	1751	969
Corpus 4	1015K	8453	1212	672
Corpus 5	1311K	10445	1613	897
Corpus 6	1246K	10009	1474	880
Total	7938K	66228	10388	6161

Table 2. Information about the 6 corpuses

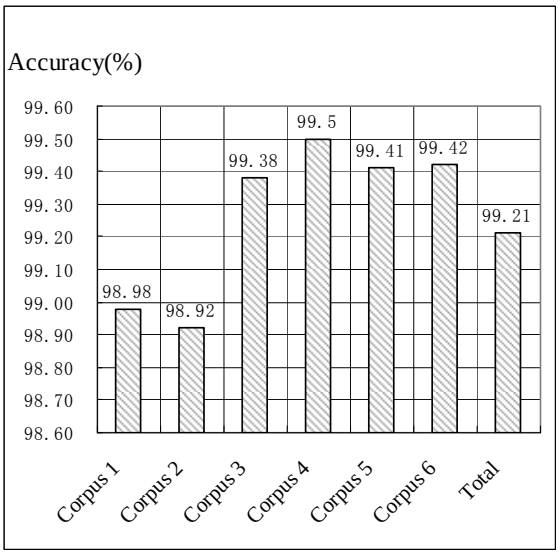

Figure 3. Accuracy of Tibetan number identification on 6 corpuses

As there is no corpus for Tibetan word segmentation, we have to make experiment on original Tibetan texts. We make use of several books which are written in Tibetan, and collect many web pages from several Tibetan web sites. After preprocessing, we get six corpuses. The basic information about the corpuses is shown in Table 2. Note that, in Table 2, the column "BNS" includes all sentences which have in it at least one number component belonging to basic number class, while the column "TNS" includes all sentences which have at least one Tibetan number in it. The count of the former is significantly larger than the count of the later because some basic numbers are used in idioms and proverbs which should be segmented as single words, thus we don't take them as number components under this circumstance. Figure 3 shows the results of our experiment. As we can see, the total identification accuracy is 99.21%. As we have included all basic numbers in our method, theoretically the recall is 100%.

After analyzing the results, we find that wrongly identified words can be divided into two classes. One is that there is a conjunction (དང) between two Tibetan numbers, but is taken as one Tibetan number, such as "བཅུ་དང་ཉི་ཤུ།" (ten and twenty), "ཁྲི་གཅིག་དང་ཁྲི་གཉིས" (ten thousand and twenty thousand). The other is that some Tibetan numbers has other non-number meanings in the context, but our algorithm takes them as numbers. For instance, "ཞེ་གཅིག" means 41 when it is used as a number, but it has another meaning of "similarly"; "དོན་ལྔ" means 75 when it is used as a number, but it has the meaning of "the five internal organs".

5 Conclusion

Tibetan syllables are separated with syllable dots. But like Chinese, there is no separator between Tibetan words. Tibetan word segmentation is essential for Tibetan information processing. People mainly use machine matching in Tibetan word segmentation base on dictionary. But machine matching can not be used to identify Tibetan numbers because we can not include all numbers in our dictionary. This paper proposes a method to tag number components according to the classes they belong to, and then apply predefined rules to update tag series, and next combine adjacent number components to

form a Tibetan number. In the testing result from 7938K Tibetan corpus, the identification accuracy is 99.21%, which means that this method is feasible to be applied to Tibetan word segmentation.

Abstract

We propose a novel MLN-based method that collectively conducts SRL on groups of news sentences. Our method is built upon a baseline SRL, which uses no parsers and leverages redundancy. We evaluate our method on a manually labeled news corpus and demonstrate that news redundancy significantly improves the performance of the baseline, e.g., it improves the F-score from 64.13% to 67.66%.

1 Introduction

Semantic Role Labeling (SRL, Màrquez, 2009) is generally understood as the task of identifying the arguments of a given predicate and assigning them semantic labels describing the roles they play. For example, given a sentence *The luxury auto maker sold 1,214 cars.*, the goal is to identify the arguments of *sold* and produce the following output: [A0 *The luxury auto maker*] [V *sold*] [A1 *1,214 cars*]. Here *A0* represents the *seller*, and *A1* represents the things *sold* (CoNLL 2008 shared task, Surdeanu et al., 2008).

Gildea and Jurafsky (2002) first tackled SRL as an independent task, which is divided into several sub-tasks such as argument identification, argument classification, global inference, etc. Some researchers (Xue and Palmer, 2004; Koomen et al., 2005; Cohn and Blunsom, 2005; Punyakanok et al., 2008; Toutanova et al., 2005; Toutanova et al., 2008) used a pipelined approach to attack the task. Some others resolved the sub-tasks simultaneously. For example, some work (Musillo and Merlo, 2006; Merlo and Musillo, 2008) integrated syntactic parsing and SRL into a single model, and another (Riedel and Meza-Ruiz, 2008; Meza-Ruiz and Riedel, 2009) jointly handled all sub-tasks using Markov Logic Networks (MLN, Richardson and Domingos, 2005).

All the above methods conduct sentence level SRL, and rely on parsers. Parsers have showed great effects on SRL performance. For example, Xue and Palmer (2004) reported that SRL performance dropped more than 10% when they used syntactic features from an automatic parser instead of the gold standard parsing trees. Even worse, parsers are not robust and cannot always analyze any input, due to the fact that some inputs are not in the language described by the parser's formal grammar, or adequately represented within the parser's training data.

Coling 2008: Poster Volume, pages 725–729,
Beijing, August 2010

We propose a novel MLN-based method that collectively conducts SRL on groups of news sentences to leverage the content redundancy in news. To isolate the negative effect of noise from parsers and thus focus on the study of the contribution of redundancy to SRL, we use no parsers in our approach. We built a baseline SRL, which depends on no parsers, and use the MLN framework to exploit redundancy. Our intuition is that SRL on one sentence can help that on other differently phrased sentences with similar meaning. For example, consider the following sentence from a news article:

> *A suicide **bomber** blew himself up Sunday in market in Pakistan's **northwest** crowded with shoppers ahead of a Muslim holiday, **killing** 12 people, including a mayor who once supported but had turned against the Taliban, officials said.*

The state-of-art MLN-based system (Meza-Ruiz and Riedel, 2009), hereafter referred to as MLNBS for brevity, incorrectly labels *northwest* instead of *bomber* as *A0* of *killing*. Now consider another sentence from another news article:

> *Police in northwestern Pakistan say that a suicide **bomber** has **killed** at least 13 people and wounded dozens of others.*

Here MLNBS correctly identify *bomber* as A0 of *killing*. When more sentences are observed where *bomber* as *A0* of *killing* is correctly identified, we will be more confident that *bomber* should be labeled as *A0* of *killing*, and that *northwest* should not be the *A0* of *killing* according to the constraint that one predicate has at most one A0.

We manually construct a news corpus to evaluate our method. In the corpus, semantic role information is annotated and sentences with similar meanings are grouped together. Experimental results show that news redundancy can significantly improve the performance of the baseline system.

Our contributions can be summarized as follows:

1. We present a novel method that conducts SRL on a set of sentences collectively, instead of on a single sentence, by extending MLNBS to leverage redundancy.
2. We show redundancy can significantly improve the performance of the baseline system, indicating a promising research direction towards open SRL.

In the next section, we introduce news sentence extraction and clustering. In Section 3, we describe our collective inference method. In Section 4, we show our experimental results. Finally, in Section 5 we conclude our paper with a discussion of future work.

2 Extraction and Clustering of News Sentences

To construct a corpus to evaluate our method, we extract sentences from clustered news articles returned by news search engines such as Bing and Google, and divide them into groups so that sentences in a group have similar meaning.

News articles in the same cluster are supposed to report the same event. Thus we first group sentences according to the news cluster they come from. Then we split sentences in the same cluster into several groups according to the similarity of meaning. We assume that two sentences are more similar in meaning if they share more synonymous proper nouns and verbs. The synonyms of verbs, like *plod* and *trudge*, are mainly extracted from the Microsoft Encarta Dictionary[1], and the proper nouns thesaurus, containing synonyms such as *U.S.* and *the United States*, is manually compiled.

As examples, below are two sentence groups which are extracted from a news cluster describing Hurricane Ida.

Group 1:

- *Hurricane Ida, the first Atlantic hurricane to target the U.S. this year, plodded yesterday toward the Gulf Coast…*
- *Hurricane Ida trudged toward the Gulf Coast…*
- …

Group 2:

- *It could make landfall as early as Tuesday morning, although it was forecast to weaken further.*

[1] http://uk.encarta.msn.com/encnet/features/dictionary/dictionaryhome.aspx

- *Authorities said Ida could make landfall as early as Tuesday morning, although it was forecast to weaken by then.*
- *…*

3 Collective Inference Based on MLN

Our method includes two core components: a baseline system that conducts SRL on every sentence; and a collective inference system that accepts as input a group of sentences with preliminary SRL information provided by the baseline.

We build the baseline by removing formulas involving syntactic parsing information from MLNBS (while keeping other rules) and retraining the system using the tool and scripts provided by Riedel and Meza-Ruiz (2008) on the manually annotated news corpus described in Section 4.

A collective inference system is constructed to leverage redundancy in the SRL information from the baseline.

We first redefine the predicate *role* and treat it as observed:

predicate ***role****: Int x Int x Int x Role;*

role has four parameters: the first one stands for the number of sentence in the input, which is necessary to distinguish the sentences in a group; the other three are taken from the arguments of the *role* predicate defined by Riedel and Meza-Ruiz (2008), which denote the positions of the predicate and the argument in the sentence and the role of the argument, respectively. If the predication holds, it returns 1, otherwise 0.

A hidden predicate *final_role* is defined to present the final output, which has the same parameters as the predicate *role*:

predicate ***final_role****: Int x Int x Int x Role;*

We introduce the following formula, which directly passes the semantic role from the baseline to the final output:

$$role(s, p, a, +r) \Rightarrow final\_role(s, p, a, +r) \quad (1)$$

Here *s* is the sentence number in a group; *p* and *a* denote the positions of the predicate and argument in *s,* respectively*; r* stands for the role of the argument; the "+" before the variable *r* indicates that different *r* has different weight.

Then we define another formula for collective inference:

$$s1 \neq s2 \wedge lemma(s1,p1,p\_lemma) \wedge lemma(s2,p2,p\_lemma) \wedge lemma(s1,a1,a\_lemma) \wedge lemma(s2,a2,a\_lemma) \wedge role(s2,p2,a2,+r) \Rightarrow final\_role(s1,p1,a1,+r) \quad (2)$$

Here *p_lemma(a_lemma)* stands for the lemma of the predicate(argument), which is obtained from the lemma dictionary. This dictionary is extracted from the dataset of CoNLL 2008 shared task and is normalized using synonym dictionary described in Section 2; *lemma* is an observed predicate that states whether or not the word has the lemma.

Formula 2 encodes our basic ideas about collective SRL: given several sentences expressing similar meaning, if one sentence has a predicate *p* with an argument *a* of role *r*, the other sentences would be likely to have a predicate *p'* with an argument *a'* of role *r*, where *p'* and *a'* are the same or synonymous with *p* and *a,* respectively, as illustrated by the example in Section 1.

Besides, we also apply structural constraints (Riedel and Meza-Ruiz, 2008) to *final_role*.

To learn parameters of the collective inference system, we use *thebeast* (Riedel and Meza-Ruiz, 2008), which is an open Markov Logic Engine, and train it on manually annotated news corpus described in Section 4.

4 Experiments

To train and test the collective inference system, we extract 1000 sentences from news clusters, and group them into 200 clusters using the method described in Section 2. For every sentence, POS tagging is conducted with the OpenNLP toolkit (Jason Baldridge et al., 2009), lemma of each word is obtained through the normalized lemma dictionary described in Section 3, and SRL is manually labeled. To reduce human labeling efforts, we retrain our baseline on the WSJ corpus of CoNLL 2008 shared task and run it on our news corpus, and then edit the SRL outputs by hand.

We implement the collective inference system with the *thebeast* toolkit. Precision, recall, and F-score are used as evaluation metrics. In both training and evaluation, we follow the CoNLL 2008 shared task and regard only heads of phrases as arguments.

Table 1 shows the averaged 10-fold cross validation results of our systems and the baseline, where the third and second line report the results of using and not using Formula 1 in our collective inference system, respectively.

Systems	Pre. (%)	Rec. (%)	F-score (%)
Baseline	**69.87**	59.26	64.13
CI-1	62.99	**72.96**	67.61
CI	67.01	68.33	**67.66**

Table 1. Averaged 10-fold cross validation results (Pre.: precision; Rec.: recall).

Experimental results show that the two collective inference engines (CI-1 and CI) perform significantly better than the baseline in terms of the recall and F-score, though a little worse in the precision. We observe that predicate-argument relationships in sentences with complex syntax are usually not recognized by the baseline, but some of them are correctly identified by the collective inference systems. This, we guess, explains in large part the difference in performance. For instance, consider the following sentences in a group, where *order* and *tell* are synonyms:

- Colombia said on Sunday it will appeal to the U.N. Security Council and the OAS after Hugo *Chavez*, the fiery leftist president of neighboring Venezuela, *ordered* his army to prepare for war in order to assure peace.
- President Hugo *Chavez ordered* Venezuela's military to prepare for a possible armed conflict with Colombia, saying yesterday that his country's soldiers should be ready if the U.S. tries to provoke a war between the South American neighbors.
- Venezuelan President Hugo *Chavez told* his military and civil militias to prepare for a possible war with Colombia as tensions mount over an agreement giving U.S. troops access to Colombian military bases.

The baseline cannot label (*ordered, Chavez, A0*) for the first sentence, partially owing to the syntactic complexity of the sentence, but can identify the relationship for the second and third sentence. In contrast, the collective inference systems can identify *Chavez* in the first sentence as A0 of *order* because of its occurrence in the other sentences of the same group.

As Table 1 shows, the CI system achieves the highest F-score (67.66%), and a higher precision than the CI-1 system, indicating the effectiveness of Formula 1. Consider the above three sentences. CI-1 mislabels (*ordered, Venezuela, A1*) for the first sentence because the baseline labels it for the second sentence. In contrast, CI does not label it for the first sentence because the baseline does not and (*ordered, Venezuela, A1*) rarely occurs in the outputs of the baseline for this sentence group.

We also find cases where the collective inference systems do not but should help. For example, consider the following group of sentences:

- A Brazilian *university* expelled a woman who was heckled by hundreds of fellow students when she wore a short, pink dress to class, *taking* out newspaper ads Sunday to publicly accuse her of immorality.
- The *university* also *published* newspaper ads accusing the student, Geisy Arruda, of immorality.

The baseline has identified *(published, university, A0)* for the second sentence. But neither the baseline nor our method labels *(taking, university, A0)* for the first one. This happens because *publish* is not considered as a synonym of *take*, and thus *(published, university, A0)* in the second provides no evidence for *(taking, university, A0)* in the first. We plan to develop a context based synonym detection component to address this issue in the future.

5 Conclusions and Future Work

We present a novel MLN-based method that collectively conducts SRL on groups of sentences. To help build training and test corpora, we design a method to collect news sentences and to divide them into groups so that sentences of similar meaning fall into the same cluster. Experimental results on a manually labeled news corpus show that collective inference, which leverages redundancy, can effectively improve the performance of the baseline.

In the future, we plan to evaluate our method on larger news corpora, and to extend our method to other genres of corpora, such as tweets.

Abstract

While ITG has many desirable properties for word alignment, it still suffers from the limitation of one-to-one matching. While existing approaches relax this limitation using phrase pairs, we propose a ITG formalism, which even handles units of non-contiguous words, using both simple and hierarchical phrase pairs. We also propose a parameter estimation method, which combines the merits of both supervised and unsupervised learning, for the ITG formalism. The ITG alignment system achieves significant improvement in both word alignment quality and translation performance.

1 Introduction

Inversion transduction grammar (ITG) (Wu, 1997) is an adaptation of CFG to bilingual parsing. It does synchronous parsing of two languages with phrasal and word-level alignment as by-product. One of the merits of ITG is that it is less biased towards short-distance reordering compared with other word alignment models such as HMM. For this reason ITG has gained more and more attention recently in the word alignment community (Zhang et al., 2005; Cherry et al., 2006; Haghighi et al., 2009) .

The basic ITG formalism suffers from the major drawback of one-to-one matching. This limitation renders ITG unable to produce certain alignment patterns (such as many-to-many alignment for idiomatic expression). For this reason those recent approaches to ITG alignment introduce the notion of *phrase* (or *block*), defined as sequence of contiguous words, into the ITG formalism (Cherry and Lin, 2007; Haghighi et al., 2009; Zhang et al., 2008). However, there are still alignment patterns which cannot be captured by phrases. A simple example is connective in Chinese/English. In English, two clauses are connected by merely one connective (like "*although*", "*because*") but in Chinese we need two connectives (e.g. There is a sentence pattern "虽然 X_1 但是 $X_2 \rightarrow X_2$ although X_1", where X_1 and X_2 are variables for clauses). The English connective should then be aligned to two non-contiguous Chinese connectives, and such alignment pattern is not available in either word-level or phrase-level ITG. As hierarchical phrase-based SMT (Chiang, 2007) is proved to be superior to simple phrase-based SMT, it is natural to ask, why don't we further incorporate hierarchical phrase pairs (henceforth h-phrase pairs) into ITG? In this paper we propose a ITG formalism and parsing algorithm using h-phrase pairs.

The ITG model involves much more parameters. On the one hand, each phrase/h-phrase pair has its own probability or score. It is not feasible to learn these parameters through discriminative/supervised learning since the repertoire of phrase pairs is much larger than the size of human-annotated alignment set. On the other hand, there are also a few useful features which cannot be estimated merely by unsupervised learning like EM. Inspired by Fraser et al. (2006), we propose a semi-supervised learning algorithm which combines the merits of both discrimina-

[*] This work has been done while the first author was visiting Microsoft Research Asia.

Coling 2008: Poster Volume, pages 730–738,
Beijing, August 2010

tive training (error minimization) and approximate EM (estimation of numerous parameters).

The ITG model augmented with the learning algorithm is shown by experiment results to improve significantly both alignment quality and translation performance.

In the following, we will explain, step-by-step, how to incorporate hierarchical phrase pairs into the ITG formalism (Section 2) and in ITG parsing (Section 3). The semi-supervised training method is elaborated in Section 4. The merits of the complete system are illustrated with the experiments described in Section 5.

2 ITG Formalisms

2.1 W-ITG : ITG with only word pairs

The simplest formulation of ITG contains three types of rules: terminal unary rules $X \rightarrow e/f$, where e and f represent words (possibly a null word, ε) in the English and foreign language respectively, and the binary rules $X \rightarrow [X, X]$ and $X \rightarrow \langle X, X \rangle$, which refer to that the component English and foreign phrases are combined in the same and inverted order respectively. From the viewpoint of word alignment, the terminal unary rules provide the links of word pairs, whereas the binary rules represent the reordering factor. Note also that the alignment between two phrase pairs is always composed of the alignment between word pairs (c.f. Figure 1(a) and (b)). The Figure 1 also shows ITG can handle the cases where two languages share the same (Figure 1(a)) and different (Figure 1(b)) word order

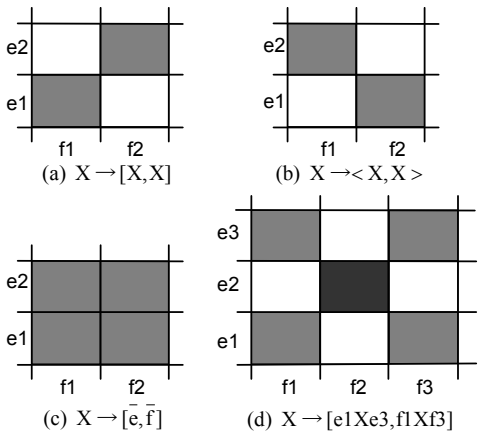

Figure 1. Four ways in which ITG can analyze a multi-word span pair.

Such a formulation has two drawbacks. First of all, the simple ITG leads to redundancy if word alignment is the sole purpose of applying ITG. For instance, there are two parses for three consecutive word pairs, viz. [a/a' [b/b' c/c']] and [[a/a' b/b'] c/c']. The problem of redundancy is fixed by adopting ITG normal form. The ITG normal form grammar as used in this paper is described in Appendix A.

The second drawback is that ITG fails to produce certain alignment patterns. Its constraint that a word is not allowed to align to more than one word is indeed a strong limitation as no idiom or multi-word expression is allowed to align to a single word on the other side. Moreover, its reordering constraint makes it unable to produce the 'inside-out' alignment pattern (c.f. Figure 2).

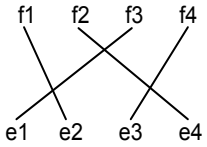

Figure 2. An example of inside-out alignment.

2.2 P-ITG : ITG with Phrase Pairs

A single word in one language is not always on a par with a single word in another language. For example, the Chinese word "白宫" is equivalent to two words in English ("white house"). This problem is even worsened by segmentation errors (i.e. splitting a single word into more than one word). The one-to-one constraint in W-ITG is a serious limitation as in reality there are always segmentation or tokenization errors as well as idiomatic expressions. Therefore, researches like Cherry and Lin (2007), Haghighi et al. (2009) and Zhang et al. (2009) tackle this problem by enriching ITG, in addition to word pairs, with pairs of phrases (or blocks). That is, a sequence of source language word can be aligned, as a whole, to one (or a sequence of more than one) target language word.

These methods can be subsumed under the term phrase-based ITG (P-ITG), which enhances W-ITG by altering the definition of a terminal production to include phrases: $X \rightarrow \bar{e}/\bar{f}$ (c.f. Figure 1(c)). $\bar{e}$ stands for English phrase and $\bar{f}$ stands for foreign phrase. As an example, if there is a simple phrase pair <white house, 白

宫>, then it is transformed into the ITG rule $C \rightarrow$"white house"/"白宫".

An important question is how these phrase pairs can be formulated. Marcu and Wong (2002) propose a joint probability model which searches the phrase alignment space, simultaneously learning translations lexicons for words and phrases without consideration of potentially sub-optimal word alignments and heuristic for phrase extraction. This method suffers from computational complexity because it considers all possible phrases and all their possible alignments. Birch et al. (2006) propose a better and more efficient method of constraining the search space which does not contradict a given high confidence word alignment for each sentence. Our P-ITG collects all phrase pairs which are consistent with a word alignment matrix produced by a simpler word alignment model.

2.3 HP-ITG : P-ITG with H-Phrase pairs

P-ITG is the first enhancement of ITG to capture the linguistic phenomenon that more than one word of a language may function as a single unit, so that these words should be aligned to a single unit of another language. But P-ITG can only treat contiguous words as a single unit, and therefore cannot handle the single units of non-contiguous words. Apart from sentence connectives as mentioned in Section 1, there is also the example that the single word "since" in English corresponds to two non-adjacent words "自" and "以来" as shown the following sentence pair:

自 上周末 ***以来***， 我 一直 在 生病 .

I have been ill ***since*** last weekend .

No matter whether it is P-ITG or phrase-based SMT, the very notion of phrase pair is not helpful because this example is simply handled by enumerating all possible contiguous sequences involving the words "自" and "以来", and thus subject to serious data sparseness. The lesson learned from hierarchical phrase-based SMT is that the modeling of non-contiguous word sequence can be very simple if we allow rules involving h-phrase pairs, like:

$C \rightarrow$"since X"/自 X 以来"

where X is a placeholder for substituting a phrase pair like "上周末/last weekend".

H-phrase pairs can also perform reordering, as illustrated by the well-known example from Chiang (2007), $C \rightarrow$ "have X_2 with X_1" / "与 X_1 有 X_2", for the following bilingual sentence fragment:

与 北韩 ***有*** 邦交

have diplomatic relations ***with*** North Korea

The potential of intra-phrase reordering may also help us to capture those alignment patterns like the 'inside-out' pattern.

All these merits of h-phrase pairs motivate a ITG formalism, viz. hierarchical phrase-based ITG (HP-ITG), which employs not only simple phrase pairs but also hierarchical ones. The ITG grammar is enriched with rules of the format: $X \rightarrow \bar{e}/\bar{f}$ where $\bar{e}$ and $\bar{f}$ refer to either a phrase or h-phrase (c.f. Figure 1(d)) pair in English and foreign language respectively[2]. Note that, although the format of HP-ITG is similar to P-ITG, it is much more difficult to handle rules with h-phrase pairs in ITG parsing, which will be elaborated in the next section.

It is again an important question how to formulate the h-phrase pairs. Similar to P-ITG, the h-phrase pairs are obtained by extracting the h-phrase pairs which are consistent with a word alignment matrix produced by some simpler word alignment model.

3 ITG Parsing

Based on the rules, W-ITG word alignment is done in a similar way to chart parsing (Wu, 1997). The base step applies all relevant terminal unary rules to establish the links of word pairs. The word pairs are then combined into span pairs in all possible ways. Larger and larger span pairs are recursively built until the sentence pair is built.

Figure 3(a) shows one possible derivation for a toy example sentence pair with three words in each sentence. Each node (rectangle) represents a pair, marked with certain phrase category, of

[2] Haghighi et al. (2009) impose some rules which look like h-phrase pairs, but their rules are essentially h-phrase pairs with at most one 'X' only, added with the constraint that each 'X' covers only one word.

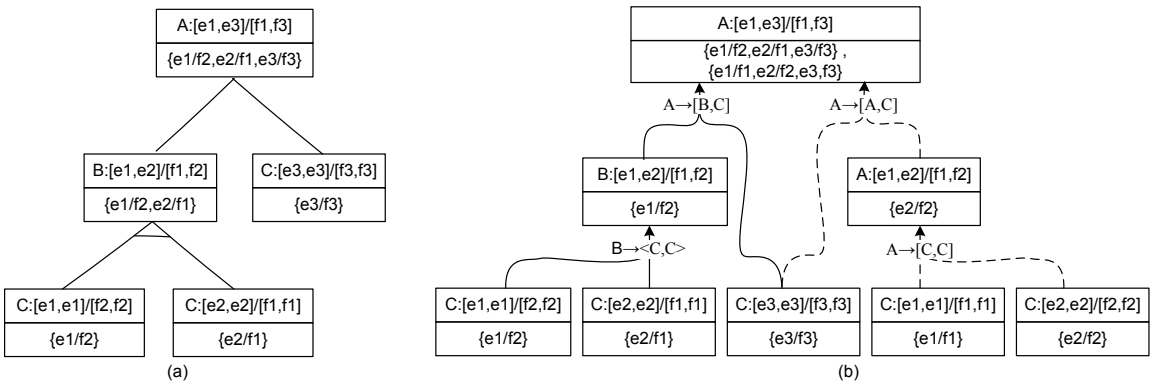

Figure 3. Example ITG parses in graph (a) and hypergraph (b).

foreign span (F-span) and English span (E-span) (the upper half of the rectangle) and the associated alignment hypothesis (the lower half). Each graph like Figure 3(a) shows only one derivation and also only one alignment hypothesis.

The various derivations in ITG parsing can be compactly represented in hypergraph (Klein et al., 2001) like Figure 3(b). Each hypernode (rectangle) comprises both a span pair (upper half) and the list of possible alignment hypotheses (lower half) for that span pair. The hyperedges show how larger span pairs are derived from smaller span pairs. Note that hypernode may have more than one alignment hypothesis, since a hypernode may be derived through more than one hyperedge (e.g. the topmost hypernode in Figure 3(b)). Due to the use of normal form, the hypotheses of a span pair are different from each other.

In the case of P-ITG parsing, each span pair does not only examine all possible combinations of sub-span pairs using binary rules, but also checks if the yield of that span pair is exactly the same as that phrase pair. If so, then this span pair is treated as a valid leaf node in the parse tree. Moreover, in order to enable the parse tree produce a complete word aligned matrix as by-product, the alignment links within the phrase pair (which are recorded when the phrase pair is extracted from a word aligned matrix produced by a simpler model) are taken as an alternative alignment hypothesis of that span pair.

In the case of HP-ITG parsing, an ITG rule like $C \rightarrow$ "have X_2 with X_1"/"与 X_1有 X_2" (originated from the hierarchical rule like $X \rightarrow$ <与 X_1 有 X_2, have X_2 with X_1>), is processed in the following manner: 1) Each span pair checks if it contains the lexical anchors: "have", "with","与" and "有"; 2) each span pair checks if the remaining words in its yield can form two sub-span pairs which fit the reordering constraint among X_1 and X_2 (Note that span pairs of any category in the ITG normal form grammar can substitute for X_1 or X_2). 3) If both conditions hold, then the span pair is assigned an alignment hypothesis which combines the alignment links among the lexical anchors and those links among the sub-span pairs.

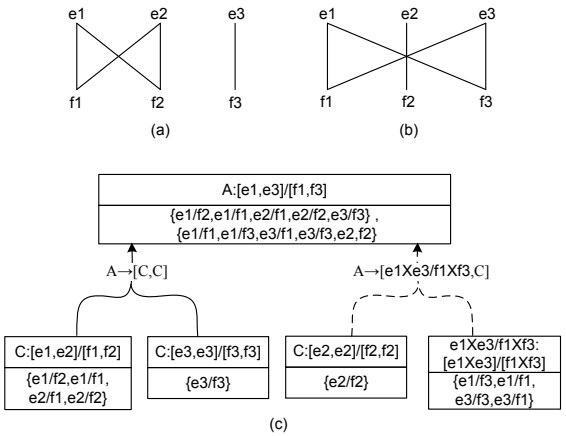

Figure 4. Phrase/h-phrase in hypergraph.

Figure 4(c) shows an example how to use phrase pair and h-phrase pairs in hypergraph. Figure 4(a) and Figure 4(b) refer to alignment matrixes which cannot be generated by W-ITG, because of the one-to-one assumption. Figure 4(c) shows how the span pair [e1,e3]/[f1,f3] can be generated in two ways: one is combining a phrase pair and a word pair directly, and the other way is replacing the *X* in the h-phrase pair with a word pair. Here we only show how h-phrase pairs with one variable be used during the

parsing, and h-phrase pairs with more than one variable can be used in a similar way.

The original (unsupervised) ITG algorithm has complexity of $O(n^6)$. When extended to supervised/discriminative framework, ITG runs even more slowly. Therefore all attempts to ITG alignment come with some pruning method. Zhang and Gildea (2005) show that Model 1 (Brown et al., 1993) probabilities of the word pairs inside and outside a span pair are useful. Tic-tac-toe pruning algorithm (Zhang and Gildea, 2005) uses dynamic programming to compute inside and outside scores for a span pair in $O(n^4)$. Tic-tac-toe pruning method is adopted in this paper.

4 Semi-supervised Training

The original formulation of ITG (W-ITG) is a generative model in which the ITG tree of a sentence pair is produced by a set of rules. The parameters of these rules are trained by EM. Certainly it is difficult to add more non-independent features in such a generative model, and therefore Cherry et al. (2006) and Haghighi et al. (2009) used a discriminative model to incorporate features to achieve state-of-art alignment performance.

4.1 HP-DITG : Discriminative HP-ITG

We also use a discriminative model to assign score to an alignment candidate for a sentence pair $(\bar{f}, \bar{e})$ as probability from a log-linear model (Liu et al., 2005; Moore, 2006):

$$P(a|\bar{e},\bar{f}) = \frac{exp(\sum_i \lambda_i \Psi_i(a,\bar{f},\bar{e}))}{\sum_{a' \in A} exp(\sum_i \lambda_i \Psi_i(a',\bar{f},\bar{e}))} \quad (1)$$

where each $\Psi_i(a,\bar{f},\bar{e})$ is some feature about the alignment matrix, and each λ is the weight of the corresponding feature. The discriminative version of W-ITG, P-ITG, and HP-ITG are then called W-DITG, P-DITG, and HP-DITG respectively.

There are two kinds of parameters in (1) to be learned. The first is the values of the features Ψ. Most features are indeed about the probabilities of the phrase/h-phrase pairs and there are too many of them to be trained from a labeled data set of limited size. Thus the feature values are trained by approximate EM. The other kind of parameters is feature weights λ, which are trained by an error minimization method. The discriminative training of λ and the approximate EM training of Ψ are integrated into a semi-supervised training framework similar to EMD3 (Fraser and Marcu, 2006).

4.2 Discriminative Training of λ

MERT (Och, 2003) is used to train feature weights λ. MERT estimates model parameters with the objective of minimizing certain measure of translation errors (or maximizing certain performance measure of translation quality) for a development corpus. Given an SMT system which produces, with model parameters λ_1^M, the K-best candidate translations $\hat{e}(f_s;\lambda_1^M)$ for a source sentence f_s, and an error measure $E(r_s, e_{s,k})$ of a particular candidate $e_{s,k}$ with respect to the reference translation r_s, the optimal parameter values will be:

$$\hat{\lambda}_1^M = \underset{\lambda_1^M}{argmin}\left\{\sum_{s=1}^{S} E(r_s, \hat{e}(f_s;\lambda_1^M))\right\}$$
$$= \underset{\lambda_1^M}{argmin}\left\{\sum_{s=1}^{S}\sum_{k=1}^{K} E(r_s, e_{s,k})\delta(\hat{e}(f_s;\lambda_1^M), e_{s,k})\right\}$$

MERT for DITG applies the same equation for parameter tuning, with different interpretation of the components in the equation. Instead of a development corpus with reference translations, we have a collection of training samples, each of which is a sentence pair with annotated alignment result. The ITG parser outputs for each sentence pair a K-best list of alignment result $\hat{e}(f_s;\lambda_1^M)$ based on the current parameter values λ_1^M. The MERT module for DITG takes alignment F-score of a sentence pair as the performance measure. Given an input sentence pair and the reference annotated alignment, MERT aims to maximize the F-score of DITG-produced alignment.

4.3 Approximate EM Training of Ψ

Three kinds of features (introduced in section 4.5 and 4.6) are calculated from training corpus given some initial alignment result: conditional probability of word pairs and two types of conditional probabilities for phrase/h-phrase.

[3] For simplicity, we will also call our semi-supervised framework as EMD.

The initial alignment result is far from perfect and so the feature values thus obtained are not optimized. There are too many features to be trained in supervised way. So, unsupervised training like EM is the best solution.

When EM is applied to our model, the E-step corresponds to calculating the probability for all the ITG trees, and the M-step corresponds to re-estimate the feature values. As it is intractable to handle all possible ITG trees, instead we use the Viterbi parse to update the feature values. In other words, the training is a kind of approximate EM rather than EM.

Word pairs are collected over Viterbi alignment and their conditional probabilities are estimated by MLE. As to phrase/h-phrase, if they are handled in a similar way, then there will be data sparseness (as there are much fewer phrase/h-phrase pairs in Viterbi parse tree than needed for reliable parameter estimation). Thus, we collect all phrase/h-phrase pairs which are consistent with the alignment links. The conditional probabilities are then estimated by MLE.

4.4 Semi-supervised training

Algorithm EMD (semi-supervised training)

input development data *dev*, test data *test*, training data with initial alignment (*train, align_train*)

output feature weights λ and features Ψ.

estimate initial features Ψ^0 with (*train, align_train*)
get an initial weights λ^0 by MERT with the initial features Ψ^0 on *dev*.
get the F-Measure e^0 for λ^0 and Ψ^0 on *test*.
for(t=1;; t++)
    get the Viterbi alignment *align_train* for *train* using λ^{t-1} and Ψ^{t-1}
    estimate Ψ^t with (*train, align_train*)
    get new feature weights λ^t by MERT with Ψ^t on *dev*.
    get the F-Measure e^t for λ^t and Ψ^t on *test*.
    if $e^t \leq e^{t-1} + 0.1$ **then**
        break
end for
return λ^{t-1} and Ψ^{t-1}

Figure 5. Semi-supervised training for HP-DITG.

The discriminative training (error minimization) of feature weights λ and the approximate EM learning of feature values Ψ are integrated in a single semi-supervised framework. Given an initial estimation of Ψ (estimated from an initial alignment matrix by some simpler word alignment model) and an initial estimation of λ, the discriminative training process and the approximate EM learning process are alternatively iterated until there is no more improvement. The sketch of the semi-supervised training is shown in Figure 5.

4.5 Features for word pairs

The following features about alignment link are used in W-DITG:

1) Word pair translation probabilities trained from HMM model (Vogel et al., 1996) and IBM model 4 (Brown et al., 1993).
2) Conditional link probability (Moore, 2006).
3) Association score rank features (Moore et al., 2006).
4) Distortion features: counts of inversion and concatenation.

4.6 Features for phrase/h-phrase pairs

For our HP-DITG model, the rule probabilities in both English-to-foreign and foreign-to-English directions are estimated and taken as features, in addition to those features in W-DITG, in the discriminative model of alignment hypothesis selection:

1) $P(\bar{e}_i/\bar{f}_i)$: The conditional probability of English phrase/h-phrase given foreign phrase/h-phrase.
2) $P(\bar{f}_i/\bar{e}_i)$: The conditional probability of foreign phrase/h-phrase given English phrase/h-phrase.

The features are calculated as described in section 4.3.

5 Evaluation

Our experiments evaluate the performance of HP-DITG in both word alignment and translation in a Chinese-English setting, taking GIZA++, BerkeleyAligner (henceforth BERK) (Haghighi, et al., 2009), W-ITG as baselines. Word alignment quality is evaluated by recall, precision, and F-measure, while translation performance is evaluated by case-insensitive BLEU4.

5.1 Experiment Data

The small human annotated alignment set for discriminative training of feature weights is the same as that in Haghighi et al. (2009). The 491

sentence pairs in this dataset are adapted to our own Chinese word segmentation standard. 250 sentence pairs are used as training data and the other 241 are test data. The large, un-annotated bilingual corpus for approximate EM learning of feature values is FBIS, which is also the training set for our SMT systems.

In SMT experiments, our 5-gram language model is trained from the Xinhua section of the Gigaword corpus. The NIST'03 test set is used as our development corpus and the NIST'05 and NIST'08 test sets are our test sets. We use two kinds of state-of-the-art SMT systems. One is a phrase-based decoder (PBSMT) with a MaxEnt-based distortion model (Xiong, et al., 2006), and the other is an implementation of hierarchical phrase-based model (HPBSMT) (Chiang, 2007). The phrase/rule table for these two systems is not generated from the terminal node of HP-DITG tree directly, but extracted from word alignment matrix (HP-DITG generated) using the same criterion as most phrase-based systems (Chiang, 2007).

5.2 HP-DITG without EMD

Our first experiment isolates the contribution of the various DITG alignment models from that of semi-supervised training. The feature values of the DITG models are estimated simply from IBM Model 4 using GIZA++. Apart from DITG, P-ITG, and HP-ITG as introduced in Section 2, we also include a variation, known as H-DITG, which covers h-phrase pairs but no simple phrase pairs at all. The experiment results are shown in Table 1.

	Precision	Recall	F-Measure
GIZA++	0.826	0.807	0.816
BERK	**0.917**	**0.814**	**0.862**
W-DITG	0.912	0.745	0.820
P-DITG	0.913	0.788	0.846
H-DITG	0.913	0.781	0.842
HP-DITG	**0.915**	**0.795**	**0.851**

Table 1. Performance gains with features for HP-DITG.

It is obvious that any form of ITG achieves better F-Measure than GIZA++. Without semi-supervised training, however, our various DITG models cannot compete with BERK. Among the DITG models, it can be seen that precision is roughly the same in all cases, while W-ITG has the lowest recall, due to the limitation of one-to-one matching. The improvement by (simple) phrase pairs is roughly the same as that by h-phrase pairs. And it is not surprising that the combination of both kinds of phrases achieve the best result.

Even HP-DITG does not achieve as high recall as BERK, it does produce promising alignment patterns that BERK fails to produce. For instance, for the following sentence pair:

自 上周末 以来， 我 一直 在 生病 .

I have been ill ***since*** last weekend .

Both GIZA++ and BERK produce the pattern in Figure 6(a), while HP-DITG produces the better pattern in Figure 6(b) as it learns the h-phrase pair "since *X*"/"自 *X* 以来".

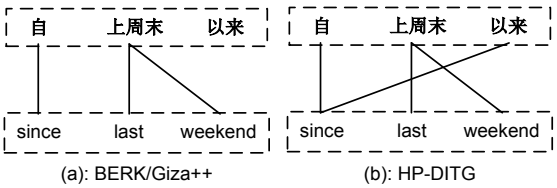

Figure 6. Partial alignment results.

5.3 Alignment Quality of HP-DITG with EMD

	Precision	Recall	F- Measure
GIZA++	0.826	0.807	0.816
BERK	0.917	0.814	0.862
EMD0	0.915	0.795	0.851
EMD1	0.923	0.814	0.865
EMD2	0.930	**0.821**	0.872
EMD3	**0.935**	0.819	**0.873**

Table 2. Semi-supervised Training Task on F-Measure.

The second experiment evaluates how the semi-supervised method of EMD improves HP-DITG with respect to word alignment quality. The results are shown in Table 2. In the table, EMD0 refers to the HP-DITG model before any EMD training; EMD1 refers to the model after the first iteration of training, and so on. It is empirically found that F-Measure is not improved after the third EMD iteration.

It can be observed that EMD succeeds to help HP-DITG improves feature value and weight estimation iteratively. When semi-supervised

training converges, the new HP-DITG model is better than before training by 2%, and better than BERK by 1%.

5.4 Translation Quality of HP-DITG with EMD

The third experiment evaluates the same alignment models in the last experiment but with respect to translation quality, measured by case-insensitive BLEU4. The results are shown in Table 3. Note that the differences between EMD3 and the two baselines are statistically significant.

	PBSMT		HPBSMT	
	05	08	05	08
GIZA++	33.43	23.89	33.59	24.39
BERK	33.76	24.92	34.22	25.18
EMD0	34.02	24.50	34.30	24.90
EMD1	34.29	24.80	34.77	25.25
EMD2	*34.25*	25.01	**35.04**	25.43
EMD3	**34.42**	**25.19**	*34.82*	**25.56**

Table 3. Semi-supervised Training Task on BLEU.

It can be observed that EMD improves SMT performance in most iterations in most cases. EMD does not always improve BLEU score because the objective function of the discriminative training in EMD is about alignment F-Measure rather than BLEU. And it is well known that the correlation between F-Measure and BLEU (Fraser and Marcu, 2007) is itself an intriguing problem.

The best HP-DITG leads to more than 1 BLEU point gain compared with GIZA++ on all datasets/MT models. Compared with BERK, EMD3 improves SMT performance significantly on NIST05 and slightly on NIST08.

6 Conclusion and Future Work

In this paper, we propose an ITG formalism which employs the notion of phrase/h-phrase pairs, in order to remove the limitation of one-to-one matching. The formalism is proved to enable an alignment model to capture the linguistic fact that a single concept is expressed in several non-contiguous words. Based on the formalism, we also propose a semi-supervised training method to optimize feature values and feature weights, which does not only improve the alignment quality but also machine translation performance significantly. Combining the formalism and semi-supervised training, we obtain better alignment and translation than the baselines of GIZA++ and BERK.

A fundamental problem of our current framework is that we fail to obtain monotonic increment of BLEU score during the course of semi-supervised training. In the future, therefore, we will try to take the BLEU score as our objective function in discriminative training. That is to certain extent inspired by Deng et al. (2008).

Appendix A. The Normal Form Grammar

Table 4 lists the ITG rules in normal form as used in this paper, which extend the normal form in Wu (1997) so as to handle the case of alignment to null.

1	$S \rightarrow A \mid B \mid C$
2	$A \rightarrow [A\ B] \mid [A\ C] \mid [B\ B] \mid [BC] \mid [C\ B] \mid [C\ C]$
3	$B \rightarrow \langle A\ A\rangle \mid \langle A\ C\rangle \mid \langle B\ A\rangle \mid \langle B\ C\rangle$
	$B \rightarrow \langle C\ A\rangle \mid \langle C\ C\rangle$
4	$C \rightarrow C_w \mid C_{fw} \mid C_{ew}$
5	$C \rightarrow [C_{ew}\ C_{fw}]$
6	$C_w \rightarrow u/v$
7	$C_e \rightarrow \varepsilon/v;\ C_f \rightarrow u/\varepsilon$
8	$C_{em} \rightarrow C_e \mid [C_{em}\ C_e];\ C_{fm} \rightarrow C_f \mid [C_{fm}\ C_f]$
9	$C_{ew} \rightarrow [C_{em}\ C_w];\ C_{fw} \rightarrow [C_{fm}\ C_w]$

Table 4. ITG Rules in Normal Form.

In these rules, S is the Start symbol; A is the category for concatenating combination whereas B for inverted combination. Rules (2) and (3) are inherited from Wu (1997). Rules (4) divide the terminal category C into subcategories. Rule schema (6) subsumes all terminal unary rules for some English word u and foreign word v, and rule schemas (7) are unary rules for alignment to null. Rules (8) ensure all words linked to null are combined in left branching manner, while rules (9) ensure those words linked to null combine with some following, rather than preceding, word pair. (Note: Accordingly, all sentences must be ended by a special token $\langle end\rangle$, otherwise the last word(s) of a sentence cannot be linked to null.) If there are both English and foreign words linked to null, rule (5) ensures that those English words linked to null precede those foreign words linked to null.

Abstract

Visually and phonologically similar characters are major contributing factors for errors in Chinese text. By defining appropriate similarity measures that consider extended Cangjie codes, we can identify visually similar characters within a fraction of a second. Relying on the pronunciation information noted for individual characters in Chinese lexicons, we can compute a list of characters that are phonologically similar to a given character. We collected 621 incorrect Chinese words reported on the Internet, and analyzed the causes of these errors. 83% of these errors were related to phonological similarity, and 48% of them were related to visual similarity between the involved characters. Generating the lists of phonologically and visually similar characters, our programs were able to contain more than 90% of the incorrect characters in the reported errors.

1 Introduction

In this paper, we report the experience of our studying the errors in simplified Chinese words. Chinese words consist of individual characters. Some words contain just one character, but most words comprise two or more characters. For instance, "卖" (mai4)[1] has just one character, and "语言" (yu3 yan2) is formed by two characters. Two most common causes for writing or typing incorrect Chinese words are due to visual and phonological similarity between the correct and the incorrect characters. For instance, one might use "划" (hwa2) in the place of "画"(hwa4) in "刻画形象" (ke1 hwa4 xing2 xiang4) partially because of phonological similarity; one might replace "拙" (zhuo2) in "心劳力拙" (xin1 lao2 li4 zhuo2) with "绌" (chu4) partially due to visual similarity. (We do not claim that the visual or phonological similarity alone can explain the observed errors.)

Similar characters are important for understanding the errors in both traditional and simplified Chinese. Liu et al. (2009a-c) applied techniques for manipulating correctness of Chinese words to computer assisted test-item generation. Research in psycholinguistics has shown that the number of neighbor characters influences the timing of activating the mental lexicon during the process of understanding Chinese text (Kuo et al. 2004; Lee et al. 2006). Having a way to compute and find similar characters will facilitate the process of finding neighbor words, so can be instrumental for related studies in psycholinguistics. Algorithms for optical character recognition for Chinese and for recognizing written Chinese try to guess the input characters based on sets of confusing sets (Fan et al. 1995; Liu et al., 2004). The confusing sets happen to be hand-crafted clusters of visually similar characters.

It is relatively easy to judge whether two characters have similar pronunciations based on their records in a given Chinese lexicon. We will discuss more related issues shortly.

To determine whether two characters are visually similar is not as easy. Image processing techniques may be useful but is not perfectly feasible, given that there are more than fifty thousand Chinese characters (HanDict, 2010) and that many of them are similar to each other in special ways. Liu et al. (2008) extend the Cangjie codes (Cangjie, 2010; Chu, 2010) to encode the layouts and details about traditional

[1] We show simplified Chinese characters followed by their Hanyu pinyin. The digit that follows the symbols for the sound is the tone for the character.

Coling 2008: Poster Volume, pages 739–747,
Beijing, August 2010

Chinese characters for computing visually similar characters. Evidence observed in psycholinguistic studies offers a cognition-based support for the design of Liu et al.'s approach (Yeh and Li, 2002). In addition, the proposed method proves to be effective in capturing incorrect traditional Chinese words (Liu et al., 2009a-c).

In this paper, we work on the errors in simplified Chinese words by extending the Cangjie codes for simplified Chinese. We obtain two lists of incorrect words that were reported on the Internet, analyze the major reasons that contribute to the observed errors, and evaluate how the new Cangjie codes help us spot the incorrect characters. Results of our analysis show that phonological and visual similarities contribute similar portions of errors in simplified and traditional Chinese. Experimental results also show that, we can catch more than 90% of the reported errors.

We go over some issues about phonological similarity in Section 2, elaborate how we extend and apply Cangjie codes for simplified Chinese in Section 3, present details about our experiments and observations in Section 4, and discuss some technical issues in Section 5.

2 Phonologically Similar Characters

The pronunciation of a Chinese character involves a sound, which consists of the nucleus and an optional onset, and a tone. In Mandarin Chinese, there are four tones. (Some researchers include the fifth tone.)

In our work, we consider four categories of phonological similarity between two characters: same sound and same tone (**SS**), same sound and different tone (**SD**), similar sound and same tone (**MS**), and similar sound and different tone (**MD**).

We rely on the information provided in a lexicon (Dict, 2010) to determine whether two characters have the same sound or the same tone. The judgment of whether two characters have similar sound should consider the language experience of an individual. One who live in the southern and one who live in the northern China may have quite different perceptions of "similar" sound. In this work, we resort to the confusion sets observed in a psycholinguistic study conducted at the Academic Sinica.

Some Chinese characters are heteronyms. Let C_1 and C_2 be two characters that have multiple pronunciations. If C_1 and C_2 share one of their pronunciations, we consider that C_1 and C_2 belong to the SS category. This principle applies when we consider phonological similarity in other categories.

One challenge in defining similarity between characters is that the pronunciations of a character can depend on its context. The most common example of tone sandhi in Chinese (Chen, 2000) is that the first third-tone character in words formed by two adjacent third-tone characters will be pronounced in the second tone. At present, we ignore the influences of context when determining whether two characters are phonologically similar.

Although we have confined our definition of phonological similarity to the context of the Mandarin Chinese, it is important to note the influence of sublanguages within the Chinese language family will affect the perception of phonological similarity. Sublanguages used in different areas in China, e.g., Shanghai, Min, and Canton share the same written forms with the Mandarin Chinese, but have quite different though related pronunciation systems. Hence, people living in different areas in China may perceive phonological similarity in very different ways. The study in this direction is beyond the scope of the current study.

3 Visually Similar Characters

Figure 1 shows four groups of visually similar characters. Characters in group 1 and group 2 differ subtly at the stroke level. Characters in group 3 share the components on their right sides. The shared component of the characters in group 4 appears at different places within the characters.

Radicals are used in Chinese dictionaries to organize characters, so are useful for finding visually similar characters. The characters in group 1 and group 2 belong to the radicals "田" and "讠", respectively. Notice that, although the radical for group 2 is clear, the radical for group 1 is not obvious because "田" is not a standalone component.

However, the shared components might not be the radicals of characters. The shared components in groups 3 and 4 are not the radicals. In

Figure 1. Examples of visually similar characters

many cases, radicals are semantic components of Chinese characters. In groups 3 and 4, the shared components carry information about the pronunciations of the characters. Hence, those characters are listed under different radicals, though they do look similar in some ways.

Hence, a mechanism other than just relying on information about characters in typical lexicons is necessary, and we will use the extended Cangjie codes for finding visually similar characters.

3.1 Cangjie Codes for Simplified Chinese

Table 1 shows the Cangjie codes for the 13 characters listed in Figure 1 and five other characters. The "ID" column shows the identification number for the characters, and we will refer to the i^{th} character by c_i, where i is the ID. The "CC" column shows the Chinese characters, and the "Cangjie" column shows the Cangjie codes. Each symbol in the Cangjie codes corresponds to a key on the keyboard, e.g. "田" and "中" collocate with "W" and "L", respectively. Information about the complete correspondence is available on the Wikipedia[2].

Using the Cangjie codes saves us from using image processing methods to determine the degrees of similarity between characters. Take the Cangjie codes for the characters in group 2 (c_5, c_6, and c_7) for example. It is possible to find that the characters share a common component, based on the shared substrings of the Cangjie codes, i.e., "戈女". Using the common substring (shown in black bold) of the Cangjie codes, we may also find the shared component "勾" for characters in group 3 (c_{10}, c_{11}, and c_{12}), the shared component "员" in c_{13} and c_{14}, the shared component "力" in c_{15} and c_{16}, and the shared component "⻥" in c_{16} and c_{17}.

Despite the perceivable advantages, these original Cangjie codes are not good enough. In order to maintain efficiency in inputting Chinese characters, the Cangjie codes have been limited to no more than five keys. Thus, users of the Cangjie input method must familiarize themselves with the principles for simplifying the Cangjie codes. While the simplified codes help the input efficiency, they also introduce difficulties and ambiguities when we compare the Cangjie codes for computing similar characters. The prefix "弓一" in c_{16} and c_{17} can represent "⻥", "鱼" (e.g., c_8), and "马" (e.g., c_9). Characters whose Cangjie codes include "弓一" may contain any of these three components, but they do not really look alike.

ID	CC	Cangjie	ID	CC	Cangjie
1	田	田	10	购	月人**心戈**
2	由	中田	11	沟	水**心戈**
3	甲	田中	12	构	木**心戈**
4	申	中田中	13	员	**口月人**
5	许	**戈女**人十	14	圆	田**口月人**
6	讦	**戈女**一十	15	勋	**口人大尸**
7	计	**戈女**十	16	劲	**弓一大尸**
8	鲳	**弓一**日日	17	颈	**弓一**一月人
9	驹	**弓一**心口	18	经	女一**弓人一**

Table 1. Examples of Cangjie codes

Therefore, we augment the original Cangjie codes by using the complete Cangjie codes and annotate each Chinese character with a layout identification that encodes the overall contours of the characters. This is how Liu and his colleagues (2008) did for the Cangjie codes for traditional Chinese characters, and we employ a similar exploration for the simplified Chinese.

3.2 Augmenting the Cangjie Codes

Figure 2 shows the twelve possible layouts that are considered for the Cangjie codes for simplified Chinese characters. Some of the layouts contain smaller areas, and the rectangles show a subarea within a character. The smaller areas are assigned IDs between one and three. Notice that, to maintain read-ability of the figures, not all IDs for subareas are shown in Figure 2. An example character is provided below each layout. From left to right and from top to bottom, each layout is assigned an identification number from 1 to 12. For example, the layout ID of "国" is 8. "国" has two parts, i.e., "口" and "玉".

Researchers have come up with other ways to

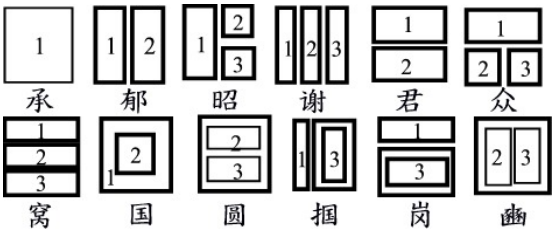

Figure 2. Layouts of Chinese characters

[2] en.wikipedia.org/wiki/Cangjie_input_method#Keyboard_layout ; last visited on 22 April 2010.

decompose individual Chinese characters. The Chinese Document Lab at the Academia Sinica proposed a system with 13 operators for describing the relationships among components in Chinese characters (CDL, 2010). Lee (2010b) propose more than 30 possible layouts.

The layout of a character affects how people perceive visual similarity between characters. For instance, c_{16} in Table 1 is more similar to c_{17} than to c_{18}, although they share "⿰". We rely on the expertise in Cangjie codes reported in (Lee, 2010a) to split the codes into parts.

Table 2 shows the extended codes for some characters listed in Table 1. The "ID" column provides links between the characters listed in both Table 1 and Table 2. The "CC" column shows the Chinese characters. The "LID" column shows the identifications for the layouts of the characters. The columns with headings "P1", "P2", and "P3" show the extended Cangjie codes, where "P*i*" shows the i^{th} part of the Cangjie codes, as indicated in Figure 2.

We decide the extended codes for the parts with the help of computer programs and subjective judgments. Starting from the original Cangjie codes, we can compute the most frequent substrings just like we can compute the frequencies of n-grams in corpora (cf. Jurafsky and Martin, 2009). Computing the most common substrings in the original codes is not a complex task because the longest original Cangjie codes contain just five symbols.

Often, the frequent substrings are simplified codes for popular components in Chinese characters, e.g., "⿰" and "⿰". The original codes for "⿰" and "⿰" are "戈弓女" and "弓人一", but they are often simplified to "戈女" and "弓一", respectively. When simplified, "⿰" have the same Cangjie code with "戌", and "⿰" have the same Cangjie code with "马" and "鱼".

After finding the frequent substrings, we verify whether these frequent substrings are simplified codes for meaningful components. For meaningful components, we replace the simplified codes with complete codes. For instance the Cangjie codes for "许" and "讦" are extended to include "弓" in Table 2, where we indicate the extended keys that did not belong to the original Cangjie codes in boldface and with a surrounding box. Most of the non-meaningful frequent substrings have two keys: one is the last key of a part, and the other is the first key of another part. They were by observed by coincidence.

ID	CC	LID	P1	P2	P3
5	许	2	戈**弓**女	人十	
6	讦	2	戈**弓**女	一十	
7	计	2	戈**弓**女	十	
10	购	10	月人	心	戈
11	沟	10	水	心	戈
12	构	10	木	心	戈
13	员	5	口	月人	
14	圆	9	田	口	月人
15	勋	2	口**月**人	大尸	
16	劲	2	弓**人**一	大尸	
17	颈	2	弓**人**一	一月人	
18	经	3	女**女**一	弓人	一
19	恸	4	心	一**一**戈	**大**尸

Table 2. Examples of extended Cangjie codes

Although most of the examples provided in Table 2 indicate that we expand only the first part of the Cangjie codes, it is absolutely possible that the other parts, i.e., P2 and P3, may need to be extended too. c_{19} shows such an example.

Replacing simplified codes with complete codes not only help us avoid incorrect matches but also help us find matches that would be missed due to simplification of Cangjie codes. Using just the original Cangjie codes in Table 1, it is not easy to determine that c_{18} ("经") in Table 1 shares a component ("⿰") with c_{16} and c_{17} ("劲" and "颈"). In contrast, there is a chance to find the similarity with the extended Cangjie codes in Table 2, given that all of the three Cangjie codes include "弓人一".

We can see an application of the LIDs, using "劲", "颈" and "经" as an example. Consider the case that we want to determine which of "颈" and "经" is more similar to "劲". Their extended Cangjie codes will indicate that "颈" is the answer to this question for two reasons. First, "劲" and "颈" belong to the same type of layout; and, second, the shared components reside at the same area in "劲" and "颈".

3.3 Similarity Measures

The main differences between the original and the extended Cangjie codes are the degrees of details about the structures of the Chinese characters. By recovering the details that were ignored in the original codes, our programs will be

better equipped to find the similarity between characters.

In the current study, we experiment with three different scoring methods to measure the visual similarity between two characters based on their extended Cangjie codes. Two of these methods had been tried by Liu and his colleagues' study for traditional Chinese characters (Liu et al., 2009b-c). The first method, denoted **SC1**, considers the total number of matched keys in the matched parts (without considering their part IDs). Let c_i denote the i^{th} character listed in Table 2. We have SC1(c_{15}, c_{16}) = 2 because of the matched "大尸". Analogously, we have SC1(c_{19}, c_{16}) = 2.

The second method, denoted **SC2**, includes the score of SC1 and considers the following conditions: (1) add one point if the matched parts locate at the same place in the characters and (2) if the first condition is met, an extra point will be added if the characters belong to the same layout. Hence, we have SC2(c_{15}, c_{16}) =SC1(c_{15}, c_{16})+1+1=4 because (1) the matched "大尸" locate at P2 in both characters and (2) c_{15} and c_{16} belong to the same layout. Assuming that c_{16} belongs to layout 5, than SC2(c_{15}, c_{16}) would become 3. In contrast, we have SC2(c_{19}, c_{16})=2. No extra weights for the matching "大尸" because it locates at different parts in the characters. The extra weight considers the spatial influences of the matched parts on the perception of similarity.

While splitting the extended Cangjie codes into parts allows us to tell that c_{15} is more similar to c_{16} than to c_{19}, it also creates a new barrier in computing similarity scores. An example of this problem is that SC2(c_{17}, c_{18})=0. This is because that "弓人一" at P1 in c_{17} can match neither "弓人" at P2 nor "一" at P3 in c_{18}.

To alleviate this problem, we consider **SC3** which computes the similarity in three steps. First, we concatenate the parts of a Cangjie code for a character. Then, we compute the longest common subsequence (**LCS**) (cf. Cormen et al., 2009) of the concatenated codes of the two characters being compared, and compute a Dice's coefficient (cf. Croft et al., 2010) as the similarity. Let X and Y denote the concatenated, extended Cangjie codes for two characters, and let Z be the LCS of X and Y. The similarity is defined by the following equation.

$$Dice_{LCS} = \frac{2 \times |Z|}{|X| + |Y|}, \text{ where } |S| \text{ is the length of string } S \quad (1)$$

We compute another Dice's coefficient between X and Y. The formula is the similar to (1), except that we set Z to the longest common *consecutive* subsequence. We call this score $Dice_{LCCS}$. Notice that $Dice_{LCCS} \le Dice_{LCS}$, $Dice_{LCCS} \le 1$, and $Dice_{LCS} \le 1$. Finally, SC3 of two characters is the sum of their SC2, $10 \times Dice_{LCCS}$, and $5 \times Dice_{LCS}$. We multiply the Dice's coefficients with constants to make them as influential as the SC2 component in SC3. The constants were not scientifically chosen, but were selected heuristically.

4 Error Analysis and Evaluation

We evaluate the effectiveness of using the phonologically and visually similar characters to captures errors in simplified Chinese words with two lists of reported errors that were collected from the Internet.

4.1 Data Sources

We need two types of data for the experiments. The information about the pronunciation and structures of the Chinese characters help us generate lists of similar characters. We also need reported errors so that we can evaluate whether the similar characters catch the reported errors.

A lexicon that provides the pronunciation information about Chinese characters and a database that contains the extended Cangjie codes are necessary for our programs to generate lists of characters that are phonologically and visually similar to a given character.

It is not difficult to acquire lexicons that show standard pronunciations for Chinese characters. As we stated in Section 2, the main problem is that it is not easy to predict how people in different areas in China actually pronounce the characters. Hence, we can only rely on the standards that are recorded in lexicons.

With the procedure reported in Section 3.2, we built a database of extended Cangjie codes for the simplified Chinese. The database was designed to contain 5401 common characters in the BIG5 encoding, which was originally designed for the traditional Chinese. After converting the traditional Chinese characters to the simplified counterparts, the database contained only 5170

different characters.

We searched the Internet for reported errors that were collected in real-world scenarios, and obtained two lists of errors. The first list[3] came from the entrance examinations for senior high schools in China, and the second list[4] contained errors observed at senior high schools in China. We used 160 and 524 errors from the first and the second lists, respectively, and we refer to the combined list as the **Ilist**. An item of reported error contained two parts: the correct word and the mistaken character, both of which will be used in our experiments.

4.2 Preliminary Data Analysis

Since our programs can compare the similarity only between characters that are included in our lexicon, we have to exclude some reported errors from the Ilist. As a result, we used only 621 errors in this section.

Two native speakers subjectively classified the causes of these errors into three categories based on whether the errors were related to phonological similarity, visual similarity, or neither. Since the annotators did not always agree on their classifications, the final results have five interesting categories: "P", "V", "N", "D", and "B" in Table 3. P and V indicate that the annotators agreed on the types of errors to be related to phonological and visual similarity, respectively. N indicates that the annotators believed that the errors were not due to phonological or visual similarity. D indicates that the annotators believed that the errors were due to phonological or visual similarity, but they did not have a consensus. B indicates the intersection of P and V.

Table 3 shows the percentages of errors in these categories. To get 100% from the table, we can add up P, V, N, and D, and subtract B from the total. In reality there are errors of type N, and Liu and his colleagues (2009b) reported this type of errors. Errors in this category happened to be missing in the Ilist. Based on our and Liu's observations, the percentages of phonological and visual similarities contribute to the errors in simplified and traditional Chinese words with similar percentages.

	P	V	N	D	B
Ilist	83.1	48.3	0	3.7	35.1

Table 3. Percentages of types of errors

4.3 Experimental Procedure

We design and employ the `ICCEval` procedure for the evaluation task.

At step 1, given the correct word and the correct character to be intentionally replaced with incorrect characters, we created a list of characters based on the selection criterion. We may choose to evaluate phonologically or visually similar characters. For a given character, `ICCEval` can generate characters that are in the SS, SD, MS, and MD categories for phonologically similar characters (cf. Section 2). For visually similar characters, `ICCEval` can select characters based on SC1, SC2, and SC3 (cf. Section 3.3). In addition, `ICCEval` can generate a list of characters that belong to the same radical and have the same number of strokes with the correct character. In the experimental results, we refer to this type of similar characters as **RS**.

At step 2, for a correct word that people originally wanted to write, we replaced the correct character with an incorrect character with the characters that were generated at step 1, submitted the incorrect word to Google AJAX Search

```
Procedure ICCEval
Input:
  ccr: the correct character; cwd:
  the correct word; crit: the selec-
  tion criterion; num: number of re-
  quested characters; rnk: the cri-
  terion to rank the incorrect
  words;
Output: a list of ranked candidates
    for ccr
Steps:
1.  Generate a list, L, of charac-
    ters for ccr with the specified
    criterion, crit. When using SC1,
    SC2, or SC3 to select visually
    similar characters, at most num
    characters will be selected.
2.  For each c in L, replace ccr in
    cwd with c, submit the resulting
    incorrect word to Google, and
    record the ENOP.
3.  Rank the list of incorrect words
    generated at step 2, using the
    criterion specified by rnk.
4.  Return the ranked list.
```

API, and extracted the estimated numbers of pages (ENOP) [5] that contained the incorrect words. In an ordinary interaction with Google, an ENOP can be retrieved from the search results, and it typically follows the string "`Results 1-10 of about`" on the upper part of the browser window. Using the AJAX API, we just have to parse the returned results with a simple method.

Larger ENOPs for incorrect words suggest that these words are incorrect words that people frequently used on their web pages. Hence, we ranked the similar characters based on their ENOPs at step 3, and return the list.

Since the reported errors contained information about the incorrect ways to write the correct words, we could check whether the real incorrect characters were among the similar characters that our programs generated at step 1 (inclusion tests). We could also check whether the actual incorrect characters were ranked higher in the ranked lists (ranking tests).

Take the word "和藹可亲" as an example. In the collected data, it is reported that people wrote this word as "和靄可亲", i.e., the second character was incorrect. Hoping to capture the error, `ICCEval` generated a list of possible substitutions for "藹" at step 1. Depending on the categories of sources of errors, `ICCEval` generated a list of characters. When aiming to test the effectiveness of visually similar characters, we could ask `ICCEval` to apply SC3 to generate a list of alternatives for "藹", possibly including "靄", "谒", "葛", and other candidates. At step 2, we created and submitted query strings "和靄可亲", "和谒可亲", and "和葛可亲" to obtain the ENOPs for the candidates. If the ENOPs were, respectively, 410000, 26100, and 7940, these candidates would be returned in the order of "靄", "谒", and "葛". As a result, the returned list contained the actual incorrect character "靄", and placed "靄" on top of the ranked list.

Notice that we considered the contexts in which the incorrect characters appeared to rank. We did not rank the incorrect characters with just the unigrams. In addition, although this running example shows that we ranked the characters directly with the ENOPs, we also ranked the list of alternatives with pointwise mutual information:

$$PMI(C,X) = \frac{\Pr(C \wedge X)}{\Pr(C) \times \Pr(X)}, \quad (2)$$

where X is the candidate character to replace the correct character and C is the correct word excluding the correct character to be replaced. To compute the score of replacing "藹" with "靄" in "和藹可亲", X = "靄", C="和□可亲", and ($C \wedge X$) is "和靄可亲". (□ denotes a character to be replaced.) PMI is a common tool for judging collocations in natural language processing. (cf. Jurafsky and Martin, 2009).

It would demand very much computation effort to find Pr(C). Fortunately, we do not have to consider Pr(C) because it is a common denominator for all incorrect characters. Let X_1 and X_2 be two competing candidates for the correct character. We can ignore Pr(C) because of the following relationship.

$$PMI(C,X_1) \geq PMI(C,X_2) \Leftrightarrow \frac{\Pr(C \wedge X_1)}{\Pr(X_1)} \geq \frac{\Pr(C \wedge X_2)}{\Pr(X_2)}$$

Hence, X_1 prevails if $score(C,X_1)$ is larger.

$$score(C,X) = \frac{\Pr(C \wedge X)}{\Pr(X)} \quad (3)$$

In our work, we approximate the probabilities used in (3) by the corresponding frequencies that we can collect through Google, similar to the methods that we used to collect the ENOPs.

4.4 Experimental Results: Inclusion Tests

We ran `ICCEval` with 621 errors in the Ilist. The experiments were conducted for all categories of phonological and visual similarity. When using SS, SD, MS, MD, and RS as the selection criterion, we did not limit the number of candidate characters. When using SC1, SC2, and SC3 as the criterion, we limited the number candidates to be no more than 30. We consider only words that the native speakers have consensus over the causes of errors. Hence, we dropped those 3.7% of words in Table 3, and had just 598 errors. The ENOPs were obtained during March and April 2010.

Table 4 shows the chances that the lists, gen-

	SS	SD	MS	MD	Phone
Ilist	82.6	29.3	1.7	1.6	97.3
	SC1	SC2	SC3	RS	Visual
Ilist	78.3	71.0	87.7	1.3	90.0

Table 4. Chances of the recommended list contains the incorrect character

[5] According to (Croft et al., 2010), the ENOPs may not reflect the actual number of pages on the Internet.

erated with different `crit` at step 1, contained the incorrect character in the reported errors. In the Ilist, there were 516 and 300[6] errors that were related to phonological and visual similarity, respectively. Using the characters generated with the SS criterion, we captured 426 out of 516 phone-related errors, so we showed 426/516 = 82.6% in the table.

Results in Table 4 show that we captured phone-related errors more effectively than visually-similar errors. With a simple method, we can compute the union of the characters that were generated with the SS, SD, MS, and MD criteria. This integrated list suggested how well we captured the errors that were related to phones, and we show its effectiveness under "Phone". Similarly, we integrated the lists generated by SC1, SC2, SC3, and RS to explore the effectiveness of finding errors that are related to visual similarity, and the result is shown under "Visual".

4.5 Experimental Results: Ranking Tests

To put the generated characters into work, we wish to put the actual incorrect character high in the ranked list. This will help the efficiency in supporting computer assisted test-item writing. Having short lists that contain relatively more confusing characters may facilitate the data preparation for psycholinguistic studies.

At step 3, we ranked the candidate characters by forming incorrect words with other characters in the correct words as the context and submitted the words to Google for ENOPs. The results of ranking, shown in Table 5, indicate that we may just offer the leading five candidates to cover the actual incorrect characters in almost all cases.

The "Total" column shows the total number of errors that were captured by the selection criterion. The column "R*i*" shows the percentage of all errors, due to phonological or visual similarity, that were re-created and ranked i^{th} at step 3 in `ICCEVAL`. The row headings show the selection criteria that were used in the experiments. For instance, using SS as the criterion, 70.3% of actual phone-related errors were rank first, 7.4% of the phone-related errors were ranked second, etc. If we recommended only 5 leading incorrect characters only with SS, we would have captured the actual incorrect characters that were phone related 81.6% (the sum of R1 to R5) of the time. For errors that were related to visual similarity, recommending the top five candidates with SC3 would capture the actual incorrect characters 87.1% of the time. Since we do not show the complete distributions, the sums over the rows are not 100%. In the current experiments, the worst rank was 21.

	Total	R1	R2	R3	R4	R5
SS	426	70.3	7.4	2.9	0.4	0.6
SD	151	25.6	2.7	0.6	0.0	0.4
MS	9	1.4	0.4	0.0	0.0	0.0
MD	8	1.6	0.0	0.0	0.0	0.0
SC1	235	61.3	10.3	4.3	2.0	0.3
SC2	213	53.7	11.0	3.7	2.3	0.3
SC3	263	66.7	12.7	5.7	1.7	0.3
RS	4	1.3	0.0	0.0	0.0	0.0

Table 5. Ranking the candidates

We also used PMI to rank the incorrect words. Due to page limits, we cannot show complete details about the results. The observed distributions in ranks were not very different from those shown in Table 5.

5 Discussion

Compared with Liu et al.'s analysis (2009b-c) for the traditional Chinese, the proportions of errors related to phonological factors are almost the same, both at about 80%. The proportion of errors related to visual factors varied, but the averages in both studies were about 48%. A larger scale of study is needed for how traditional and simplified characters affect the distributions of errors. Results shown in Table 4 suggest that it is relatively easy to capture errors related to visual factors in simplified Chinese. Although we cannot elaborate, we note that Cangjie codes are not good for comparing characters that have few strokes, e.g., c_1 to c_4 in Table 1. In these cases, the coding method for Wubihua input method (Wubihua, 2010) should be applied.

Abstract

Phrase-based statistical MT (SMT) is a milestone in MT. However, the translation model in the phrase based SMT is structure free which greatly limits its reordering capacity. To address this issue, we propose a non-lexical head-modifier based reordering model on word level by utilizing constituent based parse tree in source side. Our experimental results on the NIST Chinese-English benchmarking data show that, with a very small size model, our method significantly outperforms the baseline by 1.48% bleu score.

1 Introduction

Syntax has been successfully applied to SMT to improve translation performance. Research in applying syntax information to SMT has been carried out in two aspects. On the one hand, the syntax knowledge is employed by directly integrating the syntactic structure into the translation rules i.e. syntactic translation rules. On this perspective, the word order of the target translation is modeled by the syntax structure explicitly. Chiang (2005), Wu (1997) and Xiong (2006) learn the syntax rules using the formal grammars. While more research is conducted to learn syntax rules with the help of linguistic analysis (Yamada and Knight, 2001; Graehl and Knight, 2004). However, there are some challenges to these models. Firstly, the linguistic analysis is far from perfect. Most of these methods require an off-the-shelf parser to generate syntactic structure, which makes the translation results sensitive to the parsing errors to some extent. To tackle this problem, n-best parse trees and parsing forest (Mi and Huang, 2008; Zhang, 2009) are proposed to relieve the error propagation brought by linguistic analysis. Secondly, some phrases which violate the boundary of linguistic analysis are also useful in these models (DeNeefe et al., 2007; Cowan et al. 2006). Thus, a tradeoff needs to be found between linguistic sense and formal sense.

On the other hand, instead of using syntactic translation rules, some previous work attempts to learn the syntax knowledge separately and then integrated those knowledge to the original constraint. Marton and Resnik (2008) utilize the language linguistic analysis that is derived from parse tree to constrain the translation in a soft way. By doing so, this approach addresses the challenges brought by linguistic analysis through the log-linear model in a soft way.

Starting from the state-of-the-art phrase based model Moses (Koehn e.t. al, 2007), we propose a head-modifier relation based reordering model and use the proposed model as a soft syntax constraint in the phrase-based translation framework. Compared with most of previous soft constraint models, we study the way to utilize the constituent based parse tree structure by mapping the parse tree to sets of head-modifier for phrase reordering. In this way, we build a word level reordering model instead of phrasal/constituent level model. In our model, with the help of the alignment and the head-modifier dependency based relationship in the source side, the reordering type of each target word with alignment in source side is identified as one of pre-defined reordering types. With these reordering types, the reordering of phrase in translation is estimated on word level.

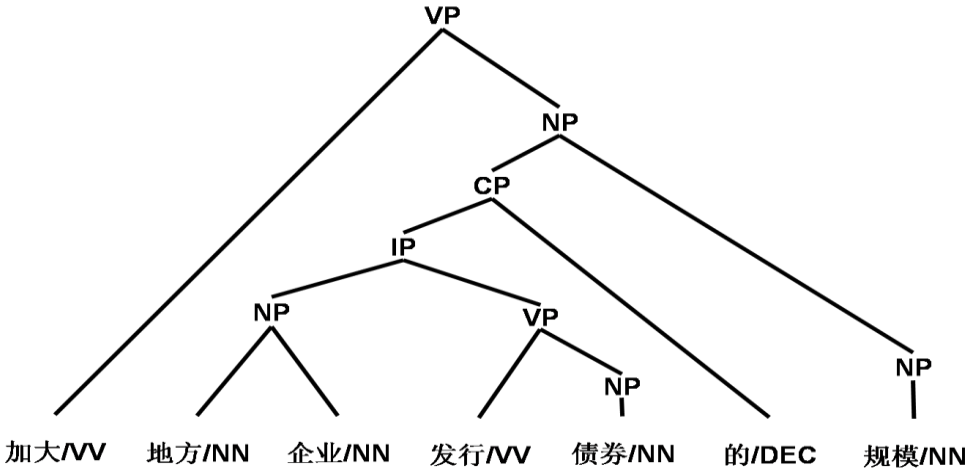

Fig 1. An Constituent based Parse Tree

2 Baseline

Moses, a state-of-the-art phrase based SMT system is used as our baseline system. In Moses, given the source language *f* and target language *e*, the decoder is to find:

$$e_{best} = \text{argmax}_e\, p(e \mid f)\, pLM(e)\, \omega^{length(e)} \quad (1)$$

where p(e|f) can be computed using phrase translation model, distortion model and lexical reordering model. pLM(e) can be computed using the language model. $\omega^{length(e)}$ is word penalty model.

Among the above models, there are three reordering-related components: language model, lexical reordering model and distortion model. The language model can reorder the local target words within a fixed window in an implied way. The lexical reordering model and distortion reordering model tackle the reordering problem between adjacent phrase on lexical level and alignment level. Besides these reordering model, the decoder induces distortion pruning constraints to encourage the decoder translate the leftmost uncovered word in the source side firstly and to limit the reordering within a certain range.

3 Model

In this paper, we utilize the constituent parse tree of source language to enhance the reordering capacity of the translation model. Instead of directly employing the parse tree fragments (Bod, 1992; Johnson, 1998) in reordering rules (Huang and Knight, 2006; Liu 2006; Zhang and Jiang 2008), we make a mapping from trees to sets of head-modifier dependency relations (Collins 1996) which can be obtained from the constituent based parse tree with the help of head rules (Bikel, 2004).

3.1 Head-modifier Relation

According to Klein and Manning (2003) and Collins (1999), there are two shortcomings in n-ary Treebank grammar. Firstly, the grammar is too coarse for parsing. The rules in different context always have different distributions. Secondly, the rules learned from training corpus cannot cover the rules in testing set.

Currently, the state-of-the-art parsing algorithms (Klein and Manning, 2003; Collins 1999) decompose the n-ary Treebank grammar into sets of head-modifier relationships. The parsing rules in these algorithms are constructed in the form of finer-grained binary head-modifier dependency relationships. Fig.2 presents an example of head-modifier based dependency tree mapped from the constituent parse tree in Fig.1.

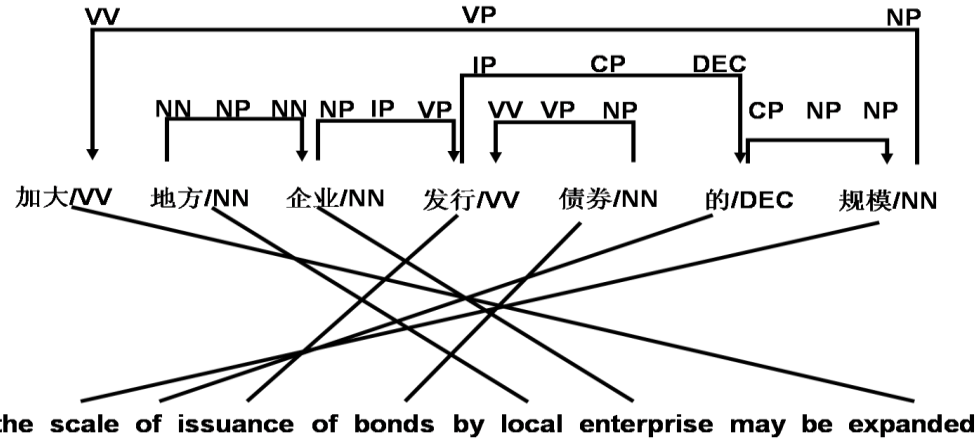

Fig. 2. Head-modifier Relationships with Aligned Translation

Moreover, there are several reasons for which we adopt the head-modifier structured tree as the main frame of our reordering model. Firstly, the dependency relationships can reflect some underlying binary long distance dependency relations in the source side. Thus, binary dependency structure will suffer less from the long distance reordering constraint. Secondly, in head-modifier relation, we not only can utilize the context of dependency relation in reordering model, but also can utilize some well-known and proved helpful context (Johnson, 1998) of constituent base parse tree in reordering model. Finally, head-modifier relationship is mature and widely adopted method in full parsing.

3.2 Head-modifier Relation Based Reordering Model

Before elaborating the model, we define some notions further easy understanding. $S=<f_1, f_2 \ldots f_n>$ is the source sentence; $T=<e_1,e_2,\ldots,e_m>$ is the target sentence; $A_S=\{a_s(i) \mid 1\leq a_s(i) \leq n\}$ where $a_s(i)$ represents that the ith word in source sentence aligned to the $a_s(i)th$ word in target sentence; $A_T=\{a_T(i) \mid 1\leq a_T(i) \leq n\}$ where $a_T(i)$ represents that the ith word in target sentence aligned to the $a_T(i)th$ word in source sentence; $D=\{(d(i), r(i)) \mid 0\leq d(i) \leq n\}$ is the head-modifier relation set of the words in S where $d(i)$ represents that the ith word in source sentence is the modifier of $d(i)th$ word in source sentence under relationship $r(i)$; $O=<o_1, o_2,\ldots, o_m>$ is the sequence of the reordering type of every word in target language. The reordering model probability is P(O| S, T, D, A).

Relationship: in this paper, we not only use the label of the constituent label as Collins (1996), but also use some well-known context in parsing to define the head-modifier relationship *r(.)*, including the POS of the modifier *m*, the POS of the head *h*, the dependency direction *d*, the parent label of the dependency label *l*, the grandfather label of the dependency relation *p*, the POS of adjacent siblings of the modifier *s*. Thus, the head-modifier relationship can be represented as a 6-tuple <*m*, *h*, *d*, *l*, *p*, *s*>.

r(.)	relationship
r(1)	<VV, - , -, -, -, - >
r(2)	<NN, NN, right, NP, IP, - >
r(3)	<NN,VV, right, IP, CP, - >
r(4)	<VV, DEC, right, CP, NP, - >
r(5)	<NN,VV, left, VP, CP, - >
r(6)	<DEC, NP, right, NP, VP, - >
r(7)	<NN, VV, left, VP, TOP, - >

Table 1. Relations Extracted from Fig 2.

In Table 1, there are 7 relationships extracted from the source head-modifier based dependency tree as shown in Fig.2. Please notice that, in this paper, each source word has a corresponding relation.

Reordering type: there are 4 reordering types for target words with linked word in the source side in our model: $R=\{rm_1, rm_2, rm_3, rm_4\}$. The reordering type of target word $a_s(i)$ is defined as follows:

- **rm_1**: if the position number of the ith word's head is less than i (d(i) < i) in source language, while the position number of the word aligned to i is less than

$a_s(d(i))$ ($a_s(i) < a_s(d(i))$) in target language;

- **rm_2**: if the position number of the ith word's head is less than i (d(i) < i) in source language, while the position number of the word aligned to i is larger than $a_s(d(i))$ ($a_s(i) > a_s(d(i))$) in target language.
- **rm_3**: if the position number of the ith word's head is larger than i (d(i) > i) in source language, while the position number of the word aligned to i is larger than $a_s(d(i))$ ($a_s(i) > a_s(d(i))$) in target language.
- **rm_4**: if the position number of the ith word's head is larger than i (d(i) > i) in source language, while the position number of the word aligned to i is less than $a_s(d(i))$ ($a_s(i) < a_s(d(i))$) in target language.

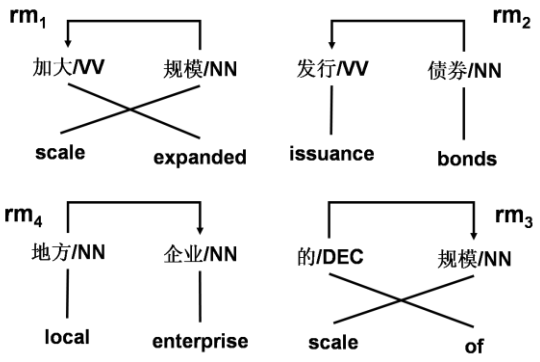

Fig. 3. An example of the reordering types in Fig. 2.

Fig. 3 shows examples of all the reordering types. In Fig. 3, the reordering type is labeled at the target word aligned to the modifier: for example, the reordering type of rm_1 belongs to the target word "*scale*". Please note that, in general, these four types of reordering can be divided into 2 categories: the target words order of rm_2 and rm_4 is identical with source word order, while rm_1 and rm_3 is the swapped order of source. In practice, there are some special cases that can't be classified into any of the defined reordering types: the head and modifier in source link to the same word in target. In such cases, rather than define new reordering types, we classify these special cases into these four defined reordering types: if the head is right to the modifier in source, we classify the reordering type into rm_2; otherwise, we classify the reordering type into rm_4.

Probability estimation: we adopt maximum likelihood (ML) based estimation in this paper. In ML estimation, in order to avoid the data sparse problem brought by lexicalization, we discard the lexical information in source and target language:

$$P(O \mid S, T, D, A) = \prod_{i=1}^{m} P(o_i \mid -,-, r(a_T(i))) \quad (2)$$

where $o_i \in \{rm1, rm2, rm3, rm4\}$ is the reordering type of ith word in target language.

To get a non-zero probability, additive smooth ing(Chen and Goodman, 1998) is used:

$$P(o_i \mid -,-, F(r(a_t(i)))) = \frac{F(o_i, r(a_T(i))) + \alpha}{\sum_{o_i \in R} F(r(a_t(i))) + |O| \times \alpha} = \frac{F(o_i, m_{a_T(i)}, h_{a_T(i)}, d_{a_T(i)}, l_{a_T(i)}, p_{a_T(i)}, s_{a_T(i)}) + \alpha}{\sum_{o_i \in R} F(m_{a_T(i)}, h_{a_T(i)}, d_{a_T(i)}, l_{a_T(i)}, p_{a_T(i)}, s_{a_T(i)}) + |O| \times \alpha} \quad (3)$$

where F(.) is the frequency of the statistic event in training corpus. For a given set of dependency relationships mapping from constituent tree, the reordering type of ith word is confined to two types: it is whether one of rm1 and rm2 or rm3 and rm4. Therefore, |O|=2 instead of |O|=4 in (2). The parameter α is an additive factor to prevent zero probability. It is computed as:

$$\alpha = \frac{1}{C \times \sum_{o_i \in R} F(m_{a_T(i)}, h_{a_T(i)}, d_{a_T(i)}, l_{a_T(i)}, p_{a_T(i)}, s_{a_T(i)})} \quad (4)$$

where c is a constant parameter(c=5 in this paper).

In above, the additive parameter α is an adaptive parameter decreasing with the size of the statistic space. By doing this, the data sparse problem can be relieved.

4 Apply the Model to Decoder

Our decoding algorithm is exactly the same as (Kohn, 2004). In the translation procedure, the decoder keeps on extending new phrases without overlapping, until all source words are translated. In the procedure, the order of the target

words in decoding procedure is fixed. That is, once a hypothesis is generated, the order of target words cannot be changed in the future. Taking advantage of this feature, instead of computing a totally new reordering score for a newly generated hypothesis, we merely calculate the reordering score of newly extended part of the hypothesis in decoding. Thus, in decoding, to compute the reordering score, the reordering types of each target word in the newly extended phrase need to be identified.

The method to identify the reordering types in decoding is proposed in Fig.4. According to the definition of reordering, the reordering type of the target word is identified by the direction of head-modifier dependency on the source side, the alignment between the source side and target side, and the relative translated order of word pair under the head-modifier relationship. The direction of dependency and the alignment can be obtained in input sentence and phrase table. While the relative translation order needs to record during decoding. A word index is employed to record the order. The index is constructed in the form of true/false array: the index of the source word is set with true when the word has been translated. With the help of this index, reordering type of every word in the phrase can be identified.

1: **Input**: alignment array A_T; the *Start* is the start position of the phrase in the source side; head-modifier relation *d(.)*; source word index *C*, where *C[i]=true* indicates that the *ith* word in source has been translated.
2: **Output:** reordering type array *O* which reserves the reordering types of each word in the target phrase
3: **for** i = 1, $|A_T|$ **do**
4: P ← a_T(i) + Start
5: **if** (d (P)<P) **then**
6: **if** C [d(p)] = false **then**
7: O[i] ← rm_1
8: **else**
9: O[i] ← rm_2
10: **end if**
11: **else**
12: **if** C[d(p)] = true **then**
13: O[i] ← rm_3
14: **else**
15: O[i] ← rm_4
16: **end if**
17: **end if**
18: C[p] ←true //update word index
19: **end for**

Fig. 4. Identify the Reordering Types of Newly Extended Phrase

After all the reordering types in the newly extended phrase are identified, the reordering scores of the phrase can be computed by using equation (3).

5 Preprocess the Alignment

In Fig. 4, the word index is to identify the reordering type of the target translated words. Actually, in order to use the word index without ambiguity, the alignment in the proposed algorithm needs to satisfy some constraints.

Firstly, every word in the source must have alignment word in the target side. Because, in the decoding procedure, if the head word is not covered by the word index, the algorithm cannot distinguish between the head word will not be translated in the future and the head word is not translated yet. Furthermore, in decoding, as shown in Fig.4, the index of source would be set with true only when there is word in target linked to it. Thus, the index of the source word without alignment in target is never set with true.

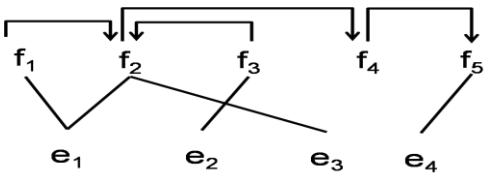

Fig. 5. A complicated Example of Alignment in Head-modifier based Reordering Model

Secondly, if the head word has more than one alignment words in target, different alignment possibly result in different reordering type. For example, in Fig. 5, the reordering type of e_2 is different when f_2 select to link word e_1 and e3 in the source side.

To solve this problem, we modify the alignment to satisfy following conditions: a) each word in source just has only one alignment word in target, and b) each word in target has at most one word aligned in source as its anchor word which decides the reordering type of the target word.

To make the alignment satisfy above constraints, we modify the alignment in corpus. In

order to explain the alignment preprocessing, the following notions are defined: if there is a link between the source word f_j and target word e_i, let $l(e_i, f_j) = 1$, otherwise $l(e_i, f_j) = 0$; the source word $f_j \in F_{1\text{-to-N}}$, iff $\sum_i l(e_i, f_j) > 1$, such as the source word f_2 in Fig. 5; the source word $f_j \in F_{NULL}$, iff $\sum_i l(e_i, f_j) = 0$, such as the source word f_4 in Fig. 5; the target word $e_i \in E_{1\text{-to-N}}$, iff $\sum_j l(e_i, f_j) > 1$, such as the target word e_1 in Fig. 5.

In preprocessing, there are 3 types of operation, including *DiscardLink(f_j)* , *BorrowLink(f_j)* and *FindAnchor*(e_i) :

DiscardLink(f_j) : if the word f_j in source with more than one words aligned in target, i.e. $f_j \in F_{1\text{-to-N}}$; We set the target word e_n with $l(e_n, f_j) = 1$, where $e_n = \text{argmax}_i\ p(e_i \mid f_j)$ and $p(e_i \mid f_j)$ is estimated by (Koehn e.t. al, 2003), while set rest of words linked to f_j with $l(e_n, f_j) = 0$.

BorrowLink(f_j): if the word f_j in source without a alignment word in target, i.e. $f_j \in F_{NULL}$; let $l(e_i, f_j)=1$ where e_i aligned to the word f_j , which is the nearest word to f_j in the source side; when there are two words nearest to f_j with alignment words in the target side at the same time, we select the alignment of the left word firstly .

FindAnchor(e_i): for the word e_i in target with more than one words aligned in source , i.e. $e_i \in E_{1\text{-to-N}}$; we select the word f_m aligned to e_i as its anchor word to decide the reordering type of e_i , where $f_m = \text{argmax}_j\ p(e_i \mid f_j)$ and $p(f_j \mid e_i)$ is estimated by (Koehn et al, 2003); For the rest of words aligned to e_i , we would set their word indexes with true in the update procedure of decoding in the 18th line of Fig.4.

With these operations, the required alignment can be obtained by preprocessing the origin alignment as shown in Fig. 6.

1: **Input**: set of alignment A between target language *e* and source language *f*
2: **Output:** the 1-to-1 alignment required by the model
3: **foreach** $f_i \in F_{1\text{-to-N}}$ **do**
4: DiscardLink(f_i)
5: **end for**
6: **foreach** $f_i \in F_{NULL}$ **do**
7: BorrowLink(f_i)
8: **end for**
9: **foreach** $e_i \in E_{1\text{-to-N}}$ **do**
10: FindAnchor(e_i)
11: **endfor**

Fig. 6. Alignment Pre-Processing algorithm

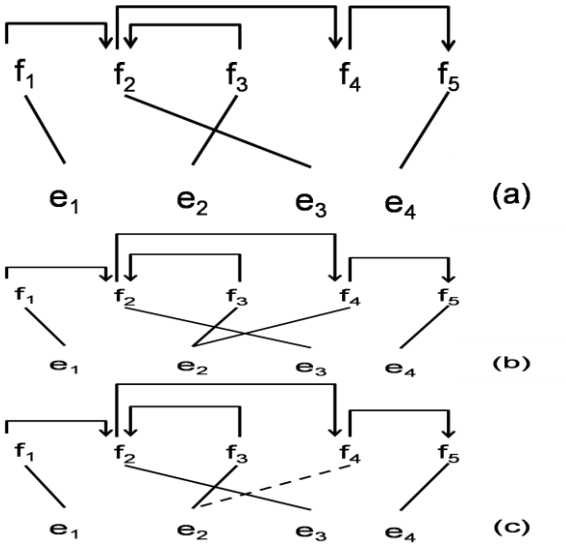

Fig. 7. An Example of Alignment Preprocessing.

An example of the preprocess the alignment in Fig. 5 is shown in Fig. 7 : firstly, *DiscardLink(f_2)* operation discards the link between f_2 and e_1 in (a); then the link between f_4 and e_3 is established by operation *BorrowLink(f_4)* in (b); at last, *FindAnchor(e_3)* select f_2 as the anchor word of e_3 in source in (c). After the preprocessing, the reordering type of e_3 can be identified. Furthermore, in decoding, when the decoder scans over e_2, the word index sets the word index of f_3 and f_4 with true. In this way, the never-true word indexes in decoding are avoided.

6 Training the Reordering Model

Before training, we get the required alignment by alignment preprocessing as indicated above. Then we train the reordering model with this alignment: from the first word to the last word in the target side, the reordering type of each word is identified. In this procedure, we skip the words without alignment in source. Finally, all the statistic events required in equation (3) are added to the model.

In our model, there are 20,338 kinds of relations with reordering probabilities which are much smaller than most phrase level reordering models on the training corpus FBIS.

Table 1 is the distribution of different reordering types in training model.

Type of Reordering	Percentage %
rm_1	3.69
rm_2	27.61
rm_3	20.94
rm_4	47.75

Table 1: Percentage of different reordering types in model

From Table 1, we can conclude that the reordering type rm_2 and rm_4 are preferable in reordering which take over nearly 3/4 of total number of reordering type and are identical with word order of the source. The statistic data indicate that most of the words order doesn't change in our head-modifier reordering view. This maybe can explain why the models (Wu, 1997; Xiong, 2006; Koehn, et., 2003) with limited capacity of reordering can reach certain performance.

7 Experiment and Discussion

7.1 Experiment Settings

We perform Chinese-to-English translation task on NIST MT-05 test set, and use NIST MT-02 as our tuning set. FBIS corpus is selected as our training corpus, which contains 7.06M Chinese words and 9.15M English words. We use GIZA++(Och and Ney, 2000) to make the corpus aligned. A 4-gram language model is trained using Xinhua portion of the English Gigaword corpus (181M words). All models are tuned on BLEU, and evaluated on both BLEU and NIST score.

To map from the constituent trees to sets of head-modifier relationships, firstly we use the Stanford parser (Klein, 2003) to parse the source of corpus FBIS, then we use the head-finding rules in (Bikel, 2004) to get the head-modifier dependency sets.

In our system, there are 7 groups of features. They are:

1. Language model score (1 feature)
2. word penalty score (1 feature)
3. phrase model scores (5 features)
4. distortion score (1 feature)
5. lexical RM scores (6 features)
6. Number of each reordering type (4 features)
7. Scores of each reordering type (4 features, computed by equation (3))

In these feature groups, the top 5 groups of features are the baseline model, the left two group scores are related with our model.

In decoding, we drop all the OOV words and use default setting in Moses: set the distortion limitation with 6, beam-width with 1/100000, stack size with 200 and max number of phrases for each span with 50.

7.2 Results and Discussion

We take the replicated Moses system as our baseline. Table 2 shows the results of our model. In the table, Baseline model is the model including feature group 1, 2, 3 and 4. $Baseline_{rm}$ model is the Baseline model with feature group 5. H-M model is the Baseline model with feature group 6 and 7. $H\text{-}M_{rm}$ model is the $Baseline_{rm}$ model with feature group 6 and 7.

Model	BLEU%	NIST
Baseline	27.06	7.7898
$Baseline_{rm}$	27.58	7.8477
H-M	28.47	8.1491
$H\text{-}M_{rm}$	29.06	8.0875

Table 2: Performance of the Systems on NIST-05(bleu4 case-insensitive).

From table 2, we can conclude that our reordering model is very effective. After adding feature group 6 and 7, the performance is improved by 1.41% and 1.48% in bleu score separately. Our reordering model is more effective than the lexical reordering model in Moses: 1.41% in bleu score is improved by adding our reordering model to Baseline model, while 0.48 is improved by adding the lexical reordering to Baseline model.

threshold	KOR	BLEU	NIST
$\geqslant 1$	20,338	29.06	8.0875
$\geqslant 2$	13,447	28.83	8.3658
$\geqslant 3$	10,885	28.64	8.0350
$\geqslant 4$	9,518	28.94	8.1002
$\geqslant 5$	8,577	29.18	8.1213

Table 3: Performance on NIST-05 with Different Relation Frequency Threshold (bleu4 case-insensitive).

Although our model is lexical free, the data sparse problem affects the performance of the model. In the reordering model, nearly half numbers of the relations in our model occur less than three times. To investigate this, we statistic

the frequency of the relationships in our model, and expertise our H-M_{full} model with different frequency threshold.

In Table 3, when the frequency of relation is not less than the *threshold*, the relation is added into the reordering model; KOR is the number of relation type in the reordering model.

Table 3 shows that, in our model, many relations occur only once. However, these low-frequency relations can improve the performance of the model according to the experimental results. Although low frequency statistic events always do harm to the parameter estimation in ML, the model can estimate more events in the test corpus with the help of low frequency event. These two factors affect the experiment results on opposite directions: we consider that is the reason the result don't increase or decrease with the increasing of frequency threshold in the model. According to the results, the model without frequency threshold achieves the highest bleu score. Then, the performance drops quickly, when the frequency threshold is set with 2. It is because there are many events can't be estimated by the smaller model. Although, in the model without frequency threshold, there are some probabilities overestimated by these events which occur only once, the size of the model affects the performance to a larger extent. When the frequency threshold increases above 3, the size of model reduces slowly which makes the overestimating problem become the important factor affecting performance. From these results, we can see the potential ability of our model: if our model suffer less from data spars problem, the performance should be further improved, which is to be verified in the future.

8 Related Work and Motivation

There are several researches on adding linguistic analysis to MT in a "soft constraint" way. Most of them are based on constituents in parse tree. Chiang(2005), Marton and Resnik(2008) explored the constituent match/violation in hiero; Xiong (2009 a) added constituent parse tree based linguistic analysis into BTG model; Xiong (2009 b) added source dependency structure to BTG; Zhang(2009) added tree-kernel to BTG model. All these studies show promising results. Making soft constrain is an easy and efficient way in adding linguistic analysis into formal sense SMT model.

In modeling the reordering, most of previous studies are on phrase level. In Moses, the lexical reordering is modeled on adjacent phrases. In (Wu, 1996; Xiong, 2006), the reordering is also modeled on adjacent translated phrases. In hiero, the reordering is modeled on the segments of the unmotivated translation rules. The tree-to-string models (Yamada et al. 2001; Liu et al.2006) are model on phrases with syntax representations. All these studies show excellent performance, while there are few studies on word level model in recent years. It is because, we consider, the alignment in word level model is complex which limits the reordering capacity of word level models.

However, our work exploits a new direction in reordering that, by utilizing the decomposed dependency relations mapped from parse tree as a soft constraint, we proposed a novel head-modifier relation based word level reordering model. The word level reordering model is based on a phrase based SMT framework. Thus, the task to find the proper position of translated words converts to score the reordering of the translated words, which relax the tension between complex alignment and word level reordering in MT.

9 Conclusion and Future Work

Experimental results show our head-modifier relationship base model is effective to the baseline (enhance by 1.48% bleu score), even with limited size of model and simple parameter estimation. In the future, we will try more complicated smooth methods or use maximum entropy based reordering model. We will study the performance with larger distortion constraint, such as the performances of the distortion constraint over 15, or even the performance without distortion model.

Abstract

Recent kernel-based PPI extraction systems achieve promising performance because of their capability to capture structural syntactic information, but at the expense of computational complexity. This paper incorporates dependency information as well as other lexical and syntactic knowledge in a feature-based framework. Our motivation is that, considering the large amount of biomedical literature being archived daily, feature-based methods with comparable performance are more suitable for practical applications. Additionally, we explore the difference of lexical characteristics between biomedical and newswire domains. Experimental evaluation on the AIMed corpus shows that our system achieves comparable performance of 54.7 in F1-Score with other state-of-the-art PPI extraction systems, yet the best performance among all the feature-based ones.

1 Introduction

In recent years, automatically extracting biomedical information has been the subject of significant research efforts due to the rapid growth in biomedical development and discovery. A wide concern is how to characterize protein interaction partners since it is crucial to understand not only the functional role of individual proteins but also the organization of the entire biological process. However, manual collection of relevant Protein-Protein Interaction (PPI) information from thousands of research papers published every day is so time-consuming that automatic extraction approaches with the help of Natural Language Processing (NLP) techniques become necessary.

Various machine learning approaches for relation extraction have been applied to the biomedical domain, which can be classified into two categories: feature-based methods (Mitsumori et al., 2006; Giuliano et al., 2006; Sætre et al., 2007) and kernel-based methods (Bunescu et al., 2005; Erkan et al., 2007; Airola et al., 2008; Kim et al., 2010).

Provided a large-scale manually annotated corpus, the task of PPI extraction can be formulated as a classification problem. Typically, for featured-based learning each protein pair is represented as a vector whose features are extracted from the sentence involving two protein names. Early studies identify the existence of protein interactions by using "bag-of-words" features (usually uni-gram or bi-gram) around the protein names as well as various kinds of shallow linguistic information, such as POS tag, lemma and orthographical features. However, these systems do not achieve promising results since they disregard any syntactic or semantic information altogether, which are very useful for the task of relation extraction in the newswire domain (Zhao and Grishman, 2005; Zhou et al., 2005). Furthermore, feature-based methods fail to effectively capture the structural information, which is essential to

* Corresponding author

Beijing, August 2010

identify the relationship between two proteins in a syntactic representation.

With the wide application of kernel-based methods to many NLP tasks, various kernels such as subsequence kernels (Bunescu and Mooney, 2005) and tree kernels (Li et al., 2008), are also applied to PPI detection.. Particularly, dependency-based kernels such as edit distance kernels (Erkan et al., 2007) and graph kernels (Airola et al., 2008; Kim et al., 2010) show some promising results for PPI extraction. This suggests that dependency information play a critical role in PPI extraction as well as in relation extraction from newswire stories (Culotta and Sorensen, 2004). In order to appreciate the advantages of both feature-based methods and kernel-based methods, composite kernels (Miyao et al., 2008; Miwa et al., 2009a; Miwa et al., 2009b) are further employed to combine structural syntactic information with flat word features and significantly improve the performance of PPI extraction. However, one critical challenge for kernel-based methods is their computation complexity, which prevents them from being widely deployed in real-world applications regarding the large amount of biomedical literature being archived everyday.

Considering the potential of dependency information for PPI extraction and the challenge of computation complexity of kernel-based methods, one may naturally ask the question: "Can the essential dependency information be maximally exploited in featured-based PPI extraction so as to enhance the performance without loss of efficiency?" "If the answer is Yes, then How?"

This paper addresses these problems, focusing on the application of dependency information to feature-based PPI extraction. Starting from a baseline system in which common lexical and syntactic features are incorporated using Support Vector Machines (SVM), we further augment the baseline with various features related to dependency information, including predicates in the dependency tree. Moreover, in order to reveal the linguistic difference between distinct domains we also compare the effects of various features on PPI extraction from biomedical texts with those on relation extraction from newswire narratives. Evaluation on the AIMed and other PPI corpora shows that our method achieves the best performance among all feature-based systems.

The rest of the paper is organized as follows. A feature-based PPI extraction baseline system is given in Section 2 while Section 3 describes our dependency-driven method. We report our experiments in Section 4, and compare our work with the related ones in Section 5. Section 6 concludes this paper and gives some future directions.

2 Feature-based PPI extraction: Baseline

For feature-based methods, PPI extraction task is re-cast as a classification problem by first transforming PPI instances into multi-dimensional vectors with various features, and then applying machine learning approaches to detect whether the potential relationship exists for a particular protein pair. In training, a feature-based classifier learning algorithm, such as SVM or MaxEnt, uses the annotated PPI instances to learn a classifier while, in testing, the learnt classifier is in turn applied to new instances to determine their PPI binary classes and thus candidate PPI instances are extracted.

As a baseline, various linguistic features, such as words, overlap, chunks, parse tree features as well as their combined ones are extracted from a sentence and formed as a vector into the feature-based learner.

1) Words

Four sets of word features are used in our system: 1) the words of both the proteins; 2) the words between the two proteins; 3) the words before M1 (the 1st protein); and 4) the words after M2 (the 2nd protein). Both the words before M1 and after M2 are classified into two bins: the first word next to the proteins and the second word next to the proteins. This means that we only consider the two words before M1 and after M2. Words features include:

- MW1: bag-of-words in M1
- MW2: bag-of-words in M2
- BWNULL: when no word in between
- BWO: other words in between except first and last words when at least three words in between
- BWM1FL: the only word before M1

- BWM1F: first word before M1
- BWM1L: second word before M1
- BWM1: first and second word before M1
- BWM2FL: the only word after M2
- BWM2F: first word after M2
- BWM2L: second word after M2
- BWM2: first and second word after M2

2) Overlap

The numbers of other protein names as well as the words that appear between two protein names are included in the overlap features. This category of features includes:

- #MB: number of other proteins in between
- #WB: number of words in between
- E-Flag: flag indicating whether the two proteins are embedded or not

3) Chunks

It is well known that chunking plays an important role in the task of relation extraction in the ACE program (Zhou et al., 2005). However, its significance in PPI extraction has not fully investigated. Here, the Stanford Parser[1] is first employed for full parsing, and then base phrase chunks are derived from full parse trees using the Perl script[2]. The chunking features usually concern about the head words of the phrases between the two proteins, which are further classified into three bins: the first phrase head in between, the last phrase head in between and other phrase heads in between. In addition, the path of phrasal labels connecting two proteins is also a common syntactic indicator of the polarity of the PPI instance, just as the path NP_VP_PP_NP in the sentence "*The ability of PROT1 to interact with the PROT2 was investigated.*" is likely to suggest the positive interaction between two proteins. These base phrase chunking features contain:

- CPHBNULL: when no phrase in between.
- CPHBFL: the only phrase head when only one phrase in between
- CPHBF: the first phrase head in between when at least two phrases in between.
- CPHBL: the last phrase head in between when at least two phrase heads in between.
- CPHBO: other phrase heads in between except first and last phrase heads when at least three phrases in between.
- CPP: path of phrase labels connecting the two entities in the chunking

Furthermore, we also generate a set of bi-gram features which combine the above chunk features except CPP with their corresponding chunk types.

4) Parse Tree

It is obvious that full pares trees encompass rich structural information of a sentence. Nevertheless, it is much harder to explore such information in featured-based methods than in kernel-based ones. Thus so far only the path connecting two protein names in the full-parse tree is considered as a parse tree feature.

- PTP: the path connecting two protein names in the full-parse tree.

Again, take the sentence "The ability of PROT1 to interact with the PROT2 was investigated." as an example, the parse path between PROT1 and PROT2 is NP_S_VP_PP_NP, which is slightly different from the CPP feature in the chunking feature set.

3 Dependency-Driven PPI Extraction

The potential of dependency information for PPI extraction lies in the fact that the dependency tree may well reveal non-local or long-range dependencies between the words within a sentence. In order to capture the necessary information inherent in the depedency tree for identifying their relationship, various kernels, such as edit distance kernel based on dependency path (Erkan et al., 2007), all-dependency-path graph kernel (Airola et al., 2008), and walk-weighted subsequence kernels (Kim et al., 2010) as well as other composite kernels (Miyao et al., 2008; Miwa et al., 2009a; Miwa et al., 2009b), have been proposed to address this problem. It's true that these methods achieve encouraging results, neverthless, they suffer from prohibitive computation burden.

1 http://nlp.stanford.edu/software/lex-parser.shtml
2 http://ilk.kub.nl/~sabine/chunklink/

Thus, our solution is to fold the structural dependency information back into flat features in a feature-based framework so as to speed up the learning process while retaining comparable performance. This is what we refer to as dependency-driven PPI extraction.

First, we construct dependency trees from grammatical relations generated by the Stanford Parser. Every grammatical relation has the form of *dependent-type* (*word1*, *word2*), Where *word1* is the head word, *word2* is dependent on *word1*, and *dependent-type* denotes the pre-defined type of dependency. Then, from these grammatical relations the following features called DependenecySet1 are taken into consideration as illustrated in Figure 1:

- DP1TR: a list of words connecting PROT1 and the dependency tree root.
- DP2TR: a list of words connecting PROT2 and the dependency tree root.
- DP12DT: a list of dependency types connecting the two proteins in the dependency tree.
- DP12: a list of dependent words combined with their dependency types connecting the two proteins in the dependency tree.
- DP12S: the tuple of every word combined with its dependent type in DP12.
- DPFLAG: a boolean value indicating whether the two proteins are directly dependent on each other.

The typed dependencies produced by the Stanford Parser for the sentence "PROT1 contains a sequence motif binds to PROT2." are listed as follows:

```
nsubj(contains-2,PROT1-1)
det(motif-5, a-3)
nn(motif-5, sequence-4)
nsubj(binds-6, motif-5)
ccomp(contains-2, binds-6)
prep_to(binds-6, PROT2-8)
```

Each word in a dependency tuple is followed by its index in the original sentence, ensuring accurate positioning of the head word and dependent word. Figure 1 shows the dependency tree we construct from the above grammatical relations.

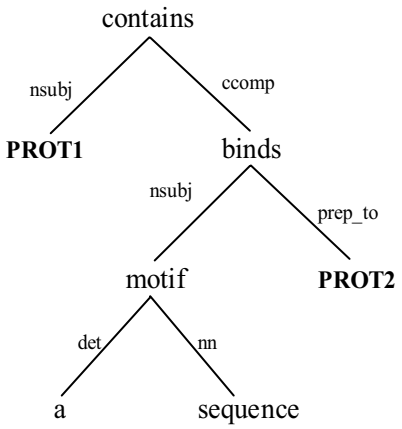

Figure 1: Dependency tree for the sentence "PROT1 contains a sequence motif binds to PROT2."

Erkan et al. (2007) extract the path information between PROT1 and PROT2 in the dependency tree for kernel-based PPI extraction and report promising results, neverthless, such path is so specific for feature-based methods that it may incure higher precision but lower recall. Thus we alleviate this problem by collapsing the feature into multiple ones with finer granularity, leading to the features such as DP12S.

It is widely acknowledged that predicates play an important role in PPI extraction. For example, the change of a pivot predicate between two proteins may easily lead to the polarity reversal of a PPI instance. Therefore, we extract the predicates and their positions in the dependency tree as predicate features called DependencySet2:

- FVW: the predicates in the DP12 feature occurring prior to the first protein.
- LVW: the predicates in the DP12 feature occurring next to the second entity.
- MVW: other predicates in the DP12 features.
- #FVW: the number of FVW
- #LVW: the number of LVW
- #MVW: the number of MVW

4 Experimentation

This section systematically evaluates our feature-based method on the AIMed corpus as well as other commonly used corpus and reports our experimental results.

4.1 Data Sets

We use five corpora[3] with the AIMed corpus as the main experimental data, which contains 177 Medline abstracts with interactions between two interactions, and 48 abstracts without any PPI within single sentences. There are 4,084 protein references and around 1,000 annotated interactions in this data set.

For corpus pre-procession, we first rename two proteins of a pair as PROT1 and PROT2 respectively in order to blind the learner for fair comparison with other work. Then, all the instances are generated from the sentences which contain at least two proteins, that is, if a sentence contains *n* different proteins, there are $\binom{n}{2}$ different pairs of proteins and these pairs are considered untyped and undirected. For the purpose of comparison with previous work, all the self-interactions (59 instances) are removed, while all the PPI instances with nested protein names are retained (154 instances). Finally, 1002 positive instances and 4794 negative instances are generated and their corresponding features are extracted.

We select Support Vector Machines (SVM) as the classifier since SVM represents the state-of-the-art in the machine learning research community. In particular, we use the binary-class SVMLigh [4] developed by Joachims (1998) since it satisfies our requirement of detecting potential PPI instances.

Evaluation is done using 10-fold document-level cross-validation. Particularly, we apply the extract same 10-fold split that was used by Bunescu et al. (2005) and Giuliano et al. (2006). Furthermore, OAOD (One Answer per Occurrence in the Document) strategy is adopted, which means that the correct interaction must be extracted for each occurrence. This guarantees the maximal use of the available data, and more important, allows fair comparison with earlier relevant work.

The evaluation metrics are commonly used Precision (P), Recall (R) and harmonic F1-score (F1). As an alternative to F1-score, the AUC (*area under the receiver operating characteristics curve*) measure is proved to be invariant to the class distribution of the training dataset. Thus we also provide AUC scores for our system as Airola et al. (2008) and Miwa et al. (2009a).

4.2 Results and Discussion

Features	P(%)	R(%)	F1
Baseline features			
Words	59.4	40.6	47.6
+Overlap	60.4	39.9	47.4
+Chunk	59.2	44.5	50.6
+Parse	60.9	44.8	51.4
Dependency-driven features			
+Dependency Set1	62.9	48.0	53.9
+Dependency Set2	**63.4**	**48.8**	**54.7**

Table 1: Performance of PPI extraction with various features in the AIMed corpus

We present in Table 1 the performance of our system using document-wise evaluation strategies and 10-fold cross-validation with different features in the AIMed corpus, where the plus sign before a feature means it is incrementally added to the feature set. Table 1 reports that our system achieves the best performance of 63.4/48.8/54.7 in P/R/F scores. It also shows that:

- Words features alone achieve a relatively low performance of 59.4/40.9/47.6 in P/R/F, particularly with fairly low recall score. This suggests the difficulty of PPI extraction and words features alone can't effectively capture the nature of protein interactions.
- Overlap features slightly decrease the performance. Statistics show that both the distributions of #MB and #WB between positives and negatives are so similar that they are by no means the discriminators for PPI extraction. Hence, we exclude the overlap features in the succeeding experiments.
- Chunk features significantly improves the F-measure by 3 units largely due to the increase of recall by 3.9%, though at the slight expense of precision. This suggests the effectiveness of shallow parsing information in the form of headwords captured by chunking on PPI extraction.
- The usefulness of the parse tree features is quite limited. It only improves the F-measure by 0.8 units. The main reason may be that these paths are usually long

and specific, thus they suffer from the problem of data sparsity. Furthermore, some of the parse tree features are already involved in the chunk features.

- The DependencySet1 features are very effective in that it can increase the precision and recall by 2.0 and 3.2 units respectively, leading to the increase of F1 score by 2.5 units. This means that the dependency-related features can effectively retrieve more PPI instances without introducing noise that will severely harm the precision. According to our statistics, there are over 60% sentences with more than 5 words between their protein entities in the AIMed corpus. Therefore, dependency information exhibit great potential to PPI extraction since they can capture long-range dependencies within sentences. Take the aforementioned sentence "PROT1 contains a sequence motif binds to PROT2." as an example, although the two proteins step over a relatively long distance, the dependency path between them is concise and accurate, reflecting the essence of the interaction.
- The predicate features also contribute to the F1-score gain of 0.8 units. It is not surprising since some predicates, such as "interact", "activate" and "inhibit" etc, are strongly suggestive of the interaction polarity between two proteins.

We compare in Table 2 the performance of our system with other systems in the AIMed corpus using the same 10-fold cross validation strategy. These systems are grouped into three distinct classes: feature-based, kernel-based and composite kernels. Except for Airola et al. (2008) Miwa et al. (2009a) and Kim et al. (2010), which adopt graph kernels, our system performs comparably with other systems. In particular, our dependency-driven system achieves the best F1-score of 54.7 among all feature-based systems.

In order to measure the generalization ability of our dependency-driven PPI extraction system across different corpora, we further apply our method to other four publicly available PPI corpora: BioInfer, HPRD50, IEPA and LLL.

Systems	P(%)	R(%)	F1
Feature-based methods			
Our system	63.4	48.8	54.7
Giuliano et al., 2006[5]	60.9	57.2	59.0
Sætre et al., 2007	64.3	44.1	52.0
Mitsumori et al., 2006	54.2	42.6	47.7
Yakushiji et al., 2005	33.7	33.1	33.4
Kernel-based methods			
Kim et al., 2010	61.4	53.3	56.7
Airola et al., 2008	52.9	61.8	56.4
Bunescu et al., 2006	65.0	46.4	54.2
Composite kernels			
Miwa et al., 2009a	-	-	62.0
Miyao et al., 2008[6]	51.8	58.1	54.5

Table 2: Comparison with other PPI extraction systems in the AIMed corpus

The corresponding performance of F1-score and AUC metrics as well as their standard deviations is present in Table 3. Comparative available results from Airola et al. (2008) and Miwa et al. (2009a) are also included in Table 3 for comparison. This table shows that our system performs almost consistently with the other two systems, that is, the LLL corpus gets the best performance yet with the greatest variation, while the AIMed corpus achieves the lowest performance with reasonable variation.

It is well known that biomedical texts exhibit distinct linguistic characteristics from newswire narratives, leading to dramatic performance gap between PPI extraction and relation detection in the ACE corpora. However, no previous work has ever addressed this problem and empirically characterized this difference. In this paper, we devise a series of experiments over the ACE RDC corpora using our dependency-driven feature-based method as a touchstone task. In order to do that, a sub-

[5] Airola et al. (2008) repeat the method published by Giuliano et al. (2006) with a correctly preprocessed AIMed and reported an F1-score of 52.4%.

[6] The results from Table 1 (Miyao et al., 2009) with the most similar settings to ours (Stanford Parser with SD representation) are reported.

set of 5796 relation instances is randomly sampled from the ACE 2003 and 2004 corpora respectively. The same cross-validation and evaluation metrics are applied to these two sets as PPI extraction in the AIMed corpus.

	Our system				Airola et al. (2008) [7]				Miwa et al. (2009a)			
Corpus	F1	σ_{F1}	AUC	σ_{AUC}	F1	σ_{F1}	AUC	σ_{AUC}	F1	σ_{F1}	AUC	σ_{AUC}
AIMed	54.7	4.5	82.4	3.5	56.4	5.0	84.8	2.3	60.8	6.6	86.8	3.3
BioInfer	59.8	3.5	80.9	3.3	61.3	5.3	81.9	6.5	68.1	3.2	85.9	4.4

Table 4: Comparison of contributions of different features to relation detection across multiple domains

Table 4 compares the performance of our method over different domains. The table reports that the words features alone achieve the best F1-score of 63.4 in ACE2004 but the lowest F1-score of 47.6 in AIMed. This suggests the wide difference of lexical distribution between these domains. We extract the words appearing before the 1st mention, between the two mentions and after the 2nd mention from the training sets of these corpora respectively, and summarize the statistics (the number of tokens, the number of occurrences) in Table 5, where the KL divergence between positives and negatives is summed over the distribution of the 500 most frequently occurring words.

Statistics	AIMed	ACE2003	ACE2004
# of tokens	2,340	2,064	2,099
# of occurrences	69,976	53,744	49,570
KL divergence	0.22	0.28	0.33

Table 5: Lexical statistics on three corpora

The table shows that AIMed uses the most kinds of words and the most words around the two mentions than the other two. More important, AIMed has the least distribution difference between the words appearing in positives and negatives, as indicated by its least KL divergence. Therefore, the lexical words in AIMed are less discriminative for relation detection than they do in the other two. This naturally explains the reason why the performance by words feature alone is AIMed<ACE2003<ACE2004. In addition, Table 4 also shows that:

- The overlap features significantly improve the performance in ACE while slightly deteriorating that in AIMed. The reason is that, as indicated in Zhou et al. (2005), most of the positive relation instances in ACE exist in local contexts, while the positive interactions in AIMed occur in relative long-range just as the negatives, therefore these features are not discriminative for AIMed.
- The chunk features consistently greatly boost the performance across multiple corpora. This implies that the headwords in chunk phrases can well capture the partial nature of relation instances regardless of their genre.
- It's not surprising that the parse feature attain moderate performance gain in all domains since these parse paths are usually

[7] The performance results of F1 and AUC on the BioInfer corpus are slightly adjusted according to Table 3 in Miwa et al. (2009b)

long and specificity, leading to data sparseness problem.

- It is interesting to note that the dependency-related features exhibit more significant improvement in AIMed than that in ACE. The reason may be that, these dependency features can effectively capture long-range relationships prevailing in AIMed, while in ACE a large number of local relationships dominate the corpora.

5 Related Work

Among feature-based methods, the PreBIND system (Donaldson et al., 2003) uses words and word bi-grams features to identify the existence of protein interactions in abstracts and such information is used to enhance manual expert reviewing for the BIND database. Mitsumori et al. (2006) use SVM to extract protein-protein interactions, where bag-of-words features, specifically the words around the protein names, are employed. Sugiyama et al. (2003) extract various features from the sentences based on the verbs and nouns in the sentences such as the verbal forms, and the part-of-speech tags of the 20 words surrounding the verb. In addition to word features, Giuliano et al. (2006) extract shallow linguistic information such as POS tag, lemma, and orthographic features of tokens for PPI extraction. Unlike our dependency-driven method, these systems do not consider any syntactic information.

For kernel-based methods, there are several systems which utilize dependency information. Erkan et al. (2007) defines similarity functions based on cosine similarity and edit distance between dependency paths, and then incorporate them in SVM and KNN learning for PPI extraction. Airola et al. (2008) introduce all-dependency-paths graph kernel to capture the complex dependency relationships between lexical words and attain significant performance boost at the expense of computational complexity. Kim et al. (2010) adopt walk-weighted subsequence kernel based on dependency paths to explore various substructures such as e-walks, partial match, and non-contiguous paths. Essentially, their kernel is also a graph-based one.

For composite kernel methods, Sætre et al. (2007) combine a "bag-of-words" kernel with dependency and PAS (Predicate Argument Structure) tree kernels to exploit both the words features and the structural syntactic information. Hereafter, Miyao et al. (2008) investigate the contribution of various syntactic features using different representations from dependency parsing, phrase structure parsing and deep parsing by different parsers. Miwa et al. (2009a) integrate "bag-of-words" kernel, PAS tree kernel and all-dependency-paths graph kernel to achieve the higher performance. They (Miwa et al., 2009b) also use similar composite kernels for corpus weighting learning across multiple PPI corpora.

6 Conclusion and Future Work

In this paper, we have combined various lexical and syntactic features, particularly dependency information, into a feature-based PPI extraction system. We find that the dependency information as well as the chunk features contributes most to the performance improvement. The predicate features involved in the dependency tree can also moderately enhance the performance. Furthermore, comparative study between biomedical domain and the ACE newswire domain shows that these domains exhibit different lexical characteristics, rendering the task of PPI extraction much more difficult than that of relation detection from the ACE corpora.

In future work, we will explore more syntactic features such as PAS information for feature-based PPI extraction to further boost the performance.

Abstract

In this paper, we propose a review selection approach towards accurate estimation of feature ratings for services on participatory websites where users write textual reviews for these services. Our approach selects reviews that comprehensively talk about a feature of a service by using information distance of the reviews on the feature. The rating estimation of the feature for these selected reviews using machine learning techniques provides more accurate results than that for other reviews. The average of these estimated feature ratings also better represents an accurate overall rating for the feature of the service, which provides useful feedback for other users to choose their satisfactory services.

1 Introduction

Most of participatory websites such as Amazon (amazon.com) do not collect from users feature[1] ratings for services, simply because it may cost users too much effort to provide detailed feature ratings. Even for a very few websites that do collect feature ratings such as a popular travel website TripAdvisor (tripadvisor.com), a big portion (approximately 43%) of users may still not provide them. However, feature ratings are useful for users to make informed consumption decisions especially in the case where users may be interested more in some particular features of the services. Machine learning techniques have been proposed for sentiment classification (Pang et al., 2002; Mullen and Collier, 2004) based on annotated samples from experts, but they have limited performance especially when estimating ratings of a multi-point scale (Pang and Lee, 2005).

In this paper, we propose a novel review selection approach for accurate feature rating estimation. More specifically, our approach selects reviews written by the users who comprehensively talk about a certain feature of a service - that are comprehensive on this feature, using information distance of reviews on the feature based on Kolmogorov complexity (Li and Vitányi, 1997). This feature is obviously important to the users. People tend to be more knowledgable in the aspects they consider important. These users therefore represent a subset of experts. Statistical analysis reveals that these expert users are more likely to agree on a common rating for the feature of the service. The rating estimation of the feature for these selected reviews based on annotated samples from experts using machine learning techniques is thus able to provide more accurate results than that for other reviews. This statistical evidence also allows us to use the average of the estimated feature ratings to better represent an overall opinion of experts for the feature of the service, which will be particularly useful for assisting other users to correctly make their consumption decisions.

We verify our approach and arguments based on real data collected from the TripAdvisor website. First, our approach is shown to be able to effectively select reviews that comprehensively talk about features of a service. We then adopt the machine learning method proposed in (Pang and Lee, 2005) and the Bayesian Network classifier (Russell and Norvig, 2002) for feature rating estimation. Our experimental results show that the accuracy of estimating feature ratings for these selected reviews is higher than that for other reviews, for both the machine learning

[1]A feature broadly means an attribute or a function of a service.

Coling 2008: Poster Volume, pages 766–774,
Beijing, August 2010

methods. And, the average of these estimated ratings is testified to closely represent the overall feature rating of the service. Our approach is therefore verified to be a successful step towards accurate feature rating estimation.

2 Related Work

Our work aims at estimating feature ratings of a service based on its textual reviews. It is related to sentiment classification. The task of sentiment classification is to determine the semantic orientations of words, sentences or documents. (Pang et al., 2002) is the earliest work of automatic sentiment classification at document level, using several machine learning approaches with common textual features to classify movie reviews. Mullen and Collier (Mullen and Collier, 2004) integrated PMI values, Osgood semantic factors and some syntactic relations into the features of SVM. Pang and Lee (Pang and Lee, 2004) proposed another machine learning method based on subjectivity detection and minimum-cut in graph. However, these approaches focus only on binary classification of reviews.

In 2005, Pang and Lee extended their earlier work in (Pang and Lee, 2004) to determine a reviewer's evaluation with respect to multi-scales (Pang and Lee, 2005). The rating estimation is viewed as multi-class sentiment categorization on documents. They used SVM regression as the multi-class classifier, and also applied a meta-algorithm based on a metric labeling formulation of the problem, which alters a given n-ary classifier's output in an explicit attempt to ensure that similar items receive similar labels. They collected movie reviews from a website named IMDB and tested the performance of their classifier under both four-class and five-class categorization. The five-class sentiment classification is adopted in the evaluation of our method (see Section 5). The performance of their approach is limited. One important reason is that their method considers every review when estimating a feature rating of a movie. However, some reviews do not contain much of the users' opinions about a certain feature simply because the users do not care much or are not knowledgable about the feature. In our work, we study the characteristics of reviews' feature ratings. We investigate which reviews are more useful for us to estimate feature ratings. From some observations stated in the next section, we will see that reviews written by different users reflect their own preferred features of a service.

3 Accurate Feature Rating Estimation

Participatory websites allow users to write textual reviews to discuss features of services that they have consumed. These reviews usually contain words that strongly express the users' opinions about the corresponding features. These words contain important information for estimating a numerical rating for the feature. The estimated ratings can be used for assisting other users when they need to choose which services to consume. Machine learning techniques are often used for training a learner based on annotated samples from experts and estimating a rating for a feature discussed in a review. However, for a review that does not mention a feature or discusses it only in a limited sense, the estimation accuracy is expected to be very low. Besides, the opinion expressed by the user who writes this kind of review is not representative because this user obviously does not care much about the feature. We believe that if we carefully select reviews for estimating feature ratings, the accuracy will be increased and the estimated ratings will be more representative.

We then statistically analyze real data collected from the TripAdvisor website. The results reveal that users who comprehensively discuss a feature of a service in their reviews are more likely to agree on a common rating for this feature of the service. This phenomenon can also be intuitively explained as follows. For the users who comprehensively discuss about a feature, the feature is obviously more important to them. People tend to be more knowledgable in the aspects they consider important. These users therefore represent a subset of experts. Experts likely provide more objective and representative feedback about the feature, and therefore the ratings from them for the feature contain less noise and

are more similar.

Based on the above discussion that experts tend to have similar opinions on a feature of a service, a learner trained by a machine learning technique based on annotated samples from experts should then be able to more accurately estimate the feature ratings from reviews written by other experts. Since the opinions of experts converge, the average of the estimated feature ratings also better represents an overall rating for the feature of the service.

We propose a review selection approach using information distance of reviews on the feature based on Kolmogorov complexity, to select reviews that comprehensively discuss a feature of a service. We rank the reviews based on the comprehensiveness on the feature. The top reviews will be selected for the estimation of feature ratings. Also, the average of these estimated feature ratings will be used for representing the overall rating for the feature. Next, we will first describe in detail how our approach selects comprehensive reviews on a given feature.

4 Our Review Selection Approach

Our review selection approach selects reviews that comprehensively talk about a feature. According to this definition, a review's comprehensiveness depends on the amount of information discussed on a feature. We use Kolmogorov complexity and information distance to measure the amount of information. Kolmogorov complexity was introduced almost half a century ago by R. Solomonoff, A.N. Kolmogorov and G. Chaitin, see (Li and Vitányi, 1997). It is now widely accepted as an information theory for individual objects parallel to that of Shannon's information theory which is defined on an ensemble of objects.

4.1 Theory

Fix a universal Turing machine U. The Kolmogorov complexity (Li and Vitányi, 1997) of a binary string x condition to another binary string y, $K_U(x|y)$, is the length of the shortest (prefix-free) program for U that outputs x with input y. It can be shown that for different universal Turing machine U', for all x, y

$$K_U(x|y) = K_{U'}(x|y) + C,$$

where the constant C depends only on U'. Thus $K_U(x|y)$ can be simply written as $K(x|y)$. They write $K(x|\epsilon)$, where ϵ is the empty string, as $K(x)$. It has also been defined in (Bennett et al., 1998) that the energy to convert between x and y to be the smallest number of bits needed to convert from x to y and vice versa. That is, with respect to a universal Turing machine U, the cost of conversion between x and y is:

$$E(x, y)=\min\{|p|: U(x, p)=y,\ U(y, p)=x\} \quad (1)$$

It is clear that $E(x, y) \leq K(x|y) + K(y|x)$. From this observation, the following theorem has been proved in (Bennett et al., 1998):

Theorem 1 $E(x, y) = \max\{K(x|y), K(y|x)\}$.

Thus, the max distance was defined in (Bennett et al., 1998):

$$D_{\max}(x, y) = \max\{K(x|y), K(y|x)\}. \quad (2)$$

This distance is shown to satisfy the basic distance requirements such as positivity, symmetricity, triangle inequality and is admissible.

Here for an object x, we can measure its information by Kolmogorov complexity $K(x)$; for two objects x and y, their shared information can be measured by information distance $D(x, y)$. In (Long et al., 2008), the authors generalize the theory of information distance to more than two objects. Similar to Equation 1, given strings $x_1, \ldots, x_n$, they define the minimum amount of thermodynamic energy needed to convert from any x_i to any x_j as:

$$E_m(x_1, .., x_n)=\min\{|p|:U(x_i, p, j)=x_j \text{ for all } i,j\}$$

Then it is proved in (Long et al., 2008) that:

Theorem 2 *Modulo to an $O(\log n)$ additive factor,*

$$\min_i K(x_1 \ldots x_n|x_i) \leq E_m(x_1, \ldots, x_n)$$

Given n objects, the left-hand side of Equation 3 may be interpreted as the most comprehensive object that contains the most information about all of the others.

4.2 Review Selection Method

Our review selection method is based on the information distance discussed in the previous section. However, our problem is that neither the Kolmogorov complexity $K(\cdot,\cdot)$ nor $D_{max}(\cdot,\cdot)$ is computable. Therefore, we find a way to "approximate" these two measures. The most useful information in a review article is the English words that are related to the features. If we can extract all of these related words from the review articles, the size of the word set can be regarded as a rough estimation of information content (or Kolmogorov complexity) of the review articles. In Section 5 we will see that this gives very good practical results.

4.2.1 Outline

Our method is outlined in the following. First, for each type of product or service (such as a hotel), a small set of core feature words (such as price and room) is generated through statistics. Then, these feature words are used to generate the expanded words. Third, a parser is used to find the dependent words associated with the occurrence of the core feature words and expanded words in a review. For each review-feature pair, the union of the core feature words, expanded words and dependent words in the review defines the related word set of the review on the feature. Lastly, information distance is used to select the most comprehensive reviews on a feature.

4.2.2 Word Extraction

Feature words are the most direct and frequent words describing a feature, for example, price, room or service of a hotel. Given a feature, the core feature words are the very few most common English words that are used to refer to that feature. For example, both "value" and "price" are used to refer to the same feature of a hotel. In (Hu and Liu, 2004), the authors indicate that when customers comment on product features, the words they use converge. If we remove the feature words with frequency lower than 1% of the total frequency of all feature words, the remaining words, which are just core feature words, can still cover more than 90% occurrences. So firstly we extract those words through statistics; then some of those with the same meaning (such as "value" and "price") are grouped into one feature. They are just "core feature words".

Apart from core feature words, many other less-frequently used words that are connected to the feature also contribute to the information content of the feature. For example, "price" is an important feature of a hotel, but the word "price" is usually dropped from a sentence. Instead, words such as "$", "dollars", "USD", and "CAD" are used. We use information distance $d(.,.)$ based on Google to expand words (Cilibrasi and Vitányi, 2007). Let α be a feature and $\mathcal{A}$ be the set of its core feature words. The distance between a word w and the feature α is then defined to be

$$d(w,\alpha) = \min_{v\in\mathcal{A}} d(w,v)$$

A distance threshold is then used to determine which words should be in the set of expanded words for a given feature.

If a core feature word or an expanded word is found in a sentence, the words which have grammatical dependent relationship with it are called the dependent words (de Marneffe et al., 2006). For example, in sentence "It has a small, but beautiful room", the words "small" and "beautiful" are both dependent words of the core feature word "room". All these words also contribute to the reviews and are important to determine the reviewer's attitude towards a feature.

The Stanford Parser (de Marneffe et al., 2006) is used to parse each review. For review i and feature j, the core feature words and expanded words in the review are first computed. Then the parsing result is examined to find all the dependent words for the core feature words and expanded words, all of which are called "related words".

4.2.3 Computing Information Distance

If there are m reviews $x_1, x_2, \ldots, x_m$, n features $u_1, u_2, \ldots, u_n$, and the related word set S_i is defined to be the union of all the related words that occur in the review x_i. From the left-hand side of Equation 3, the most comprehensive x_i

on feature u_k is such that

$$i = \arg\min_i K(S_1 \dots S_n | S_i, u_k). \quad (3)$$

Let S_i and S_j be two sets of words,

$$K(S_i S_j | u_k) = K(S_i \cup S_j | u_k),$$

$$K(S_i | S_j, u_k) = K(S_i \setminus S_j | u_k),$$

and

$$K(S_i|u_k) = \sum_w K(w|u_k) \approx \sum_w (K(w, u_k) - K(u_k))$$

where $w \in S_i$ and w is in x_i's related word set on feature u_k. For each word w in a set S, the Kolmogorov complexity can be estimated through coding theorem (Li and Vitányi, 1997):

$$K(w, u_k) = -\log P(w, u_k), \;\; K(u_k) = -\log P(u_k)$$

where $P(w, u_k)$ can be estimated by $df(w, u_k)$, which is the document frequency of word w and feature u_k co-exist on the whole corpus. Similarly, $P(u_k)$ can be estimated by feature u_k's document frequency on the corpus. In the next section, Equation 3 will be used to select reviews that comprehensively talk about a feature.

5 Experimental Verification

In this section, we present a set of experimental results to support our work. Our experiments are carried out using real data collected from the travel website TripAdvisor. This website indexes hotels from cities across the world. It collects feedback from travelers. Feedback of each traveler consists of a textual review written by the traveler and numerical ratings (from 1, lowest, to 5, highest) for different features of hotels (e.g., value, service, rooms).

Table 1: Summary of the Data Set

Location	# Hotels	# Feedback	# Feedback with feature rating
Boston	57	3949	2096
Sydney	47	1370	879
Vegas	40	5588	3144

We crawled this website to collect travelers' feedback for hotels in three cities: Boston, Sydney and Las Vegas. Note that during this crawling process, we carefully removed information about travelers and hotels to protect their privacy. For users' feedback, we recorded only the textual reviews and the numerical ratings on four features: Value(V), Rooms(R), Service(S) and Cleanliness(C). These features are rated by a significant number of users. Table 1 summarizes our data set. For each one of the cities, this table contains information about the number of hotels, the total amount of feedback and the amount of feedback with feature ratings. In general, each hotel has sufficient amount of feedback with feature ratings for us to evaluate our work.

Table 2: Comprehensive Reviews on Each Feature (Boston)

Top #	V	R	S	C
1	Y	Y	Y	Y
2	Y	Y	Y	Y
3	N	Y	Y	N
4	Y	Y	Y	N
5	Y	Y	Y	Y
6	Y	Y	N	Y
⋮	⋮	⋮	⋮	⋮

5.1 Evaluation of Review Selection

We first evaluate the performance of our review selection approach using manually annotated data. More specifically, in our data set, for one city, 40 reviews (120 reviews in total) are selected for manual annotation. The annotator looks over each review and decides whether the review is comprehensive on a given feature. Comprehensive reviews on the feature are annotated as "Y", and the reviews that are not comprehensive on this feature are annotated as "N". For the review set of each city, the number of reviews annotated as comprehensive is equal to or less than 20% of the total number of the selected reviews for this city (eight in this experiment). Note that it is possible that one review can be comprehensive on more than one features.

We then use our review selection approach

discussed in Section 4 to rank the reviews for hotels in each city, according to their comprehensiveness on each feature. For example, the most comprehensive review on the feature "Value", which has the minimal information distance to this feature (see Equation 3), is ranked No.1. Table 2 shows the annotated reviews for Boston hotels that are ranked on top six on each feature. It can be obviously seen from the table that most of these top reviews are labeled as comprehensive reviews on respective features. Our comprehensive review selection approach generally performs well.

Table 3: Performance of Comprehensive Review Selection

City	Feature	Precision	Recall	F-Score
Boston	V	0.833	0.714	0.769
	R	1.000	0.875	0.933
	S	0.857	1.000	0.923
	C	0.833	1.000	0.909
Sydney	V	0.667	1.000	0.800
	R	0.600	0.857	0.706
	S	0.667	0.857	0.750
	C	0.750	1.000	0.857
Vegas	V	0.778	1.000	0.875
	R	0.727	1.000	0.842
	S	0.714	0.714	0.714
	C	0.667	0.800	0.727

To clearly present the performance of our comprehensive review selection approach, we use the measures of precision, recall and f-score. The measure f-score is a single value that can represent the result of our evaluation. It is the harmonic mean of precision and recall. Suppose there are n reviews in total. Let p_{jk} $(1 \leq k \leq n)$ be the review ranked the kth comprehensive on feature j. Define

$$z_{jk} = \begin{cases} 1 & \text{if } p_{jk} \text{ is labelled comprehensive on } j; \\ 0 & \text{otherwise.} \end{cases}$$

The precision P, recall R, and f-score F of top k comprehensive reviews on feature j are formalized as follows

$$P_{jk} = \frac{\sum_{l=1}^{k} z_{jl}}{k}, R_{jk} = \frac{\sum_{l=1}^{k} z_{jl}}{\sum_{l=1}^{N} z_{jl}},$$

$$F_{jk} = \frac{2P_{jk}R_{jk}}{P_{jk} + R_{jk}}$$

For each ranked review set on feature j, the maximum F_{jk} and its associated P_{jk} and R_{jk} are listed in Table 3. From this table, it can be seen that for the best f-scores, the precision and recall values are mostly larger than 70%, that is, a great part of reviews that are labeled as comprehensive receive top rankings from our comprehensive review selection approach. Our approach is thus carefully verified to be able to accurately select comprehensive reviews on any given feature.

5.2 Statistical Analysis

A group of users who comprehensively discuss a certain feature are more likely to agree on a common rating for that feature. In this experiment, we use our review selection approach to verify this argument.

Table 4: Deviation of Feature Ratings

City	Feature	20%	50%	All
Boston	V	0.884 (0.0003)	1.030	1.136
	R	0.940 (0.2248)	1.037	1.013
	S	1.026 (0.0443)	1.130	1.144
	C	0.798 (0.0093)	0.892	0.949
Sydney	V	0.862 (0.0266)	1.009	1.054
	R	0.788 (0.0497)	0.932	0.945
	S	0.941 (0.0766)	1.162	1.116
	C	0.651 (0.0037)	0.905	0.907
Vegas	V	0.845 (0.0002)	1.236	1.291
	R	1.105 (0.2111)	1.148	1.175
	S	1.112 (0.0574)	1.286	1.269
	C	0.936 (0.0264)	1.096	1.158

More specifically, for each city, hotels that receive no less than 10 reviews with feature ratings are selected. We use our comprehensive review selection approach to select top 20% and 50% comprehensive reviews on each feature for hotels in each city. We calculate the standard deviation of their feature ratings, as well as that of all feature ratings, for each hotel in a city. We then average these standard deviations over the hotels in the same city. The average values are listed in Table 4. The feature ratings of comprehensive reviews on the feature have smaller average stan-

dard deviations. Standard T-test is used to measure the significance of the results between top 20% comprehensive reviews and all reviews, city by city and feature by feature. Their p-values are shown in the braces, and they are significant at the standard 0.05 significance threshold. It can be seen from the table that although for some items there does not seem to be a significant difference, the results are significant for the entire data set.

Therefore, when these travelers write reviews that are comprehensive on one feature, their ratings for this feature tend to converge. This evidence indicates that the estimation of ratings for the feature from these comprehensive reviews can provide better results, which will be confirmed in Section 5.3. These estimated feature ratings can also be averaged to represent a specific opinion of these travelers on the feature, which will be verified in Section 5.4.

5.3 Feature Rating Estimation

In this section, we carry out experiments to testify that the estimation of feature ratings for comprehensive reviews using our review selection approach provides better performance than that for all reviews. We adopt the approach of Pang and Lee (Pang and Lee, 2005) described in Section 2 for feature rating estimation. In short, they applied a meta-algorithm, based on a metric labeling formulation of the problem to alter a given n-ary SVM's output in an explicit attempt. We also adopt a Baysian Network classifier for feature rating estimation.

Similar to the method of Pang and Lee, we build up a feature rating classification system to estimate reviews' feature ratings. However, the method of Pang and Lee focuses only on single rating classification for a review and assumes that every word of the review can contribute to this single rating. While it comes to feature rating classification, the system has to decide which terms or phrases in the review are talking about this feature. We train a Naive Bayes classifier to retrieve all the sentences related to a feature. Then all the core feature words, expanded words and dependent words are extracted to train a SVM classifier and the Bayesian Network classifier for five-class classification (1 to 5). The eight-fold cross-validation is used to train and test the performance of feature rating estimation on all the reviews and the top 20% comprehensive reviews, respectively.

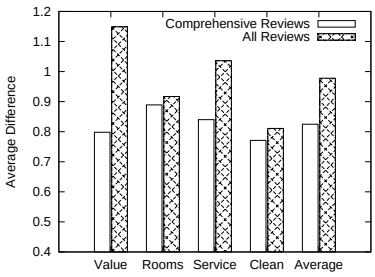

Figure 1: Average Error of Feature Rating Estimation for the Adopted Method of Pang and Lee

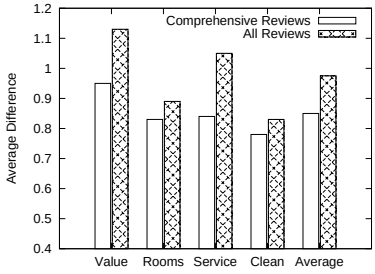

Figure 2: Average Error of Feature Rating Estimation for the Bayesian Network classifier

We formalize a performance measure as follows. Suppose there are n reviews in total. For a test review i ($1 \leq i \leq n$), its real feature rating (given by the review writer) is f_i, and its predicated feature rating (predicted by our classification system) is g_i. Both f_i and g_i are integers between 1 and 5. The performance of the classification on all n reviews can be measured by the average of the absolute difference (d) between each f_i and g_i pair,

$$d = \frac{\sum_{i=1}^{n} |f_i - g_i|}{n}. \quad (4)$$

The lower d is, the better performance the classifier can provide.

Figures 1 and 2 show the results for the performance of feature rating estimation on all reviews versus that on selected comprehensive reviews,

for the adopted approach of Pang and Lee and the Baysian Network classifier respectively. It can be seen that the average difference between real feature ratings and estimated feature ratings on each feature when using selected comprehensive reviews is significantly lower than that when using all reviews, for both the approaches. On average, the performance of feature rating estimation is improved by more than 12.5% using our review selection approach. And, our review selection approach is generally applicable to different classifiers.

5.4 Estimating Overall Feature Rating

Supported by the statistical evidence verified in Section 5.2 that the users who write comprehensive reviews on one feature will more likely agree on a common rating for this feature, we can then use an average of the feature ratings for top 20% comprehensive reviews to reflect a general opinion of knowledgable/expert users. In this section, we show directly the performance of estimating an overall feature rating for a hotel using ratings for the selected comprehensive reviews, and compare it with that for all reviews.

Table 5: Performance of Estimating Overall Feature Rating for Comprehensive Reviews

City	V	R	S	C	AVG
Boston	0.637	0.426	0.570	0.660	0.573
Sydney	0.273	0.729	0.567	0.680	0.562
Vegas	0.485	0.502	0.277	0.613	0.469
Average	0.465	0.552	0.471	0.651	0.535

Table 6: Performance of Estimating Overall Feature Rating for All reviews

City	V	R	S	C	AVG
Boston	0.809	0.791	0.681	0.642	0.731
Sydney	0.433	0.886	0.588	0.593	0.625
Vegas	0.652	0.733	0.502	0.942	0.707
Average	0.631	0.803	0.590	0.726	0.688

Suppose there are m hotels. For each hotel j, we first select the top 20% comprehensive reviews on each feature using our review selection approach. We average the real ratings of one feature provide by travelers for these reviews, denoted as $\bar{f}_j$. We then estimate the feature ratings for these comprehensive reviews using the adopted machine learning method of Pang and Lee. The average of these estimated ratings is denoted as $\bar{g}_j$. Similar to Equation 4, the average difference between all $\bar{f}_j$ and $\bar{g}_j$ pairs on each feature for hotels in each city are calculated and listed in Table 5. From this table, we can see that the average difference between the estimated average feature rating and real average feature rating is only about 0.53. Our review selection approach produces fairly good performance for estimating an overall feature rating for a hotel. We then also calculate the average difference for all reviews. The results are listed in Table 6. We can see that the average difference is larger (about 0.69) in this case. The performance of estimating an overall feature rating is increased by nearly 23.2% through our review selection approach.

6 Conclusion

In this paper, we presented a novel review selection approach to improve the accuracy of feature rating estimation. We select reviews that comprehensively talk about a feature of one service, using information distance of reviews on the feature based on Kolmogorov complexity. As evaluated using real data, the rating estimation for the feature from these reviews provides more accurate results than that for other reviews, independent of which classifiers are used. The average of these estimated feature ratings also better represents an accurate overall rating for the feature of the service.

In future work, we will further improve the accuracy of estimating a general rating for a feature of a service based on the selected comprehensive reviews on this feature using our review selection approach. Comprehensive reviews may contribute differently to the estimation of an overall feature rating. In our next step, a more sophisticated model will be developed to assign different weights to these different reviews.

Connective-Based Measuring of the Inter-Annotator Agreement in the Annotation of Discourse in PDT

Institute of Formal and applied Linguistics
{mirovsky,mladova,zikanova}@ufal.mff.cuni.cz

Abstract

We present several ways of measuring the inter-annotator agreement in the ongoing annotation of semantic inter-sentential discourse relations in the Prague Dependency Treebank (PDT). Two ways have been employed to overcome limitations of measuring the agreement on the exact location of the start/end points of the relations. Both methods – skipping one tree level in the start/end nodes, and the connective-based measure – are focused on a recognition of the existence and of the type of the relations, rather than on fixing the exact positions of the start/end points of the connecting arrows.

1 Introduction

1.1 Prague Dependency Treebank 2.0

The Prague Dependency Treebank 2.0 (PDT 2.0; Hajič et al., 2006) is a manually annotated corpus of Czech. It belongs to the most complex and elaborate linguistically annotated treebanks in the world. The texts are annotated on three layers of language description: morphological, analytical (which expresses the surface syntactic structure), and tectogrammatical (which expresses the deep syntactic structure). On the tectogrammatical layer, the data consist of almost 50 thousand sentences.

For the upcoming release of PDT, many additional features are planned, coming as results of several projects. Annotation of semantic inter-sentential discourse relations is one of the planned additions.

To ensure the highest possible quality of the annotated data, it would be best if several annotators annotated the whole data in parallel. After solving discrepancies in the annotations of the individual annotators, we would get a high-quality annotation. This approach is sometimes employed, but most of the times, the available resources prohibit it (which is also the case of the discourse annotation project). Manual annotation of data is a very expensive and time consuming task. To overcome the restriction of limited resources, each part of the data is annotated by one annotator only, with the exception of a small overlap for studying and measuring the inter-annotator (dis-)agreement.

1.2 Inter-Annotator Agreement in Computational Linguistics

Measuring the inter-annotator agreement has long been studied (not only) in computational linguistics. It is a complex field of research and different domains require different approaches.

Classical measures *recall*, *precision* and *F-measure* offer the most straightforward and intuitively interpretable results. Since they do take into account neither the contribution of chance in agreement, nor different importance of different types of disagreement, etc., other more or less elaborate coefficients for measuring the inter-annotator agreement have been developed. Cohen's κ (Cohen, 1960) is suitable for classification tasks and tries to measure the agreement "above chance". Krippendorff's α (Krippendorff, 1980) can be used if we need to distinguish various levels of disagreement. Rebecca Passonneau (2004) offered a solution for measuring agreement between sets of elements (like words in coreferential chains). Variants of these coefficients can be used for measuring agreement among more than two annotators. A comprehensive overview of methods for measuring the inter-annotator agreement in various areas of

Coling 2008: Poster Volume, pages 775–781,
Beijing, August 2010

computational linguistics was given in Artstein and Poesio (2008).

For measuring the inter-annotator agreement in the annotation of semantic inter-sentential discourse relations in PDT, we have chosen two measures. The relations do not form natural chains (unlike e.g. textual and grammatical coreference) and a simple *F_1-measure* is well suited for the agreement on existence of the relations. For the agreement on types of the relations, which is a typical classification task, we use Cohen's κ.

Our research has then been focused not on "how to measure" the agreement (which coefficient to use), but rather on "what to measure" (which phenomena), which is the topic of this paper.

2 Annotated Phenomena

Since the Prague Dependency Treebank 2.0 already contains three layers of linguistic annotation, two of which (the analytical layer – surface syntax, and the tectogrammatical layer – underlying syntax and semantics) are tree representations, we took advantage of these existing analyses and carry out the annotation of discourse phenomena directly on the trees (the tectogrammatical layer). It means that we capture the discourse relation between any two (sub)trees in the document by drawing a link (an arrow) between the highest nodes in the (sub)trees, see Figure 1.

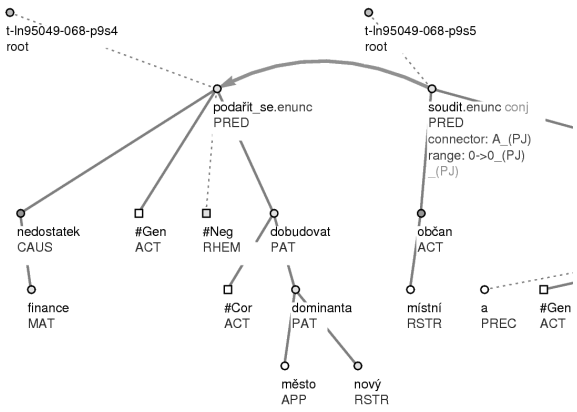

Figure 1. A discourse arrow between two nodes represents a discourse relation between two trees – subtrees of the nodes.

Discourse relations we annotate are in principle semantic relations that apply between two abstract objects (Asher, 1993) (i.e. discourse units or text spans) and help make the text a coherent whole. These relations are often signaled by the presence of a discourse connective, i.e. expressions as *"ale"*, *ačkoliv"*, *"tedy"*, *"ovšem"* (in English *"but"*, *"although"*, *"then"*, *"however"* etc. In the first phase of the project, we only annotate relations (link the (sub)trees) where such a connective is present.

Every relation gets assigned two important attributes: first, the discourse connective that anchors the relation, and, second, the semantic type of the relation. For assigning semantic relations in the discourse, we developed a set of 22 discourse-semantic tags (Mladová et al., 2009). It is inspired partly by the set of semantic labels used for the annotation of the tectogrammatical layer in PDT 2.0, relations within the sentence (the tectogrammatical syntactico-semantic labels called functors, Mikulová et al., 2005) – since some of the semantic relations apply also intra-sententially, like causal or contrastive relations; and partly by the set of semantic tags in the Penn Discourse Treebank 2.0 (Prasad et al., 2008), a discourse annotation project for English with similar aims.

Hence, there are three important issues for the inter-annotator measurement on the discourse level of annotation in PDT: the agreement on the start and target nodes of the discourse relation (and so the extent of the discourse arguments), the agreement on the discourse connective assigned to the relation, and, last but not least, the agreement on the semantic type of the relation.

3 Measuring the Inter-Annotator Agreement in the Annotation of Discourse in PDT 2.0

3.1 Simple (Strict) Approach

The basic method we use for measuring the inter-annotator agreement requires a perfect match in the start and end points of the relations. We calculate *recall* and *precision* between the two annotators. Since these measures are not symmetric in respect to the annotators, we use their combination – *F_1-measure* – which is symmetric. At each node, we compare target

nodes of the discourse relations created by the two annotators. We consider two relations to be in agreement strictly only if they share both the start node and the target node.

A second number we measure is an agreement on the relation and the type. For considering two relations to be in agreement, we require that they share their start and target nodes, and also have attached the same type.

Similarly, we measure an agreement on the relation and the connective, and an agreement on the relation, the type and the connective.

Attaching a type to a relation can be understood as a classification task. We calculate two numbers – simple ratio agreement and Cohen's κ – on the types attached to those relations where the annotators agreed on the start and the target nodes. Cohen's κ shows the level of agreement on the types above chance.

For completeness, we also calculate simple ratio agreement on the connectives attached to those relations the annotators agreed on.

Table 1 shows results of these measurements on two hundred sentences annotated in parallel by two annotators.[1]

measure	value
F_1-measure on relations	0.43
F_1-measure on relations + types	0.34
F_1-measure on relations + connectives	0.41
F_1-measure on rel. + types + connect.	0.32
agreement on types	0.8
agreement on connectives	0.95
Cohen's κ on types	0.74

Table 1. The inter-annotator agreement for a strict match.

3.2 Skipping a Tree Level

Requiring a perfect agreement on the start node and the target node of the discourse relations turns out to be too strict for a fair evaluation of the inter-annotator agreement. It often happens that the annotators recognize the same discourse relation in the data but they disagree either in the start node or the target node of the relation.

In Zikánová et al. (2010), we elaborate on typical cases of this type of disagreement and show that in many times, the difference in the start node or the target node is only one level in the tree. We have also shown that these disagreements usually depend on a subtle and not crucial difference in the interpretation of the text.

Figure 2 shows an example of a disagreement caused by a one-level difference in the target node of a relation. The two trees (a cut of them) represent these two sentences:

"Vím, že se nás Rusů bojíte, že nás nemáte rádi, že námi trochu pohrdáte. Ale Rusko není jenom Žirinovskij, Rusko není jenom vraždění v Čečensku."

(In English: *"I know that you are afraid of us Russians, that you dislike us, that you despise us a little. But Russia is not only Zhirinovsky, Russia is not only murdering in Chechnya."*)

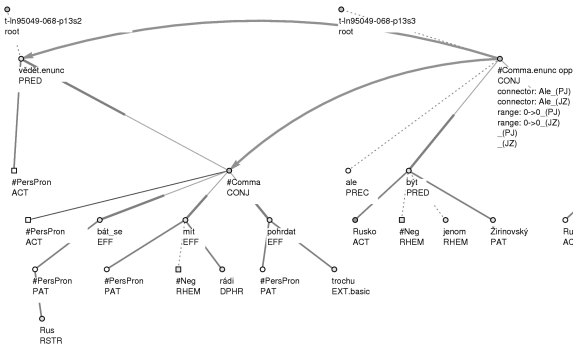

Figure 2. Disagreement in the target node.

Both annotators recognized the discourse relation between the two sentences, both selected the same type (opposition), and both marked the same connective (*"Ale"*, in English *"But"*). The disagreement in the target node is caused by the fact that one annotator has connected the second sentence with *"knowing that something is going on"*, while the other has connected it directly with the expression *"something is going on"*.

We have shown in Zikánová et al. (2010) that allowing for skipping one tree level either at the start node or the target node of the relations leads to an improvement in the inter-annotator

[1] The annotators did not know which part of the data will be used for the measurement. The agreement was measured on 200 sentences (6 documents). PDT 2.0 contains data from three sources. The proportion of the sentences selected for the measurement reflected the total proportion of these data sources in the whole treebank.

agreement (F_1-*measure* on the relations) of about 10%. To be exact, by allowing to skip one tree level we mean: if node A is a parent of node B, then we consider arrows A→C and B→C to be in agreement, as well as arrows D→A and D→B. Table 2 shows present results of this type of measurement, performed on the same data as Table 1.

measure	value
F_1-measure on relations	0.54
F_1-measure on relations + types	0.43
F_1-measure on relations + connectives	0.49
F_1-measure on rel. + types + connect.	0.39
agreement on types	0.8
agreement on connectives	0.92
Cohen's κ on types	0.73

Table 2. The inter-annotator agreement with one-level skipping.

The results seem to be consistent, since the improvement here is similar to the previously published test. The F_1-*measure* on the relations improved from 0.43 to 0.54. On the other hand (and also consistently with the previous test), simple ratio agreement on types (or connectives) and Cohen's κ on types, all measured on those arrows the annotators agreed on, do not change (more or less) after skipping one level is allowed. For these three measures, skipping one level only adds more data to evaluate and does not change conditions of the evaluation.

3.3 Connective-Based Approach

Further studies of discrepancies in parallel annotations show that skipping one level does not cover all "less severe" cases of disagreement.

Figure 3 presents an example of a disagreement in the start node of a relation with a two-level distance between the nodes. The two trees (a cut of them) represent these two sentences:

"Racionální kalkulace vlastníků nájemních bytů je proto povede k jedinému závěru: jakékoliv investice do oprav a modernizace nájemního bytového fondu jsou a budou ztrátové. Proto je další chátrání nájemních domů neodvratné."

(In English: *A rational calculation of the owners of the apartments will lead them to the only conclusion: any investment in repairs and renovation of the rental housing resources is and will be loss-making. Therefore, further dilapidation of the apartment buildings is inevitable."*)

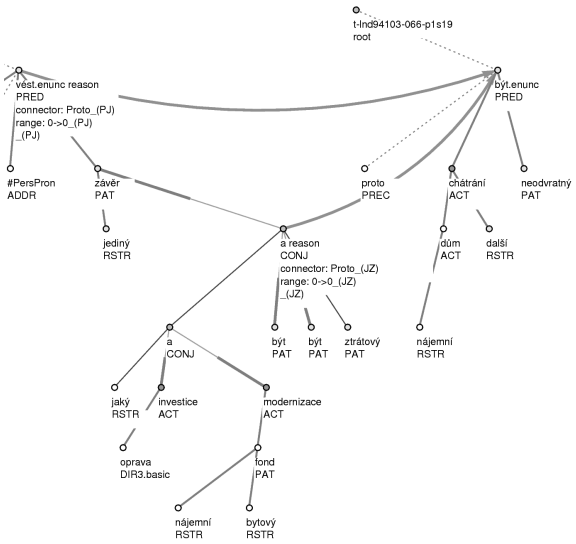

Figure 3. Two-level disagreement in the start nodes

The difference between the annotators is that one of them started the relation at the phrase *"will lead to the only conclusion: any investment ... is and will be ..."*, while the other started the relation directly at the phrase *"any investment ... is and will be ..."*.

However, both the annotators admittedly recognized the existence of the discourse relation, they also selected the same type (reason), and marked the same connective (*"Proto"*, in English *"Therefore"*).

Figure 4 shows an example of a disagreement caused by a different selection of nodes and by the opposite direction of the arrows. The trees represent these sentences: *"To je jasné, že bych byl radši, kdyby tady dosud stál zámek a ne tohle monstrum. Ale proč o tom stále uvažovat?"*

(In English: *It is clear that I would prefer if there still was a castle here and not this monster. But why keep thinking about it forever?"*)

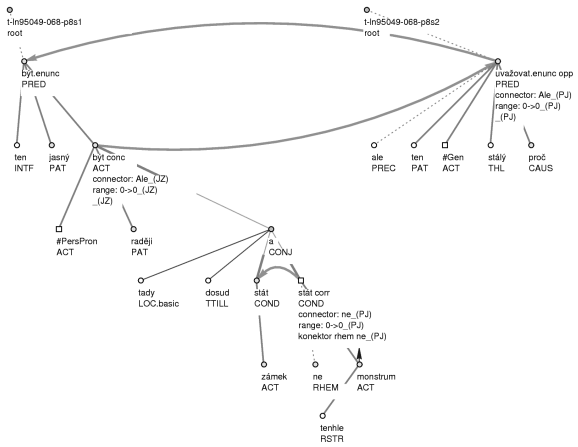

Figure 4. Disagreement in the nodes and in the direction of the arrows.

This time, both annotators recognized a presence of a discourse relation and marked the same connective (*"Ale"*, in English *"But"*). They did not agree on the start/end nodes and on the type of the relation (opposition vs. concession).

Figure 5 shows another type of "slight" disagreement. This time, the annotators agreed on everything but the range of the relation. They agreed both on the type (reason) and the connective (*"tak"*, in English *"Thus"*). The three trees (again a cut of them) represent these three sentences:

"Podle šéfa kanceláře představenstva a. s. Škoda Zdeňka Lavičky jsou však v říjnu schopny fungovat prakticky všechny závody bez vážnějšího omezení. To je v rozporu s tvrzením vedení koncernu z minulého týdne, ve kterém škodovácký management tvrdil, že se odstávka dotkne většiny provozů a závodů Škody Plzeň, která má v současnosti 28000 zaměstnanců. Vzniká tak podezření, že se vedení koncernu snažilo vyvinout tlak na vládu a donutit ji k zaplacení dluhů."

(In English: *"According to Zdeněk Lavička, the chief of the board of directors of Škoda corp., virtually all factories are able to operate in October without serious limitations. It contradicts the statement of the syndicate administration from the last week, in which the management of Škoda claimed that the downtime would affect most of the plants and factories of Škoda Plzeň, which presently has 28,000 employees. Thus a suspicion arises that the syndicate administration tried to exert pressure on the government and force it to pay the debts."*)

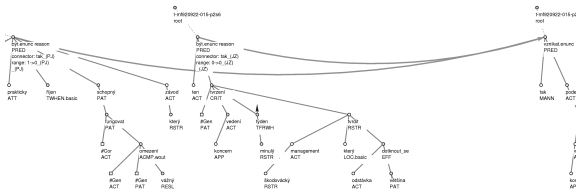

Figure 5. Disagreement in the range of the discourse relation.

The difference between the annotators is in the range of the start part of the arrows. One of the annotators marked the two first sentences as a start point of the relation, while the other marked the second sentence as the start point only. They agreed on the target point of the relation being the third sentence.

Inspired by these examples, we designed another – a connective-based – measure for evaluating the inter-annotator agreement of the discourse relations. It seems that although the annotators sometimes fail to mark the same start/target nodes, or to select the same type or the same range of the relations, they usually agree on the connective. This idea is also supported by high levels of the simple ratio agreement on connectives measured on relations the annotators agreed on from Tables 1 and 2 (0.95 and 0.91). These numbers show that once the annotators agree on a relation, they almost always agree also on the connective.[2]

The connective-based measure considers the annotators to be in agreement on recognizing a discourse relation if they agree on recognizing the same connective (please note that we only annotate discourse relations with explicitly expressed connectives).

Table 3 shows results of the evaluation of the inter-annotator agreement, performed using the connective-based measure, on the same data as Tables 1 and 2.

[2] This is only an interpretation of the numbers, not a description of the annotation process; in fact, the annotators usually first find a connective and then search for the arguments of the discourse relation.

measure	value
F_1-measure on relations	0.86
F_1-measure on relations + types	0.56
F_1-measure on rel. + start/end nodes	0.43
F_1-measure on rel. + types + nodes	0.34
agreement on types	0.65
agreement on start/end nodes	0.50
Cohen's κ on types	0.56

Table 3. The inter-annotator agreement evaluated with the connective-based measure.

This time (compared with Tables 1 and 2, i.e. the simple strict measure and the one-level skipping measure), the agreement (*F_1-measure*) on relations is much higher – 0.86 (vs. 0.43 and 0.54). On the other hand, simple ratio agreement (and Cohen's κ) measured on relations recognized by both annotators are lower than in Tables 1 and 2. Although the annotators might have recognized the same discourse relation, a (possibly small) difference in the interpretation of the text caused sometimes not only a disagreement in the positions of the start/end nodes, but also in the type of the relation.

The simple ratio agreement on types from Table 3 (0.65) is probably the closest measure to the way of measuring the inter-annotator agreement on subtypes in the annotation of discourse relations in the Penn Discourse Treebank 2.0, reported in Prasad et al. (2008). Their agreement was 0.8.

4 Conclusion

We have presented several ways of measuring the inter-annotator agreement in the project of annotating the semantic inter-sentential discourse relations with explicitly expressed connectives in the Prague Dependency Treebank. We have shown examples from parallel annotations that substantiate the importance of the alternative approaches to the evaluation of the agreement.

Skipping a tree level in the start node or the end node of the relations helps to recognize factual agreement in some cases where the strict approach detects disagreement. We have shown that it is still too strict and that there are cases which we would like to classify as agreement but the measure does not recognize them.

The connective-based measure seems to be the closest one to what we would like to consider a criterion of agreement. It disregards the actual nodes that are connected with a discourse relation, and even disregards the direction of the relation. In this sense, it is the most benevolent of the three measures.

It does not mean that the simple strict measure or skipping a tree level are inferior or obsolete ways of measuring the agreement. All the measures focus on different aspects of the agreement and they are all important in the process of annotating the corpus, studying the parallel annotations and improving the annotation instructions. We may agree on the fact that on this level of language description, it is very hard to achieve perfect agreement (Lee at al., 2006), yet we should never cease the effort to further specify and clarify the ways of annotation, in order to catch the same linguistic phenomena in the same way, and thus provide systematic and coherent linguistic data.

Opinion Target Extraction in Chinese News Comments

Tengfei Ma **Xiaojun Wan***

Institute of Compute Science and Technology
The MOE Key Laboratory of Computational Linguistics
Peking University
{matengfei, wanxiaojun}@icst.pku.edu.cn

Abstract

News Comments on the web express readers' attitudes or opinions about an event or object in the corresponding news article. And opinion target extraction from news comments is very important for many useful Web applications. However, many sentences in the comments are irregular and informal, and sometimes the opinion targets are implicit. Thus the task is very challenging and it has not been investigated yet. In this paper, we propose a new approach to uniformly extracting explicit and implicit opinion targets from news comments by using Centering Theory. The approach uses global information in news articles as well as contextual information in adjacent sentences of comments. Our experimental results verify the effectiveness of the proposed approach.

1 Introduction

With the dramatic development of web 2.0, there are more and more news web sites allowing users to comment on news events. These comments have become valuable resources for researchers to make advanced opinion analysis, such as tracking the attitudes to a focused event, person or corporation. In these advanced opinion analysis tasks, opinion target extraction is a necessary step. Unfortunately, former works did not focus on the domain of news comments. Though some researchers and workshops have investigated the task of opinion target extraction in product reviews and news articles, the methods cannot perform well on news comments. Actually, target extraction in news comments significantly differs from that in product reviews and news articles in the following ways.

1) Products usually have a set of definite attributes (e.g. size) and related opinion words (e.g. large), and thus researchers can use a small fixed set of keywords to recognize frequent feature words (Zhuang et al., 2006), or leverage the associated rules between feature words and opinion words to improve the performance (Hu and Liu, 2004; Su et al., 2008; Jin and Ho, 2009; Du and Tan, 2009). But news comments are more complicated. There are much more potential opinion targets in news comments. In other words, the candidate targets are in a much more open domain. On the other hand, the opinion targets in news comments are not strongly associated with the opinion words. We cannot judge a target by a special opinion word as easily as in product reviews.

2) The opinionated sentences in news articles mostly contain opinion operators (e.g. believe, realize), which can be used to find the positions of opinion expressions. However, news comments have already been considered to be declared by readers and they do not have many operators to indicate the positions of opinion targets.

3) Furthermore, many comment sentences are of free style. In many cases, there are even no manifest targets in the comment sentences. For example, a news article and its relational comment are as follows:

News: "迪拜将建超千米全世界最高摩天大楼"
(Dubai will build the highest skyscraper in the world)
Comment:
"真的很高，起到什么作用呢？"
(Really high, but what (is it) used for?)

Beijing, August 2010

The comment sentence obviously comments on "skyscraper" by human understanding, but in the sentence we cannot find the word or an alternative. Instead, the real target is included in the news article. Now we give two definitions of the phenomenon.

Implicit targets: The implicit targets are those opinion targets which do not occur in the current sentence. The sentence is called implicit sentence.

Explicit targets: The explicit targets are those opinion targets which occur in the current right sentence, and the sentence is called explicit sentence.

In Chinese comments, the phenomena of implicit targets are fairly common. In our dataset, the sentences with implicit targets make up nearly 30 percents of the total.

In this paper, we focus on opinion target extraction from news comments and propose a novel framework uniformly extracting explicit and implicit opinion targets. The method uses both information in news articles and information in comment contexts to improve the result. We extract focused concepts in news articles as candidate implicit targets, and exploit a new approach based on Centering Theory to taking advantage of comment contexts.

We evaluate our system on a test corpus containing different topics. The results show that it improves the baseline by 8.8%, and the accuracy is also 8.1% higher over the popular SVM-based method.

The rest of this paper is organized as follows: The next section gives an overview of the related work in opinion analysis. Section 3 introduces the background of Centering Theory and Section 4 describes our framework based on Centering Theory. In Section 5 we test the results and give a discussion on the errors. Finally Section 6 draws a conclusion.

2 Related Work

The early research of opinion mining only focused on the sentiment classification (Turney et al., 2002; Pang et al., 2002). However, for many applications only judging the sentiment orientation is not sufficient (eg. Hu and Liu, 2004). Fine-grained opinion analysis has attracted more and more attention these years. It mainly includes these types: opinion holder extraction (Kim and Hovy, 2005; Choi et al., 2005), opinion target extraction (Kim and Hovy, 2006; Ruppenhofer et al., 2008), and the identification of opinion proposals (Bethard et al., 2004) and some special opinion expressions (Bloom et al., 2007). Also, there are some other related tasks, such as detecting users' needs and wants (Kanayama and Nasukawa, 2008). However, these general systems are different from ours because they do not have or use any contextual information, and implicit opinion targets are not recognized and handled there.

A more special domain of feature extraction is product and movie reviews. Hu and Liu (2004) design a system to mine product features and generate opinion summaries of customer reviews. Frequent features are extracted by a statistical approach, and infrequent features are generated by the associated opinion words. The product features are limited in amount and they are strongly associated with specific opinion words, so researchers can use a fixed set of keywords or templates to extract frequent features (Zhuang et al., 2006; Popescu and Etzioni, 2005) or try various methods to augment the database of product features and improve the extraction accuracy by using the relations between attributes and opinions (Ghani et al., 2006; Su et al., 2008; Jin and Ho, 2009; Du and Tan, 2009). However, in news comments, the opinion targets are not strongly associated with specific opinion words and these techniques cannot be used.

There are also some works focusing on the target extraction in news articles, such as NTCIR7-MOAT (Seki et al., 2008). Different from the news comments, there are opinion indicators in the subjective sentences. However, in our task of this paper, the opinion holders are pre-assigned as the reviewers, so few opinion indicators and holders can be found.

To our best knowledge, this paper is the first work of extracting opinion targets in news comments. We analyze the complex phenomena in news comments and propose a framework to solve the problems of implicit targets. Our method synthesizes the information from related articles and contexts of comments, and it can effectively improve the extracting results.

3 Background of Centering Theory

Centering Theory (Grosz, Joshi and Weinstein, 1995) was developed for an original purpose of indicating the coherence of a discourse and choosing a referring expression. In the theory, the term "***centers***" of an utterance is used to refer to the entities serving to link this utterance to another utterance in a discourse. But this is not the only function of centers, and there are some other useful characteristics of centers to be recognized. Our observation shows that a center always represents the focus of attention, and the salience of a center indicates the significance of the component as a commented target. In news comments, we consider a comment as a discourse and a sentence as an utterance. If an utterance has a "center", then the center can be regarded as the target of the sentence.

Before introducing the common process of choosing the centers in utterances, several definitions are elaborated as follows:

Forward-looking center: Given an utterance U, there is a set of forward-looking centers $C_f(U)$ assigned. The set is a collection of all potential centers that may be realized by the next utterance.

Backward-looking center: Each utterance is assigned exactly one (in fact at most one) backward-looking center C_b. The backward-looking center of utterance U_{n+1} connects with one of the forward-looking centers of U_n. The C_b is the real focus of the utterance.

Rank: The rank is the salience of an element of C_f. Ranking of elements in $C_f(U_n)$ guides determination of $C_b(U_{n+1})$. The more highly ranked an element of $C_f(U_n)$, the more likely it is to be $C_b(U_{n+1})$. The most highly ranked element of $C_f(U_n)$ that is realized in U_{n+1} is the $C_b(U_{n+1})$. The rank is affected by several factors, the most important of which depends on the grammatical role, with SUBJECT > OBJECT(S) > OTHER.

Preferred center: In the set of $C_f(U_n)$, the element with the highest rank is a preferred center $C_p(U_n)$. This means that it has the highest probability to be $C_b(U_{n+1})$.

Table 1 is an example of the centers. In the example, the target of the first sentence is "Jack", which is exactly the preferred center; while in the second sentence, it is easy to see that "him" gets more attention than "the company" in this environment and thus the backward-looking center is more likely to be the target. So we assume that if $C_b(U_n)$ exists, it can be regarded as the opinion target of U_n, otherwise the $C_p(U_n)$ is the target.

Utterance	Center
U_1:杰克是把公司看作他的生命来做的。 (Jack regards the company as his life.)	C_f: 杰克(Jack)/ 公司(the company)/ 生命(life) C_b: null C_p: 杰克(Jack)
U_2: 公司能有今天的成果都是因为他。 (It attributes to him that the company can obtain today's achievement.)	C_f: 公司(the company)/ 成果(achievement)/ 他(杰克) (him(Jack)) C_b:他(杰克) (him(Jack)) C_p:公司(the company)

Table 1 Example of different centers.

4 Proposed Approach

Due to the problems we introduced in Section 1, the techniques of target extraction in other domains are not appropriate in news comments, and general approaches encounter the problems of free style sentences and implicit targets. Fortunately, news comments have their own characteristics, which can be used to improve the target extraction performance.

One important characteristic is that though potential opinion targets may be in large quantities, most comments focus on several central concepts in the corresponding news article, especially in the title. So we can extract the focused concepts in the news and use them as potential implicit targets for the comments.

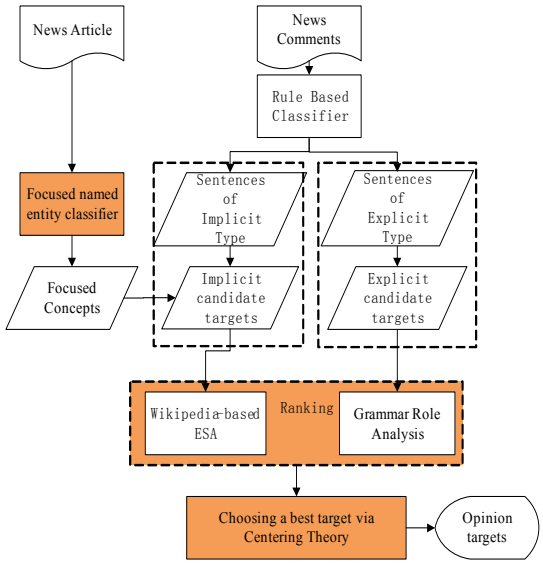

Figure 1: Framework of opinion target extraction in news comments

The other useful information comes from the fact that the sentences in one comment are usually coherent. As the comments may be long and each comment contains several sentences, the sentences within one comment are relevant and coherent. So the opinion targets in previous sentences have some influence on that in subsequent sentences. Using this kind of contextual information, we can eliminate noisy candidates and relax the dependence on an unreliable syntactic parser.

Considering the above characteristics, we propose a framework of target extraction based on focused concepts recognition and Centering Theory, as shown in Figure 1.

Given a news article and its relevant comments, we first adopt some syntactic rules to classify the comment sentences into implicit or explicit type. Whether a sentence includes an explicit target is mainly decided by whether it owns a subject. A few heuristic rules, such as the appearance of the subject, the combination of the POS, and the position of the predicate, are used based on the parse result by using a Chinese NLP toolkit[1], and the rule-based classification can attain an accuracy of 77.33%.

Then we exploit two different approaches for dealing with the two types of sentences, respectively. For the implicit type, we extract the focused concepts in the news article as candidate implicit targets, and rank them by calculating the semantic relatedness between the targets and the sentence. For the explicit type, all nouns and pronouns in the sentence are extracted as candidate targets and ranked mainly by their grammatical roles. At last, Centering Theory is used to choose the best candidate using the ranks and contextual information.

The details of the main parts are explained in the following sections.

4.1 Focused Concepts (FC) Recognition

As the comments usually point to the news article, it is highly probable that the implicit targets appear in the news article. Generally, the focused concepts of the news article are more likely to be the commented targets. Thus, if we extract the focused concepts of the news article, we will get the candidate implicit targets.

In general, the focused concepts are named entities (Zhang et al. 2004) or specific noun phrases. Taking the news

> "迪拜将建超千米全世界最高摩天大楼(*Dubai will build the highest skyscraper in the world*)" ----NEWS1

as an example, "迪拜(*Dubai*)" and "摩天大楼(*skyscraper*)" are the potential opinion targets. "*Dubai*" is a named entity, and "*skyscraper*" is a specific noun phrase. In addition, the focused concepts may also appear in the content of the news article, if they attract enough attention or have strong relations with the focused named entities in the title.

As the number of noun phrases is usually large, if we extract the two types of concepts together, there must be much noise to impact the final result. To be simple and accurate, we first extract focused named entities (FNE), and then expand them with other focused noun phrases, for the reason that the focused noun phrases usually have a strong relation with the focused named entities.

Entity Type	Person, Location, Organization, Time
Title	In title or not
Frequency	The number of occurrence
Relative Frequency	Frequency/the number of total words

[1] LTP, http://ir.hit.edu.cn/demo/ltp/Sharing_Plan.htm
LTP is an integrated NLP toolkit which contains segmentation, parsing, semantic role labeling, and etc.

Distribution Entropy (Here we take N=5 according to the length of articles)	$Entropy = \sum_{i=1}^{N} p_i \log p_i$, where $p_i = \frac{Occurrence\ in\ the\ i^{th}\ Section}{Occurrence\ in\ Total}$

Table 2 Features of FNE classification

Extracting FNEs can be seen as a classification problem. In this work, we choose the features in Table 2.

Given a news document, we first recognize all named entities with our own named entity recognizer (NER).Then all named entities are classified based on the above mentioned features. The noun phrases in the title are also extracted and filtered by their frequency in the news article and co-occurrences with FNEs. The filtering threshold is set to a relatively high value to guarantee that not much noise is brought in. Thus we can get a small set of focused concepts in the news article.

4.2 Ranking Implicit Targets

We use the semantic relatedness to decide which potential target is most likely to be the right implicit target. There are many methods to calculate the semantic relatedness. We choose the Wikipedia-base explicit semantic analysis (ESA) (Gabrilovich and Markovitch, 2007), for its adaptability and effectiveness for Chinese language. The method converts a word or a sentence to a series of wiki concepts, and then calculates the similarity between words or sentences.

Input: a Focused Concept t_0 in the news

Output: a vector C with a length of N. C= $<(c_j,w_j)>$, where c_j is a Wikipedia concept, and w_j is the weight of c_j

1. Find all nouns, adjectives and verbs co-occurring with t_0 in the same sentence, and put them into the set S= $\{t_i\}$.
2. Compute MI (Mutual information) of each t_i with t_0.
3. Choose 10 words in S with the highest MI (according to the total number of words, 10 is a proper value). Combine them with t_0 into a word vector and assign each word t_i a weight of its frequency v_i in the news article. The vector V= $<(t_i,v_i)>$, $|V|\leq 11$.
4. Let $<k_{ij}>$ be an inverted index entry for t_i, where k_{ij} quantifies the strength of association of t_i with Wikipedia concept c_j. Then the vector V can be interpreted as a vector constructed by All Wikipedia concepts. Each concept c_j has a weight $w_j = \sum_{t_i \in V} v_i k_{ij}$.
5. Select N concepts with the highest weights.

Table 3: Algorithm that converts a focused concept to a vector of Wikipedia concepts

Chinese Wikipedia is not as large as English Wikipedia. When some words are not included in the database, the original ESA algorithm will fail. To solve the problem, we first expand the input FC with a few words extracted from the news article. The words represent the semantic information related to the article, so they are more informative than a single concept while easily recognized by the Wikipedia database. The details of the algorithm are shown in Table 3.

On the other hand, when given a comment sentence, we segment it to words and remove the stop words (e.g. "的 (of)"). Then the serial of words are also converted by ESA into a vector of Wikipedia concepts.

After getting the vectors of wiki concepts for focused concepts and the comment sentence, we use the cosine metric to obtain their relatedness scores. In this way, the focused concepts are ranked by their relatedness scores with the sentence.

4.3 Ranking Explicit Targets

A comment sentence with explicit targets usually has a complete syntactic structure. According to Centering Theory, the ranks of explicit targets are decided mainly by their grammatical roles. Generally, a subject is most likely to be the opinion target, and the rank can be heuristically assigned by SUBJECT > OBJECT(S) > OTHER.

4.4 Choosing Best Candidate target via Centering Theory (CT)

After getting the candidate targets and their ranks, we start the matching step to make use of contextual information. The algorithm originates from the process of choosing preferred centers and backward-looking centers. A subtle adaption is that we add some global information in the news article as the context when dealing with the first sentence in a comment. The details of the algorithm are represented in Table 4.

Now we give an example to show the whole process of the framework. The following comment is associated with NEWS1 in Section 4.1.

U1:迪拜现在大力发展旅游和自由贸易。

(Dubai is developing travel and trades.)

U2:是一个很有活力的城市。

((It) is an active city.)

U3:在迪拜你可以感受到很多惊奇。

(In Dubai you can encounter many miracles.)

First, U1, U2 and U3 are classified as explicit, implicit and explicit, respectively. Then for U1 and U3 we choose noun phrases and pronouns in the sentence as candidate targets and rank them according to their grammatical roles. U2 chooses FC as candidates, and "Dubai" is more related than "skyscraper". At last, the final target is chosen by the algorithm in Table 4 and the whole process is illustrated in Table5.

Input: A comment with M sentences $S=\{s_i\}$, each sentence has a candidate target set $C_f(s_i)=\{c_i\}$;
The Focused Concepts set FC in the news article.

Output: A target set $\{t_i\}$, where each t_i is the opinion target of sentence s_i.

1. **For** each s_i in S
2. **If** $i=1$ (s_i is the first sentence)
3. **For** each c_i in $C_f(s_i)$
4. **If** c_i is contained in FC
5. Add c_i into the set $C_b(s_i)$
6. **If** $C_b(s_i)$ is not void
7. Choose the highest ranked element in $C_b(s_i)$ as t_i
8. **Else**
9. Choose the highest ranked element in $C_f(s_i)$ as t_i
10. **Else**
11. **For** each c_i in $C_f(s_i)$
12. **If** c_i realizes (equals or refers to) an element c'_i in $C_f(s_{i-1})$
13. Add c'_i into the set $C_b(s_i)$
14. **If** $C_b(s_i)$ is not void
15. Choose the highest ranked element in $C_b(s_i)$ as t_i
16. **Else**
17. Choose the highest ranked element in $C_f(s_i)$ as t_i

Table 4 Algorithm of choosing the best candidate target via CT

	type	ranks of candidates	target
U1	Explicit	迪拜>旅游>自由贸易 (Dubai >travel >trade)	迪拜 (Dubai)
U2	Implicit	迪拜>摩天大楼 (Dubai>skyscraper)	迪拜 (Dubai)
U3	Explicit	你>惊奇>迪拜 (you>miracles>Dubai)	迪拜 (Dubai)

Table 5 Example of the extraction process

5 Experiments

5.1 Evaluation Setup

To evaluate the whole system, we evaluate not only the result of the final target extraction but also some key steps. This makes the analysis of the bottleneck possible.

We first build a FNE dataset to evaluate the FNE classification result. As our target extraction task focuses on news comments, we collect 1000 news articles and the associated user comments from *http://comment.news.sohu.com,* which is a famous website offering a platform for users to comment on the news. Every news articles are annotated with its focused named entities, which are also the most possible commented targets.

Then we build the target dataset to evaluate the final target extraction. 9 articles and associated comments are randomly chosen from the FNE dataset, and each of their comment sentences is annotated with the opinion target. The target dataset focuses on 3 different topics: economics, technology and sports. Each document contains a news article and about 100 relevant comments, and there are 1597 comment sentences in total.

We assume that each comment sentence has one opinion target, but 108 sentences have more than one focused objects. In that case, we annotate all targets for evaluation and the result is regarded as true if we extract only one of the annotated targets.

In the target dataset, there are 444 sentences with implicit targets. This demonstrates that the implicit target extraction problem is prevalent and worth solving.

For the final target extraction, we use the accuracy metric to evaluate the result. It is defined as follows:

$$\text{Accuracy}=\frac{\text{Number of sentences with right extraction}}{\text{Number of total sentences}}$$

We do not use the precision and recall metric because every comment sentence in our dataset must have a target after extracting. The precision and the recall are both equal to the accuracy.

5.2 Evaluation Results

5.2.1 FNE Results

We perform a 4:1 cross-validation on the FNE dataset using a commonly used classifier SVM-light[2] and gain a mean f-measure of 80.43%.

Then, to assess the improvement by the FNE step and the classification of implicit and explicit sentences, we estimate the theoretic upper limit of the following three target extractions on the target dataset. **Test 1** assumes every noun phrases or nouns in the sentence can be possible to be extracted as the target. So if there is one candidate matching the target, we can recognize the sentence as extractable. **Test 2** adopts the annotation results of the classification of explicit and implicit sentences. For the manually annotated implicit targets, we adapt the candidate to be FC. Then, as same as Test 1, all candidates are determined whether to be the target. In **Test 3**, we follow the ruled-based classification of implicit and explicit sentences in our system and then judge the sentences whether extractable or not.

	Proportion of extractable sentences
Test 1	55.0%
Test 2	69.6%
Test 3	61.7%

Table 6 Improvement of the proportion of extractable sentences by FNE classification and explicit/implicit sentence classification

Table 6 shows the proportions of extractable sentences in the three tests. It is easy to see that the proportion of extractable sentences means the theoretic optimization of target extraction. So, by Test 2 we can see the extracted FC set is an effective complement of the candidate targets, while Test 3 demonstrates that the system still has much potential to improve the baseline after the rule-based classification of explicit and implicit sentences.

5.2.2 Target Extraction Results

To demonstrate the effectiveness of our approach, we design two baselines.

Baseline 1 treats all sentences as explicit type. In the method, we extract all noun phrases and pronouns in a sentence as candidates and obtain their ranks according to their grammatical roles.

Baseline 2, a SVM-based approach, is offered to compare with the popular target extraction methods. In this method we regard the target extraction as a classification problem. We extract the candidate noun phrases in a sentence first, and then use the semantic features to classify them as targets or not. The features mainly include: POS, whether or not a Named Entity, the positions in the sentence, the syntactic relations with the verb, and etc. As it is a supervised approach, the result is tested by a 2:1 cross validation.

Then we use a method called **FC-only (using only Focused Concepts)** to improve Baseline 1 by using the global information in news articles. For sentences of explicit type, we use the method in Baseline1. For sentences of implicit type, we take focused concepts in news articles as potential targets, and choose the highest ranked element as the final target.

Finally, our proposed approach **CT (using Centering Theory)** uses both Focused Concepts and Centering Theory. When the size of Wikipedia concept vector is set to be 800, the comparison results of the four approaches are shown in Table 7:

	Accuracy
Baseline1	34.38%
Baseline2(SVM-based)	35.13%
FC-only	37.25%
CT	**43.20%**

Table 7 Comparison results

FC-only is better than Baseline1, which demonstrates that the focused concepts are useful to provide information to implicit targets extraction. 444 implicit sentences are a large proportion of the total corpus. And the focused concepts do represent the global information and have influence on the target extraction.

Centering Theory is naturally another improvement. It mainly takes advantage of the information of contexts within a comment, using a rule of coherence to decide the center of attention. And the result indicates that it is very helpful.

Compared with the SVM-based approach, our approach is also much better. The SVM-based approach is only a little higher than Baseline 1. It seems that the manually annotated information is not very useful in target extraction in news comments. The reason may be that the target rules are complicated and exist not only in the current sentence. Using global and contextual

[2] http://svmlight.joachims.org/

information is a more economic and effective way to improve the result.

In the Wikipedia-based ESA algorithm,there is a parameter of *N*, which is the vector size of the expanded vector. It is important to choose a proper parameter value to achieve a high accuracy and meanwhile keep a low computational complexity. The accuracy curves for FC and CT with different values of *N* are represented in Figure 2. Apparently, when *N* exceeds 600, the extraction performance almost does not change any more. So we finally take 800 as the value of *N* .

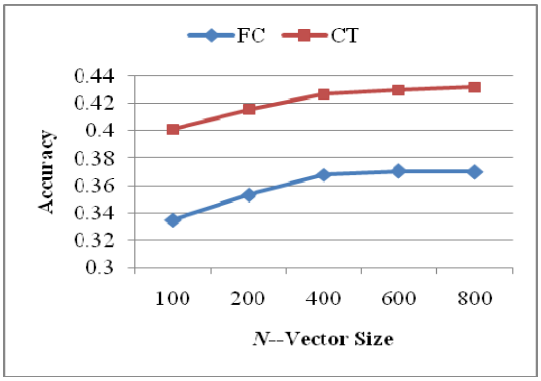

Figure 2: Accuracy vs. vector size *N*

5.3 Error Analysis

Generally there are two major types of errors in the extraction results. One common error is that the target is not in our extracted candidate nouns or noun phrases. For example:

> "可口买汇源，可真是中国饮料的灾难了." (It is a disaster of Chinese beverage that Coca Cola buys HuiYuan.)

The sentence comments on the event of "Coca Cola buys HuiYuan" but not a single concept "Coca Cola" or "HuiYuan". But our system cannot recognize this type of targets properly. Also there are some cases that the noun phrases missed to be extracted by the LTP toolkit. It causes that the target is not matched by the candidates.

Another error originates from the wrong classification of explicit and implicit sentences. For example,

> "还利于民才能化解中小企业生存危机." (Returning profits to civilians can get through the crisis of little companies.)

In this sentence, "还利于民(Returning profits to civilians)" is the opinion target and the sentence has a explicit target. But the rules based on the Chinese parser failed to recognize the phrase as a subject and thus the sentence is considered as implicit type by our approach. And lastly the target is extracted incorrectly.

In 5.2.1, we test the theoretic upper limit of the target extraction and prove the potential effectiveness of two steps. The tests also can be used to estimate the proportion of the types of errors and analyze the bottleneck. In Test 2, there are 298 un-extractable sentences among the annotated explicit sentences. It shows that there is at least 18.6% loss in accuracy caused by the candidate recognition, which accounts for the first error type. As for the second error type, its proportion can be computed by the reduction from Test 2 to Test 3, which is 7.9%.

6 Conclusion and Future Work

In this paper, we propose a novel approach to extracting opinion targets in Chinese news comments. In order to solve the problem of implicit target extraction, we extract focused concepts and rank their importance by computing the semantic relatedness with sentences via Wikipedia. In addition, we apply Centering Theory to the target extraction system, for utilizing contextual information. The experiment results demonstrate that our approach is effective.

Currently, the result does not reach an absolutely high accuracy. One bottleneck is that Chinese parsing results are far from satisfactory. Actually this bottleneck has impacted the general target extraction long, such as the low performances of all participants in the target extraction task of NTCIR7-MOAT-CS. We hope to improve our results by avoid this disadvantage. Moreover, the phenomenon of implicit opinion targets exists not only in Chinese but also in English and other languages, while sometimes it is similar to zero anaphora. So the approach in this paper can be extended to news comments in other languages.

Abstract

We use robust and fast Finite-State Machines (FSMs) to solve scriptural translation problems. We describe a *phonetico-morphotactic pivot* UIT (universal intermediate transcription), based on the common phonetic repository of Indo-Pak languages. It is also extendable to other language groups. We describe a *finite-state scriptural translation model* based on finite-state transducers and UIT. We report its performance on Hindi, Urdu, Punjabi and Seraiki corpora. For evaluation, we design two classification scales based on the word and sentence accuracies for translation system classifications. We also show that subjective evaluations are vital for real life usage of a translation system in addition to objective evaluations.

1 Introduction

Transliteration refers to phonetic translation across two languages with different writing systems, such as Arabic to English (Arbabi *et al.*, 1994; Stall and Knight, 1998; Al-Onaizan and Knight, 2002; AbdulJaleel and Larkey, 2003). Most prior work on transliteration has been done for MT of English, Arabic, Japanese, Chinese, Korean, etc., for CLIR (Lee and Choi., 1998; Jeong *et al.*, 1999; Fujii and Ishikawa, 2001; Sakai *et al.*, 2002; Pirkola *et al.*, 2003; Virga and Khudanpur, 2003; Yan *et al.*, 2003), and for the development of multilingual resources (Kang and Choi, 2000; Yan, Gregory et al., 2003).

The terms transliteration and transcription are often used as generic terms for various processes like transliteration, transcription, romanization, transcribing and technography (Halpern, 2002). In general, the speech processing community uses the term transcription to denote a process of conversion from the script or writing system to the sound (phonetic representation). For example, the transcription of the word "love" in the International Phonetic Alphabet (IPA) is [ləv]. While the text processing community uses the term transliteration and defines it as a process of converting a word written in one writing system into another writing system while preserving the sound of the original word (Al-Onaizan and Knight, 2002; AbdulJaleel and Larkey, 2003). More precisely, the text processing community defines the term transliteration as two transcription processes "source script to sound transcription" and "sound to target script transcription" and sometimes as one transcription process "source script to target script transcription".

We propose a new term *Scriptural Translation* for this combined process. Scriptural translation is a process of transcribing a word written in the source language script into the target language script by preserving its articulation in the original language in such a way that the native speaker of the target language can produce the original pronunciation.

FSMs have been successfully used in various domains of Computational Linguistics and Natural Language Processing (NLP). The successful use of FSMs have already been shown in various fields of computational linguistics (Mohri, 1997; Roche and Schabes, 1997; Knight and Al-Onaizan, 1998). Their practical and advantageous features make them very strong candidates to be used for solving *scriptural translation problems*.

First, we describe scriptural translation and identify its problems that fall under weak translation problems. Then, we analyze various challenges for solving weak scriptural translation problems. We describe our finite-state scriptural translation model and report our results on Indo-Pak languages.

Coling 2008: Poster Volume, pages 791–800,
Beijing, August 2010

2 Scriptural Translation – a weak translation problem

A weak translation problem is a translation problem in which the number of possible valid translations, say *N*, is either very small, less than 5, or almost always 1.

Scriptural Translation is a sub-problem of general translation and almost always a *weak translation problem*. For example, French-IPA and Hindi-Urdu scriptural translation problems are weak translation problems due to their small number of valid translations. On the other hand, Japanese-English and French-Chinese scriptural translation problems are not weak.

Scriptural translation is not only vital for translation between different languages, but also becomes inevitable when the same language is written in two or more mutually incomprehensible scripts. For example, Punjabi is written in three different scripts: Shahmukhi (a derivation of the Perso-Arabic script), Gurmukhi and Devanagari. Kazakh and Kurdish are also written in three different scripts, Arabic, Latin and Cyrillic. Malay has two writing systems, Latin and Jawi (a derivation of the Arabic script), *etc.* Figure 1 shows an example of scriptural divide between Hindi and Urdu.

دنیا کو امن کی ضرورت ہے۔

दुनिया को अमन की ज़रूरत है।

[d̪ʊnɪjɑ ko əmən ki zərurət̪ hæ.]

The world needs peace.

Figure 1: Example of scriptural divide

Thus, solving the scriptural translation problem is vital to bridge the scriptural divide between the speakers of different languages as well as of the same language.

Punjabi, Sindhi, Seraiki and Kashmiri exist on both sides of the common border between India and Pakistan and all of them are written in two or more mutually incomprehensible scripts. The Hindi–Urdu pair exists both in India and Pakistan. We call all these languages the *Indo-Pak* languages.

3 Challenges of Scriptural Translation

In this section, we describe the main challenges of scriptural translation.

3.1 Scriptural divide

There exists a written communication gap between people who can understand each other verbally but cannot read each other. They are virtually divided and become *scriptural aliens*. Examples are the Hindi & Urdu communities, the Punjabi/Shahmukhi & Punjabi/Gurmukhi communities, *etc.* An example of scriptural divide is shown in Figure 1. Such a gap also appears when people want to read some foreign language or access a bilingual dictionary and are not familiar with the writing system. For example, Japanese–French or French–Urdu dictionaries are useless for French learners because of the scriptural divide. Table 1 gives some figures on how this scriptural divide affects a large population of the world.

Sr.	Language	Number of Speakers
1	Hindi	853,000,000
2	Urdu	164,290,000
3	Punjabi	120,000,000
4	Sindhi	21,382,120
5	Seraiki	13,820,000
6	Kashmir	5,640,940
Total		**1178,133,060**

Table 1: Number of Speakers of Indo-Pak languages

3.2 Under-resourced languages

Under-resourced and under-written features of the source or target language are the second big challenge for *scriptural translation*. The lack of standard writing practices or even the absence of a standard code page for a language makes transliteration or transcription very hard. The existence of various writing styles and systems for a language leads towards a large number of variants and it becomes difficult and complex to handle them.

In the case of Indo-Pak languages, Punjabi is the largest language of Pakistan (more than 70 million) and is more a spoken language than a written one. There existed only two magazines (one weekly and one monthly) in 1992 (Rahman, 1997). In the words of (Rahman, 2004), "… *there is little development in Punjabi, Pashto, Balochi and other languages*…". (Malik, 2005) reports the first effort towards establishing a standard code page for Punjabi-Shahmukhi and till date, a standard code page for Shahmukhi does not exist. Similar problems also exist for the Kashmiri and Seraiki languages.

3.3 Absence of necessary information

There are cases where the necessary and indispensable information for scriptural translation are missing in the source text. For example, the first word دنیا [d̪ʊnɪjɑ] (world) of the example sentence of Figure 1 misses crucial diacritical information, mandatory to perform Urdu to Hindi scriptural translation. Like in Arabic, diacritical marks are part of the Urdu writing system but are sparingly used in writings (Zia, 1999; Malik *et al.*, 2008; Malik *et al.*, 2009).

Figure 2(a) shows the example word without diacritical marks and its wrong Hindi conversion according to conversion rules (explained later). The Urdu community can understand the word in its context or without the context because people are tuned to understand the Urdu text or word without diacritical marks, but the Hindi conversion of Figure 2(a) is not at all acceptable or readable in the Hindi community.

Figure 2(b) shows the example word with diacritical marks and its correct Hindi conversion according to conversion rules. Similar problems also arise for the other Indo-Pak languages. Therefore, missing information in the source text makes the scriptural translation problem computationally complex and difficult.

[ɑ] ا [j] ی [ɪ] ِ [n] ن [ʊ] ُ [d̪] د = دُ نِیا
दुनिया = द [d̪] ु [ʊ] न [n] ि [ɪ] य [j] ा[ɑ]
(b) with necessary information
[ɑ] ا [j] ی [n] ن [d̪] د = دنیا
दनया = द [d̪] न [n] य [j] ा[ɑ]
(a) without necessary information

Figure 2: Example of missing information

3.4 Different spelling conventions

Different spelling conventions exist across different scripts used for the same language or for different languages because users of a script are tuned to write certain words in a traditional way. For example, the words یہ [je] (this) = ی [j] + ہ [h] and وہ [vo] (that) = و [v] + ہ [h] are used in Urdu and Punjabi/Shahmukhi. The character ہ [h] produces the vowel sounds [e] and [o] in the example words respectively. On the other hand, the example words are written as ये [je] & वो [vo] and ਯੇ [je] & ਵੋ [vo] in Devanagari and Gurmukhi, respectively. There exist a large number of such conventions between Punjabi/Shahmukhi–Punjabi Gurmukhi, Hindi–Urdu, *etc.*

Different spelling conventions are also driven by different religious influences on different communities. In the Indian sub-continent, Hindi is a part of the Hindu identity, while Urdu is a part of the Muslim identity[1] (Rahman, 1997; Rai, 2000). Hindi derives its vocabulary from Sanskrit, while Urdu borrows its literary and scientific vocabulary from Persian and Arabic. Hindi and Urdu not only borrow from Sanskrit and Persian/Arabic, but also adopt the original spellings of the borrowed word due the sacredness of the original language. These differences make scriptural translation across scripts, dialects or languages more challenging and complex.

3.5 Transcriptional ambiguities

Character level scriptural translation across different scripts is ambiguous. For example, the Sindhi word اِنسان [ɪnsɑn] (human being) can be converted into Devanagari either as इंसान [ɪnsɑn] or इसान* [ɪsɑn] (* means wrong spellings). The transliteration process of the example word from Sindhi to Devanagari is shown in Figure 3(a). The transliteration of the third character from the left, Noon (ن) [n], is ambiguous because in the middle of a word, Noon may represent a consonant [n] or the nasalization [ɲ] of a vowel.

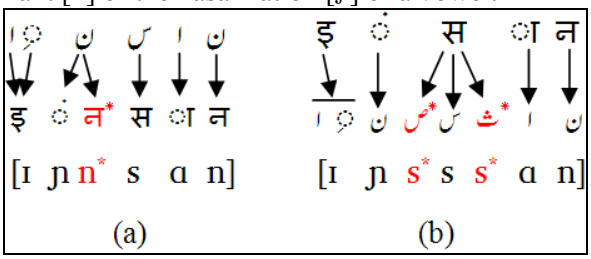

Figure 3: Sindhi transliteration example

In the reverse direction, the Sindhi Devanagari word इंसान [ɪnsɑn] can be converted into a set of possible transliterations [اِنسان, اِنصان*, اِنثان*]. All these possible transliterations have the same pronunciation [ɪnsɑn] but have different spellings in

[1] The Hindi movement of the late 19th century played a central role in the ideologization of Hindi. The movement started in reaction to the British Act 29 of 1837 by which Persian was replaced by Hindustani/Urdu, written in Persian script, as the official vernacular of the courts of law in North India. It is the moment in history, when Hindi and Urdu started to emerge as Hindu and Muslim identities.

the Perso-Arabic script, as shown in Figure 3(b). Similar kinds of ambiguities also arise for other pairs of scripts, dialects or languages. Thus these ambiguities increase the complexity and difficulty of *scriptural translation*.

3.6 Distinctive sound inventories

Sound inventories across dialects or languages can be different. Consider the English–Japanese pair. Japanese make no distinction between the 'L' [l] and 'R' [r] sounds so that these two English sounds collapse onto the same Japanese sound (Knight and Al-Onaizan, 1998).

For Indo-Pak languages, Punjabi/Gurmukhi (a dialect of Punjabi spoken in India) possesses two additional sounds than Punjabi/Shahmukhi (a dialect of Punjabi spoken in Pakistan). Similarly, Hindi, Punjabi, Sindhi and Seraiki have the retroflex form [ɳ], but Urdu and Kashmiri do not. Marathi has 14 vowels in contrast to Hindi's 11 vowels, shown in Table 2.

Hindi Vowels
अ [ə] आ [ɑ] इ [ɪ] ई [i] उ [ʊ] ऊ [u] ऋ [r̥] ए [e] ऐ [æ] ओ [o] औ [ɔ]
Marathi Vowels
अ [ə] आ [ɑ] इ [ɪ] ई [i] उ [ʊ] ऊ [u] ऋ [r̥] ए [e] ऐ [æ] ओ [o] औ [ɔ] अं [əŋ] अः [əh] ऌ [l̥]

Table 2: Hindi and Marathi vowel comparison

Scriptural translation approximates the pronunciation of the source language or dialect in the target due to different sound inventories. Thus a distinctive sound inventory across scripts, dialects or languages increases ambiguities and adds to the complexity of the *scriptural translation* problem.

4 Universal Intermediate Transcription

UIT (Universal Intermediate Transcription) is a multipurpose pivot. In the current study, it is used as a *phonetico-morphotactic* pivot for the *surface morphotactic translation* or scriptural translation.

Although we have not used IPA as encoding scheme, we have used the IPA coding associated with each character as the encoding principle for our ASCII encoding scheme. We selected the printable ASCII characters to base the UIT encoding scheme because it is universally portable to all computer systems and operating systems without any problem (Boitet and Tchéou, 1990; Hieronymus, 1993; Wells, 1995). UIT is a deterministic and unambiguous scheme of transcription for Indo-Pak languages in ASCII range 32–126, since a text in this rage is portable across computers and operating systems (Hieronymus, 1993; Wells, 1995).

Speech Assessment Methods Phonetic Alphabet (SAMPA)[2] is a widely accepted scheme for encoding IPA into ASCII. The purpose of SAMPA was to form the basis of an international standard machine-readable phonetic alphabet for the purpose of international collaboration in speech research (Wells, 1995). The UIT encoding of Indo-Pak languages is developed as an extension of the SAMPA and X-SAMPA that covers all symbols on the IPA chart (Wells, 1995).

4.1 UIT encodings

All characters of the Indo-Pak languages are subdivided into three categories, consonants, vowels and other symbols (punctuations and digits).

Consonants are further divided into aspirated consonants and non-aspirated consonants. For aspiration, in phonetic transcription a simple 'h' following the base consonant symbol is considered adequate (Wells, 1995). In the Indo-Pak languages, we have two characters with IPA [h]. Thus to distinguish between the 'h' consonants and the aspiration, we use *underscore* '_' to mark the aspirate and we encode an aspiration as '_h'. For example, the aspirated consonants ٹھ [t^h], پھ [p^h] and ڇھ [$ʧ^h$] of the Indo-Pak languages are encoded as 't`_h', 'p_h' and 't_S_h' respectively. Similarly for the dental consonants, we use the '_d' marker. For example, the characters د [d̪] and ت [t̪] are encoded as 'd_d' and 't_d' in UIT. Table 3 shows the UIT encodings of Hindi and Urdu aspirated consonants.

Hindi	Urdu	UIT	Hindi	Urdu	UIT
भ	بھ [b^h]	b_h	ह्र	رھ [r^h]	r_h
फ	پھ [p^h]	p_h	ढ़	ڑھ [$ɽ^h$]	r`_h
थ	تھ [$t̪^h$]	t_d_h	ख	کھ [k^h]	k_h
ठ	ٹھ [$ʈ^h$]	t`_h	घ	گھ [g^h]	g_h
झ	جھ [$ʤ^h$]	d_Z_h	ल्ह	لھ [l^h]	l_h
छ	چھ [$ʧ^h$]	t_S_h	म्ह	مھ [m^h]	m_h

[2] http://www.phon.ucl.ac.uk/home/sampa/

ध	دھ [d̪ʰ]	d_d_h	न्ह	نھ [nʰ]	n_h
ढ	ڈھ [ɖʰ]	d`_h			

Table 3: UIT encodings of Urdu aspirated consonants

Similarly, we can encode all characters of Indo-Pak languages. Table 4 gives UIT encodings of Hindi and Urdu non-aspirated consonants. We cannot give all encoding tables here due to shortage of space.

Hindi	Urdu	UIT	Hindi	Urdu	UIT
ब	ب [b]	b	स	ص [s]	s2
प	پ [p]	p	ज़	ض [z]	z2
त	ت [t̪]	t_d	त	ط [t̪]	t_d1
ट	ٹ [ʈ]	t`	ज़	ظ [z]	z3
स	ٹ [s]	s1	-	ع [ʔ]	?
ज	ج [ʤ]	d_Z	ग़	غ [ɣ]	X
च	چ [ʧ]	t_S	फ़	ف [f]	f
ह	ح [h]	h1	क़	ق [q]	q
ख़	خ [x]	x	क	ک [k]	k
द	د [d̪]	d_d	ग	گ [g]	g
ड	ڈ [ɖ]	d`	ल	ل [l]	l
ज़	ذ [z]	z1	म	م [m]	m
र	ر [r]	r	न	ن [n]	n
ड़	ڑ [ɽ]	r`	व	و [v]	v
ज़	ز [z]	z	ह	ہ [h]	h
ज़	ژ [ʒ]	Z	य	ی [j]	j
स	س [s]	s	त	ۃ [t̪]	t_d2
श	ش [ʃ]	S	ण	- [ɳ]	n`
ष	ش [ʃ]	S1	ं	ں [ŋ]	~

Table 4: UIT encodings of Urdu non-aspirated consonants

5 Finite-state Scriptural Translation Model

Figure 4 shows the system architecture of our finite-state scriptural translation system.

`Text Tokenizer` receives and converts the input source language text into constituent words or tokens. This list of the source language tokens is then passed to the `UIT Encoder` that encodes these tokens into a list of UIT tokens using the source language to UIT conversion transducer from the repertoire of *Finite-State Transducers*. These UIT tokens are given to the `UIT Decoder` that decodes them into target language tokens using the UIT to target language conversion transducer from the repertoire of Transducers. Finally, `Text Generator` generates the target language text from the translated target language tokens.

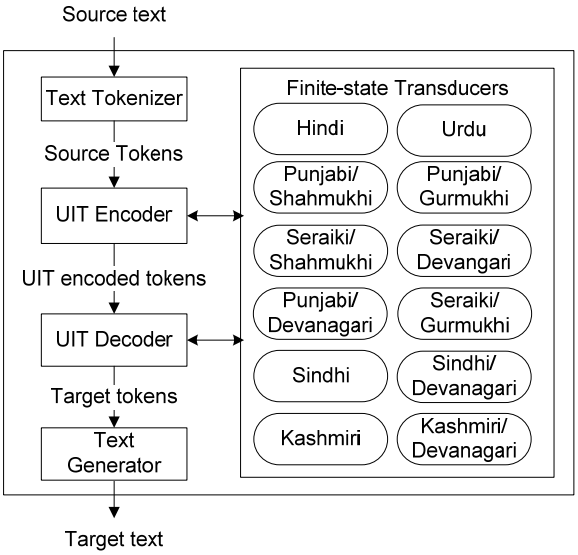

Figure 4: System Architecture of fintie-state scriptural translation

5.1 Finite-state Transducers

Both conversions of the source language text into the UIT encoded text and from the UIT encoded text into the target language text are regular relations on strings. Moreover, regular relations are closed under serial composition and a finite set of conversion relations when applied to each other's output in a specific order, also defines a regular expression (Kaplan and Kay, 1994). Thus we model the conversions from the source language to UIT and from UIT to the target language as finite-state transducers. These translational transducers can be deterministic and non-deterministic.

Character Mappings: Table 5 shows regular relations for converting Hindi and Urdu aspirated consonants into UIT.

IPA	Hindi to UIT	Urdu to UIT
b^h	भ → b_h	ﮪ → b_h
p^h	फ → p_h	ﭫ → p_h
$\underset{\frown}{t}^h$	थ → t_d_h	ﺗ → t_d_h
$ʈ^h$	ठ → t`_h	ﭨ → t`_h
$ʤ^h$	झ → d_Z_h	ﺟ → d_Z_h
$ʧ^h$	छ → t_S_h	ﭽ → t_S_h

$d̪^h$	ध → d_d_h	دھ → d_d_h
$ɖ^h$	ढ → d`_h	ڈھ → d`_h
r^h	ह़ → r_h	رھ → r_h
$ɽ^h$	ढ़ → r`_h	ڑھ → r`_h
k^h	ख → k_h	کھ → k_h
g^h	घ → g_h	گھ → g_h
l^h	ल्ह → l_h	لھ → l_h
m^h	म्ह → m_h	مھ → m_h
n^h	न्ह → n_h	نھ → n_h

Table 5: Regular rules for aspirated consonants of Hindi and Urdu

By interchanging the UIT encodings before the arrow sign and the respective characters of Hindi and Urdu after the arrow, we can construct regular conversion relations from UIT to Hindi and Urdu. We have used XFST (Xerox finite-state engine) to build finite-state transducers. Table 6 shows a sample XFST code.

Contextual Mappings: A contextual mapping is a contextual rule that determines a desired output when a character appears in a certain context. The third command of Table 6 models another contextual mapping saying that 'ह्' is translated by '_h' when it is preceded by any of the characters र, ल, म, and न. The second last rule of Table 6 models the contextual mapping rule that 'A1' is translated into 'ہ' when it is at the end of a word and preceded by a consonant.

```
clear stack
set char-encoding UTF-8
read regex [ि -> I];
read regex [ख -> [k "_" h], घ -> [g
  "_" h], छ -> [t "_" S "_" h], झ -
  > [d "_" Z "_" h], ठ -> [t "`" "_"
  h], ढ -> [d "`" "_" h], थ -> [t
  "_" d "_" h], ध -> [d "_" d "_"
  h], फ -> [p "_" h], भ -> [b "_"
  h], ढ़ -> [r "`" "_" h], स -> s, त
  -> [t "_" d], र -> r, ल -> l, म ->
  m, न -> n, व -> v, ह -> h];
read regex [[् ह] -> ["_" h] || [र |
ल | म | न] _ ];
compose net
```

Table 6: Sample XFST code

Vowel representations in Urdu, Punjabi/Shahmukhi, Sindhi, Seraiki/Shahmukhi and Kashmiri are highly context-sensitive (Malik *et al.*, 2010).

6 Experiments and Results

A sample run of our finite-state scriptural translation system on the Hindi to Urdu example sentence of Figure 1 is shown in Table 7.

Text Tokenizer	UIT Encoder	UIT Decoder	
		Unique output	*Ambiguous outputs*
दुनिया	dUnIjA1	دُنِیا	[دُنِیہ , دُنیا]
को	ko	کو	[قو , کو]
अमन	@mn	امن	[امن]
की	ki	کی	[قی , کی]
ज़रूरत	zrurt_d	زرُوت	[زرُرت , ضرُورت , ذرُورت , ظرُورت , ژرُورت , …]
है	h{	ہَے	[حَے , ہے]

Table 7: Sample run of finite-state scriptural translation model on Hindi to Urdu example

`Text Generator` converts the unique output of the UIT Decoder into an Urdu sentence with one error in the fifth word (highlighted), shown in Figure 5.

دنِیا کو امن کی زرورت ہے

Figure 5: Unique output of the sample run by deterministic FSTs

On the other hand, from the ambiguous output of the UIT Decoder, we can generate 240 output sentences, but only one is the correct scriptural translation of the source Hindi sentence in Urdu. The correct sentence is shown in Figure 6. The sole difference between the output of the deterministic FST and the correct scriptural translation is highlighted in both sentences shown in Figure 5 and 6.

دنِیا کو امن کی ضرورت ہے

Figure 6: Correct scriptural translation of the example

6.1 Test Data

Table 8 shows test sets for the evaluation of our finite-state scriptural translation system.

Data set	Language pair	No. of words	No. of sentences	Source
HU 1	Hindi–Urdu	52,753	-	Platts dictionary
HU 2	Hindi–Urdu	4,281	200	Hindi corpus
HU 3	Hindi–Urdu	4,632	226	Urdu corpus
PU	Punjabi/Shahmukhi–Punjabi/Gurmukhi	5,069	500	Classical poetry
SE	Seraiki/Shahmukhi–Seraiki/Devanagari	2,087	509	Seraiki poetry

Table 8: Test Sets of Hindi, Urdu, Punjabi and Seraiki

HU 1 is a word list obtained from the Platts dictionary[3] (Platts, 1884).

6.2 Results

For Hindi to Urdu scriptural translation, we have applied the finite-state model to all Hindi inputs of HU Test sets 1, 2 and 3. In general, it gives us an Urdu output with the necessary diacritical marks. To evaluate the performance of Hindi to Urdu scriptural translation of our finite-state system against the Urdu without diacritics, we have created a second Urdu output by removing all diacritical marks from the default Urdu output of the finite-state system. We have calculated the *Word Accuracy Rate* (WAR) and *Sentence Accuracy Rate* (SAR) for the default and the processed Urdu outputs by comparing them with the Urdu references with and without diacritics respectively. To compute WAR and SAR, we have used the SCLITE utility from the Speech Recognition Scoring Toolkit (SCTK)[4] of NIST. The results of Hindi to Urdu scriptural translation are given in Table 24.

Test Set	Default output		Processed output	
	Word Level	Sentence Level	Word Level	Sentence Level
HU 1	32.5%	-	78.9%	-
HU 2	90.8%	26.5%	91.0%	27%
HU 3	81.2%	8.8%	82.8%	9.7%

Table 9:Hindi to Urdu scriptural translation restuls

The finite-state scriptural translation system for Hindi to Urdu produces an Urdu output with diacritics. However, we know that the Urdu community is used to see the Urdu text without diacritics. Thus, we removed all diacritical marks from the Urdu output text that is more acceptable to the Urdu community. By this post-processing, we gain more than 40% accuracy in case of HU Test Set 1. We also gain in accuracy for the other test sets.

For the classification of our scriptural translation systems, we have devised two scales. One corresponds to the word accuracy rate and the other corresponds to the sentence level accuracy. They are shown in Figure 7 and 8.

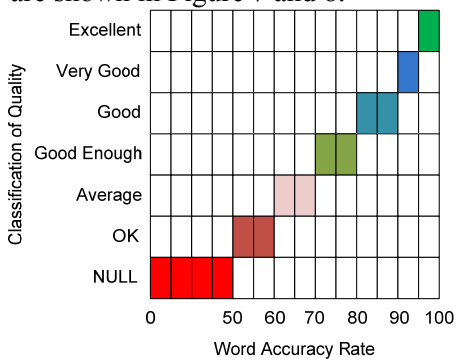

Figure 7: Classification scale based on the word accuracy rate for scriptural transaltion

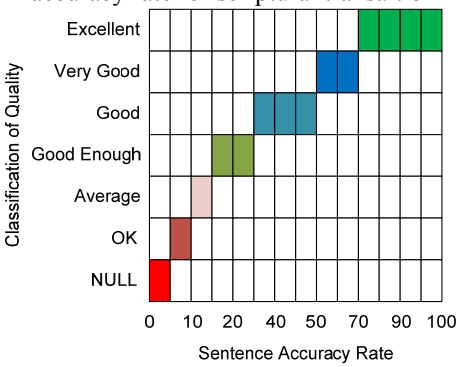

Figure 8: Classification scale based on the sentence accucary rate for scriptural translation

According to the scale of Figure 7 and 8, the Hindi to Urdu scriptural translation system is classified as 'Good' and 'Good Enough', respectively.

The subjective evaluations like usability, effectiveness and adequacy depend on several factors. A user with a good knowledge of Hindi and Urdu languages would rate our Hindi to Urdu system quite high and would also rate the Urdu output very usable. Another user who wants to read a Hindi text, but does not know Hindi, would also rate this system and the Urdu output quite high and very usable respectively, because it serves its purpose.

On the other hand, a user who wants to publish a Hindi book in Urdu, would rate this system not very good. This is because he has to localize the Hindi vocabulary of Sanskrit origin as the acceptance of the Hindi vocabulary in the Urdu

[3] Shared by University of Chicago for research purposes.

[4] http://www.itl.nist.gov/iad/mig//tools/

community, target of his published book, is very low. Thus the subjective evaluation depends on various factors and it is not easy to compute such measures for the evaluation of a scriptural translation system, but they are vital in real life.

For Urdu to Hindi scriptural translation, we have two inputs for each HU Test Set. One input contains all diacritical marks and the other does not contain any. On Hindi side, we have a single Hindi reference with which we will compare both Hindi outputs. We already know that it will give us less accuracy rates for the Urdu input without diacritical marks that are mandatory for correct Urdu to Hindi scriptural translation. The results for Urdu to Hindi scriptural translation are given in Table 10.

Test Set	With diacritics		Without diacritics	
	Word Level	Sentence Level	Word Level	Sentence Level
HU 1	68.0%	-	31.2%	-
HU 2	83.9%	10%	53.0%	1%
HU 3	98.4%	73.9%	58.9%	0.4%

Table 10: Urdu to Hindi scriptural translation results

For the Urdu input with diacritics, the accuracy of the Urdu to Hindi finite-state scriptural translation system is 83.9% at word level for HU Test Set 2 and it is classified as 'GOOD' the classification scale of Figure 7. On the other hand, it shows a sentence-level accuracy of 10% for the same test set and is classified as 'AVERAGE' by the classification scale of Figure 8.

For the Urdu input without diacritics, the Urdu to Hindi scriptural translation system is classified as 'OK' by the scale of Figure 7 for HU Test set 2 and 3. It is classifies as 'NULL' for HU Test Set 1. According to the scale of Figure 8, it is classified as 'NULL' for all three test sets.

For Punjabi scriptural translation, we also developed two types of output default and processed for Gurmukhi to Shahmukhi translation. In the reverse direction, it has two types of inputs, one with diacritics and the other without diacritics. Table 11 and 12 shows results of Punjabi scriptural translation.

Test Set	Default output		Processed output	
	Word Level	Sentence Level	Word Level	Sentence Level
PU	84.2%	27.8%	85.2%	29.9%

Table 11: Gurmukhi to Shahmukhi scriptural translation results

Test Set	With diacritics		Without diacritics	
	Word Level	Sentence Level	Word Level	Sentence Level
PU	98.8%	90.3%	67.3%	6.4%

Table 12: Shahmukhi to Gurmukhi scriptural translation results

Compared to the Hindi–Urdu pair, the Punjabi/Shahmukhi–Punjabi/Gurmukhi pair is computationally less hard. The post-processing to the default out of the finite-state scriptural translation systems for Punjabi/Gurmukhi to Punjabi/Shahmukhi also helps to gain an increase of approximately 1% and 2% at word and sentence levels respectively. The Shahmukhi to Gurmukhi scriptural translation system is classified as 'GOOD' by both scales of Figure 7 and 8. Thus the usability of the Punjabi finite-state scriptural translation system is higher than the Hindi–Urdu finite-state scriptural translation system.

In the reverse direction, the Shahmukhi to Gurmukhi scriptural translation system gives an accuracy of 98.8% and 67.3% for the Shahmukhi input text with and without diacritics respectively. For the Shahmukhi input text with diacritics, the scriptural translation system is classified as 'EXCELLENT' by both scales. On the other hand, it is classified as 'NULL' according to the scale of Figure 8 for the Shahmukhi input text without diacritical marks.

Similar to Hindi–Urdu and Punjabi finite-state scriptural translation, we have applied our finite-state system to the Seraiki test set. Here again, we have developed a processed Seraiki/Shahmukhi output from the default output of our finite-state system by removing the diacritics. The results are given in Table 13 and 14.

Test Set	Default output		Processed output	
	Word Level	Sentence Level	Word Level	Sentence Level
SE	81.3%	19.4%	83.7%	20.3%

Table 13: Seraiki/Devanagari to Seraiki/Shahmukhi scriptural translation results

Test Set	With diacritics		Without diacritics	
	Word Level	Sentence Level	Word Level	Sentence Level
SE	95.2%	76.4%	58.6%	8.6%

Table 14: Seraiki/Shahmukhi to Seraiki/Devanagari scriptural translation results

In the case of the Seraiki/Devanagari to Seraiki/Shahmukhi scriptural translation system, the post-processing also helps to gain an increase in word accuracy of approximately 1 to 2 percent

both at the word and the sentence levels. The accuracy for both the default and the processed Seraiki/Shahmukhi outputs is also more than 80% at word level. The system is classified as 'GOOD' and 'GOOD ENOUGH' according to the scale of Figure 7 and 8 respectively.

The absence of diacritical marks in the Seraiki/Shahmukhi has a very bad effect on the accuracy of the finite-state scriptural translation system. The scriptural translation system is classified as 'NULL' for the Seraiki/Shahmukhi input text without diacritics.

7 Conclusion

Finite-state methods are robust and efficient to implement scriptural translation rules in a very precise and compact manner.

The missing information and the diacritical marks in the source text proved to be very critical, crucial and important for achieving high and accurate results. The above results support our hypothesis that lack of important information in the source texts considerably lowers the quality of scriptural translation. They are crucial and their absence in the input texts decreases the performance considerably, from more than 80% to less than 60% at word level. Thus restoration of the missing information and the diacritical marks or reducing the effect of their absence on the scriptural translation is one of the major questions for further study and work.

In general, only word accuracy rates are reported. We have observed that only word accuracy rates may depict a good performance, but the performance of the same system at sentence-level may be not very good. Therefore, subjective evaluations and usage of translation results in real life should also be considered while evaluating the translation quality.

Dimensionality Reduction for Text using Domain Knowledge

Yi Mao and **Krishnakumar Balasubramanian** and **Guy Lebanon**
Georgia Institute of Technology

Abstract

Text documents are complex high dimensional objects. To effectively visualize such data it is important to reduce its dimensionality and visualize the low dimensional embedding as a 2-D or 3-D scatter plot. In this paper we explore dimensionality reduction methods that draw upon domain knowledge in order to achieve a better low dimensional embedding and visualization of documents. We consider the use of geometries specified manually by an expert, geometries derived automatically from corpus statistics, and geometries computed from linguistic resources.

1 Introduction

Visual document analysis systems such as INSPIRE have demonstrated their applicability in managing large text corpora, identifying topics within a document and quickly identifying a set of relevant documents by visual exploration. The success of such systems depends on several factors with the most important one being the quality of the dimensionality reduction. This is obvious as visual exploration can be made possible only when the dimensionality reduction preserves the structure of the original space, i.e., documents that convey similar topics are mapped to nearby regions in the low dimensional 2D or 3D space.

Standard dimensionality reduction methods such as principal component analysis (PCA), locally linear embedding (LLE) (Roweis and Saul, 2000), or t-distributed stochastic neighbor embedding (t-SNE) (van der Maaten and Hinton, 2008) take as input a set of feature vectors such as bag of words. An obvious drawback is that such methods ignore the textual nature of documents and instead consider the vocabulary words $v_1, \ldots, v_n$ as abstract orthogonal dimensions.

In this paper we introduce a framework for incorporating domain knowledge into dimensionality reduction for text documents. Our technique does not require any labeled data, therefore is completely unsupervised. In addition, it applies to a wide variety of domain knowledge.

We focus on the following type of non-Euclidean geometry where the distance between document x and y is defined as

$$d_T(x,y) = \sqrt{(x-y)^\top T(x-y)}. \qquad (1)$$

Here $T \in \mathbb{R}^{n\times n}$ is a symmetric positive semidefinite matrix, and we assume that documents x, y are represented as term-frequency (tf) column vectors. Since T can always be written as $H^\top H$ for some matrix $H \in \mathbb{R}^{n\times n}$, an equivalent but sometimes more intuitive interpretation of (1) is to compose the mapping $x \mapsto Hx$ with the Euclidean geometry

$$d_T(x,y) = d_I(Hx,Hy) = \|Hx - Hy\|_2. \quad (2)$$

We can view T as encoding the semantic similarity between pairs of words and H as smoothing the tf vector by mapping observed words to related but unobserved words. Therefore, the geometry realized by (1) or (2) may be used to derive novel dimensionality reduction methods that are customized to text in general and to specific text domains in particular. The main challenge is to obtain the matrices H or T that describe the relationship among vocabulary words appropriately.

We consider three general ways of obtaining H or T using domain knowledge. The first corresponds to manually specifying H or T based on the semantic relationship among words (determined by domain expert). The second corresponds to constructing H or T by analyzing relationships between different words using corpus statistics. The third is based on knowledge obtained from linguistic resources. Whether to specify H directly or indirectly by specifying T =

Coling 2008: Poster Volume, pages 801–809,
Beijing, August 2010

$H^\top H$ depends on the knowledge type and is discussed in detail in Section 4.

We investigate the performance of the proposed dimensionality reduction methods for three text domains: sentiment visualization for movie reviews, topic visualization for newsgroup discussion articles, and visual exploration of ACL papers. In each of these domains we evaluate the dimensionality reduction using several different quantitative measures. All the techniques mentioned in this paper are unsupervised, making use of labels only for evaluation purposes.

Our take home message is that all three approaches mentioned above improves dimensionality reduction for text upon standard embedding ($H = I$). Furthermore, geometries obtained from corpus statistics are superior to manually constructed geometries and to geometries derived from standard linguistic resources such as WordNet. Combining heterogenous types of knowledge provides the best results.

2 Related Work

Despite having a long history, dimensionality reduction is still an active research area. Broadly speaking, dimensionality reduction methods may be classified as projective or manifold based (Burges, 2009). The first projects data onto a linear subspace (e.g., PCA and canonical correlation analysis) while the second traces a low dimensional nonlinear manifold on which data lies (e.g., multidimensional scaling, isomap, Laplacian eigenmaps, LLE and t-SNE). The use of dimensionality reduction for text documents is surveyed by Thomas and Cook (2005) who also describe current homeland security applications.

Dimensionality reduction is closely related to metric learning. Xing et al. (2003) is one of the earliest papers that focus on learning metrics of the form (1). In particular they try to learn matrix T in an supervised way by expressing relationships between pairs of samples. A representative paper on unsupervised metric learning for text documents is Lebanon (2006) which learns a metric on the simplex based on the geometric volume of the data.

We focus in this paper on visualizing a corpus of text documents using a 2-D scatter plot. While this is perhaps the most popular and practical text visualization technique, other methods such as Spoerri (1993), Hearst (1997), Havre et al. (2002), Paley (2002), Blei et al. (2003), Mao et al. (2007) exist. Techniques developed in this paper may be ported to enhance these alternative visualization methods as well.

3 Non-Euclidean Geometries

Dimensionality reduction methods often assume, either explicitly or implicitly, Euclidean geometry. For example, PCA minimizes the reconstruction error for a family of Euclidean projections. LLE uses the Euclidean geometry as a local metric. t-SNE is based on a neighborhood structure, determined again by the Euclidean geometry. The generic nature of the Euclidean geometry makes it somewhat unsuitable for visualizing text documents as the relationship between words conflicts with Euclidean orthogonality. We consider in this paper several alternative geometries of the form (1) or (2) which are more suited for text and compare their effectiveness in visualizing documents.

As mentioned in Section 1, H smooths the tf vector x by mapping the observed words into observed and non-observed (but related) words. In case H is nonnegative, it can be further decomposed into a product of a non-negative column normalized matrix $R \in \mathbb{R}^{n\times n}$ and a non-negative diagonal matrix $D \in \mathbb{R}^{n\times n}$. The decomposition $H = RD$ shows that H has two key roles. It smooths related vocabulary words (realized by R) and it emphasizes some words over others (realized by D). Setting R_{ij} to a high value if w_i, w_j are similar and 0 if they are unrelated maps an observed word to a probability vector over related words in the vocabulary. The value D_{ii} captures the importance of v_i and therefore should be higher for important content words than for less important words or stop-words[1].

It is instructive to examine the matrices R and D in the case where the vocabulary words cluster in some meaningful way. Figure 1 gives an example where vocabulary words form two clusters. The matrix R may become block-diagonal with non-zero elements occupying diagonal blocks representing within-cluster word

[1]The nonnegativity assumption of H is useful when constructing H by domain experts such as the method A in Section 4. In general, H needs not to be nonnegative for dimensionality reduction as in (2).

$$\begin{pmatrix} 0.8 & 0.1 & 0.1 & 0 & 0 \\ 0.1 & 0.8 & 0.1 & 0 & 0 \\ 0.1 & 0.1 & 0.8 & 0 & 0 \\ 0 & 0 & 0 & 0.9 & 0.1 \\ 0 & 0 & 0 & 0.1 & 0.9 \end{pmatrix} \begin{pmatrix} 5 & 0 & 0 & 0 & 0 \\ 0 & 5 & 0 & 0 & 0 \\ 0 & 0 & 5 & 0 & 0 \\ 0 & 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & 0 & 3 \end{pmatrix}$$

Figure 1: An example of a decomposition $H = RD$ in the case of two word clusters $\{v_1, v_2, v_3\}$, $\{v_4, v_5\}$. The block diagonal elements in R represent the fact that words are mostly mapped to themselves, but sometimes are mapped to other words in the same cluster. The diagonal matrix indicates that the first cluster is more important than the second cluster for the purposes of dimensionality reduction.

blending, i.e., words within each cluster are interchangeable to some degree. The diagonal matrix D represents the importance of different clusters. The word clusters are formed with respect to the visualization task at hand. For example, in the case of visualizing the sentiment content of reviews we may have word clusters labeled as "positive sentiment words", "negative sentiment words" and "objective words".

In general, the matrices R, D may be defined based on the language or may be specific to document domain and visualization purpose. It is reasonable to expect that the words emphasized for visualizing topics in news stories might be different than the words emphasized for visualizing writing styles or sentiment content.

Applying the geometry (1) or (2) to dimensionality reduction is easily accomplished by first mapping document tf vectors $x \mapsto Hx$ and proceeding with standard dimensionality reduction techniques such as PCA or t-SNE. The resulting dimensionality reduction is Euclidean in the transformed space but non-Euclidean in the original space. In many cases, the vocabulary contains tens of thousands of words or more making the specification of T or H a complicated and error prone task. We describe in the next section several techniques for specifying these matrices in practice.

4 Domain Knowledge

Method A: Manual Specification

In this method, a domain expert manually specifies $H = RD$ by specifying (R, D) based on the perceived relationship among the vocabulary words. More specifically, the user first constructs a hierarchical word clustering that may depend on the current text domain, and then specifies the matrices (R, D) based on the clustering.

Denoting the clusters by $C_1, \ldots, C_r$ (a partition of $\{v_1, \ldots, v_n\}$), R is set to

$$R_{ij} \propto \begin{cases} \rho_a, & i = j, v_i \in C_a \\ \rho_{ab}, & i \neq j, v_i \in C_a, v_j \in C_b \end{cases}.$$

The values $\rho_{ab}, a \neq b$ capture the semantic similarity between two clusters and the value ρ_{aa} captures the similarity of two different words within the cluster a. These values may be set manually by domain expert or automatically computed based on the clustering hierarchy (for example ρ_{ab} can be the inverse of the minimal number of tree edges traversed in moving from a to b). To maintain a probabilistic interpretation, the matrix R should be normalized so that its columns sum to 1. The diagonal matrix D is specified by setting the values

$$D_{ii} = d_a, \quad v_i \in C_a$$

according to the importance of word cluster C_a to the current visualization task.

We emphasize that as with the rest of the methods in this paper, the manual specification is done without access to labeled data. Since manual clustering assumes some form of human intervention, it is reasonable to also consider cases where the user specifies H or T in an interactive manner. For example, the expert specifies an initial clustering of words and values for (R, D), views the resulting embeddings and adjusts the selection interactively until reaching a satisfactory embedding.

Method B: Contextual Diffusion

An alternative to manually specifying $T = DR^\top RD$ is to construct it based on similarity between the contextual distributions of the vocabulary words. The contextual distribution of word v is defined as

$$q_v(w) = p(w \text{ appears in } x | v \text{ appears in } x) \quad (3)$$

where x is a randomly drawn document. In other words q_v is the distribution governing the words appearing in the context of word v.

A natural similarity measure between distributions is the Fisher diffusion kernel proposed by Lafferty and Lebanon (2005). Applied to contextual distributions as in Dillon et al. (2007) we arrive at the following similarity matrix

$$T(u,v) = \exp\left(-c \arccos^2\left(\sum_w \sqrt{q_u(w) q_v(w)}\right)\right).$$

where $c > 0$. Intuitively, the word u will be diffused into v depending on the geometric diffusion between the distributions of likely contexts.

We use the following formula to estimate the contextual distribution from a corpus

$$\begin{aligned} q_v(w) &= \sum_{x'} p(w, x'|v) = \sum_{x'} p(w|x', v) p(x'|v) \\ &= \sum_{x'} \mathrm{tf}(w, x') \frac{\mathrm{tf}(v, x')}{\sum_{x''} \mathrm{tf}(v, x'')} \qquad (4) \\ &= \left(\frac{1}{\sum_{x'} \mathrm{tf}(v, x')}\right) \left(\sum_{x'} \mathrm{tf}(w, x') \mathrm{tf}(v, x')\right) \end{aligned}$$

where $\mathrm{tf}(w, x)$ is the number of times word w appears in document x divided by the length of the document x. The contextual distribution q_v or diffusion matrix T above may be computed in an unsupervised manner without labels.

Method C: Web n-Grams

In method B the contextual distribution is computed using a large external corpus that is similar to the text being analyzed. An alternative that is especially useful when such a corpus is not easily available is to use generic resources to estimate the contextual distribution (3)-(4). One option is to use the publicly available Google n-gram dataset (Brants and Franz, 2006) to estimate T. More specifically, we compute the contextual distribution by considering the proportion of times two words appear together within the n-grams e.g., for $n = 2$ we have

$$q_v(w) = \frac{\#\text{ of bigrams containing both } w \text{ and } v}{\#\text{ of bigrams containing } v}.$$

Method D: Word-Net

In the last method, we consider using Word-Net, a standard linguistic resource, to specify T. This is similar to manual specification (method A) in that it builds upon experts' knowledge rather than corpus statistics. In contrast to method A, however, Word-Net is a carefully built resource containing more accurate and comprehensive linguistic information such as synonyms, hyponyms and holonyms. On the other hand, its generality puts it at a disadvantage as method A may be adapted to a specific text domain.

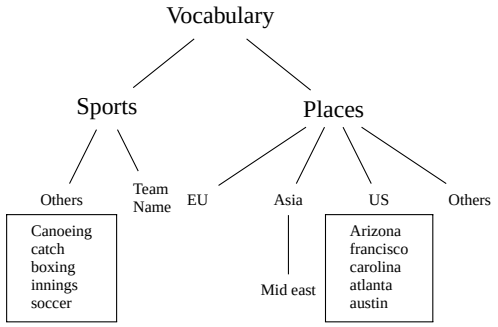

Figure 2: Manually specified hierarchical word clustering for the 20 newsgroup domain. The words in the frames are examples of words belonging to several bottom level clusters.

We follow Budanitsky and Hirst (2001) who compared five similarity measures between words based on Word-Net. In our experiments we use the measure of Jiang and Conrath (1997) (see also Jurafsky and Martin (2008))

$$T(u,v) = \log \frac{p(u)p(v)}{2p(\mathrm{lcs}(u,v))}$$

as it was shown to outperform the others. Above, lcs stands for the lowest common subsumer, i.e., the lowest node in the hierarchy that subsumes (is a hypernym of) both u and v. The quantity $p(u)$ is the probability that a randomly selected word in a corpus is an instance of the synonym set that contains word u.

Combination of Methods

In addition to individual methods we also consider their convex combinations

$$H^* = \sum_i \alpha_i H_i \quad \text{s.t.} \quad \alpha_i \geq 0, \sum_i \alpha_i = 1 \qquad (5)$$

where H_i are matrices from methods A-D (obtained implicitly by specifying R and D for method A and T for methods B-D). Doing so allows us to combine heterogeneous types of domain knowledge including experts' knowledge

and corpus statistics, leverage their diverse nature and potentially achieve better performance than any of the methods on its own.

5 Experiments

We evaluate the proposed methods by experimenting on two text datasets where domain knowledge is relatively easy to obtain (especially for method A and B). Preprocessing includes lower-casing, stop words removal, stemming, and selecting the most frequent 2000 words for both datasets.

The first is the Cornell sentiment scale dataset of movie reviews from 4 critics (Pang and Lee, 2004). The visualization in this case focuses on the sentiment quantity of either 1 (very bad) or 4 (very good) (Pang et al., 2002). For method A, we use the General Inquirer resource[2] to partition the vocabulary into three clusters conveying positive, negative or neutral sentiment. While visualizing documents from one particular author, the rest of the reviews from other three authors can be used as an estimate of contextual distribution for method B.

The second text dataset is the 20 newsgroups. It consists of newsgroup articles from 20 distinct newsgroups and is meant to demonstrate topic visualization. In this case one of the authors designed a hierarchical clustering of the vocabulary words based on general knowledge of English language (see Figure 2 for a partial clustering hierarchy) without access to labels. The contextual distribution for method B is estimated from the Reuters RCV1 dataset (Lewis et al., 2004) which consists of news articles from Reuters.com in the year 1996 and 1997.

Method C uses Google n-gram which provides a massive scale resource for estimating the contextual distribution. In the case of Word-Net (method D) we used Pedersen's implementation of Jiang and Conrath's similarity measure[3]. Note, for these two methods, the obtained information is not domain specific but rather represents general semantic relationships between words.

In our experiments below we focused on two dimensionality reduction methods: PCA and t-SNE. PCA is a well known classical method while t-SNE (van der Maaten and Hinton, 2008) is a recent dimensionality reduction technique for visualization purposes. The use of t-SNE is motivated by the fact that it was shown to outperform LLE, CCA, MVU, Isomap, and Laplacian eigenmaps when the dimensionality of the data is reduced to two or three.

To measure the dimensionality reduction quality, we visualize the data as a scatter plot with different data groups (topics, sentiments) displayed with different markers and colors. Our quantitative evaluation of the visualization is based on the fact that documents belonging to different groups (topics, sentiments) should be spatially separated in the 2-D space. Specifically, we used the following indices:

(i) The weighted intra-inter criteria is a standard clustering quality index that is invariant to non-singular linear transformations of the embedded data. It equals $\mathrm{tr}(S_T^{-1}S_W)$ where S_W is the within-cluster scatter matrix, $S_T = S_W + S_B$ is the total scatter matrix, and S_B is the between-cluster scatter matrix (Duda et al., 2001).

(ii) The Davies Bouldin index is an alternative to (i) that is similarly based on the ratio of within-cluster scatter to between-cluster scatter (Davies and Bouldin, 2000).

(iii) Classification error rate of a k-NN classifier that applies to data groups in the 2-D embedded space. Despite the fact that we are not interested in classification per se (otherwise we would classify in the original high dimensional space), it is an intuitive and interpretable measure of cluster separation.

(iv) An alternative to (iii) is to project the embedded data onto a line which is the direction returned by applying Fisher's linear discriminant analysis to the embedded data. The projected data from each group is fitted to a Gaussian whose separation is used as a proxy for visualization quality. In particular, we summarize the separation of the two Gaussians by measuring the overlap area. While (iii) corresponds to the performance of a k-NN classifier, method (iv) corresponds to the performance of Fisher's LDA classifier.

Labeled data is not used during the dimensionality reduction stage but it is used in each of the above measures for evaluation purposes.

[2] http://www.wjh.harvard.edu/∼inquirer/

[3] http://wn-similarity.sourceforge.net/

Figure 3 displays both qualitative and quantitative evaluation of PCA and t-SNE for the sentiment and newsgroup domains for $H = I$ (left column), manual specification (middle column) and contextual distribution (right column). In general for both domains, methods A and B perform better both qualitatively and quantitatively (indicating by the numbers in the top two rows) than the original dimensionality reduction with method B outperforming method A.

Tables 1-2 compare evaluation measures (i) and (iii) for different types of domain knowledge. Table 1 corresponds to the sentiment domain where we conducted separate experiments for four movie critics. Table 2 corresponds to the newsgroup domain where two tasks were considered. The first involves three newsgroups (comp.sys.mac.hardware vs. rec.sports.hockey vs. talk.politics.mideast) and the second involves four newsgroups (rec.autos vs. rec.motorcycles vs. rec.sports.baseball vs. rec.sports.hockey). It is clear from these two tables that the contextual diffusion, Google n-gram, and Word-Net generally outperform the original $H = I$ matrix. The best method varies from task to task but the contextual diffusion and Google n-gram in general result in good performance.

	PCA (1)	PCA (2)	t-SNE (1)	t-SNE (2)
$H = I$	1.5391	1.4085	1.1649	1.1206
B	1.2570	**1.3036**	1.2182	1.2331
C	**1.2023**	1.3407	**0.7844**	**1.0723**
D	1.4475	1.3352	1.1762	1.1362
	PCA (1)	PCA (2)	t-SNE (1)	t-SNE (2)
$H = I$	0.8461	0.5630	0.9056	0.7281
B	0.7381	**0.6815**	0.9110	0.6724
C	0.8420	0.5898	**0.9323**	0.7359
D	**0.8532**	0.5868	0.9013	**0.7728**

Table 2: Quantitative evaluation of dimensionality reduction for visualization for two tasks in the news article domain. The numbers in the top five rows correspond to measure (i) (lower is better), and the numbers in the bottom five rows correspond to measure (iii) ($k = 5$) (higher is better). We conclude that contextual diffusion (B), Google n-gram (C), and Word-Net (D) tend to outperform the original $H = I$.

We also examined convex combinations

$$\alpha_1 H_A + \alpha_2 H_B + \alpha_3 H_C + \alpha_4 H_D \qquad (6)$$

with $\sum \alpha_i = 1$ and $\alpha_i \geq 0$. Table 3 displays quantitative results using evaluation measures (i), (ii) and (iii) where k is chosen to be 5 for (iii). The first four rows correspond to method A, B, C and D and the bottom row corresponds to a convex combination found which minimizes the unsupervised evaluation measure (ii) (i.e. the search for the optimal combination is based on (ii) that does not require labeled data). Note that the convex combination also outperforms method A, B, C, and D for measure (i) and more impressively for measure (iii) which is a supervised measure that uses labeled data. In general, by combining heterogeneous types of domain knowledge, we may further improve the quality of dimensionality reduction for visualization, and the search for such a combination may be accomplished without the use of labeled data.

$(\alpha_1, \alpha_2, \alpha_3, \alpha_4)$	(i)	(ii)	(iii) (k=5)

Table 3: Three evaluation measures (i), (ii), and (iii) (see the beginning of the section for description) for convex combinations (6) using different values of α. The first four rows represent methods A, B, C, and D. The bottom row represents a convex combination whose coefficients were obtained by searching for the minimizer of measure (ii). Interestingly the minimizer also performs well on measure (i) and more impressively on the labeled measure (iii).

Finally, we demonstrate the effect of domain knowledge on a new dataset that consists of all oral papers appearing in ACL 2001 – 2009. For the purpose of manual specification, we obtain 1545 unique words from paper titles, and assign for each word relatedness scores for the following clusters: morphology/phonology, syntax/parsing, semantics, discourse/dialogue, generation/summarization, machine translation, retrieval/categorization and machine learning. The score takes value from 0 to 2, where 2 represents the most relevant. The score information is then used to generate the transformation matrix R. We also assign for each word an importance value ranging from 0 to 3 (larger the value, more important the word). This information is used to generate the diagonal matrix D.

Figure 4 shows the projection of all 2009 papers using t-SNE (papers from 2001 to 2008 are used to estimate contextual diffusion). Using Euclidean geometry $H = I$ (Figure 4 left) results in a Gaussian like distribution which does not provide much insight into the data. Using a manually

Table 1: Quantitative evaluation of dimensionality reduction for visualization in the sentiment domain. Each of the four columns corresponds to a different movie critic from the Cornell dataset (see text). The top five rows correspond to measure (i) (lower is better) and the bottom five rows correspond to measure (iii) ($k = 5$, higher is better). Results were averaged over 40 cross validation iterations. We conclude that all methods outperform the original $H = I$ with the contextual diffusion and manual specification generally outperforming the others.

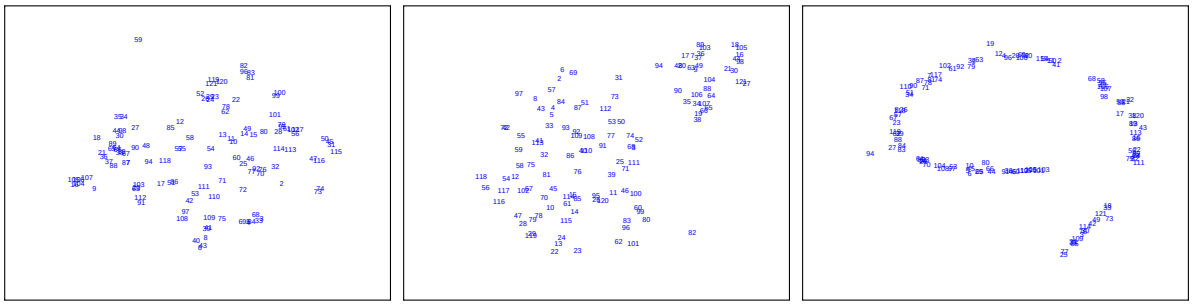

Figure 4: Qualitative evaluation of dimensionality reduction for the ACL dataset using t-SNE. Left: no domain knowledge ($H = I$); Middle: manual specification (method A); Right: contextual diffusion (method B). Each document is labeled by its assigned id from ACL anthology. See text for more details.

specified H (Figure 4 left) we get two clear clusters, the smaller containing papers dealing with machine translation and multilingual tasks. Interestingly, the contextual diffusion results in a one-dimensional manifold. Investigating the papers along the curve (from bottom to top) we find that it starts with papers discussing semantics and discourse (south), continues to structured prediction and segmentation (east), continues to parsing and machine learning (north), and then moves to sentiment prediction, summarization and IR (west) before returning to the center. Another interesting insight that we can derive is the relative discontinuity between the bottom part (semantics and discourse) and the rest of the curve. It seems spatial separability is higher in that area than in the other areas where the curve nicely traverses different regions continuously.

6 Discussion

In this paper we introduce several ways of incorporating domain knowledge into dimensionality reduction for visualizing text documents. The proposed methods all outperform in general the baseline $H = I$, which is the one currently used in most text visualization systems.

The answer to the question of which method is best depends on both the domain and the task at hand. For small tasks with limited vocabulary, manual specification could achieve best results. A large vocabulary size makes manual specification less accurate and effective. In cases where we have access to a large external corpus that is similar to the one we are interested in visualizing, contextual diffusion is an excellent choice. Lacking such a domain specific dataset estimating the contextual distribution using the generic Google n-gram is a good substitute. Word-Net captures relationships (such as synonyms and hyponyms) other than occurrence statistics between vocabulary words, and could be useful for certain tasks. Finally, the effectiveness of dimensionality reduction methods can be increased further by carefully combining different types of domain knowledge ranging from semantic similarity to occurrence statistics.

Varro: An Algorithm and Toolkit for Regular Structure Discovery in Treebanks

Scott Martens
Centrum voor Computerlinguïstiek, KU Leuven
scott@ccl.kuleuven.be

Abstract

The *Varro* toolkit is a system for identifying and counting a major class of regularity in treebanks and annotated natural language data in the form of tree-structures: frequently recurring unordered subtrees. This software has been designed for use in linguistics to be maximally applicable to actually existing treebanks and other stores of tree-structurable natural language data. It minimizes memory use so that moderately large treebanks are tractable on commonly available computer hardware. This article introduces *condensed canonically ordered trees* as a data structure for efficiently discovering frequently recurring unordered subtrees.

2 Introduction

Treebanks and similarly enhanced corpora are increasingly available for research, but these more complex structures are resistant to the techniques used in NLP for the statistical analysis of strings. This paper introduces a new treebank analysis suite *Varro*, named after Roman philologist Marcus Terentius Varro (116 BC-27 BC), who made linguistic regularity and irregularity central to his philosophy of language in *De Lingua Latina*. (Harris and Taylor, 1989)

The *Varro* toolkit focuses on a general problem in performing statistical analyses on treebanks: identifying, counting and extracting the distributions of frequently recurring unordered subtrees in treebanks. From this base, it is possible to construct more linguistically motivated schemes for performing treebank analysis. Complex statistical analyses are constructed from knowledge about frequency and distribution, so this constitutes a low level task on top of which higher level analyses can be performed.

An algorithm that can efficiently extract frequently recurring subtrees from treebanks has a number of immediate applications in computational linguistics:

- Speeding up treebank search algorithms like Tgrep2. (Rohde, 2001)
- Rule discovery for tree transducers used in parsing and machine translation. (Knight and Graehl, 2005; Knight, 2007)
- Generalizing lexical statistics techniques in NLP – e.g., collocation – to a broader array of linguistic structures. (Sinclair, 1991)
- Efficiently identifying useful features for tree kernel methods. (Moschitti, 2006)

3 Theory and Previous Work

For the purposes of this paper, a treebank is any collection of disjoint labeled trees. While in practice this mostly means parsed natural language sentences, the approach described here is equally applicable to other kinds of data, including semantic feature structures, morphological analyses, and

[1] http://www.cs.kuleuven.be/~liir/projects/amass/

Coling 2008: Poster Volume, pages 810–818,
Beijing, August 2010

doubtless many other kind of linguistically motivated structures. Figure 1 is an example of a parse tree from a Dutch-language treebank.

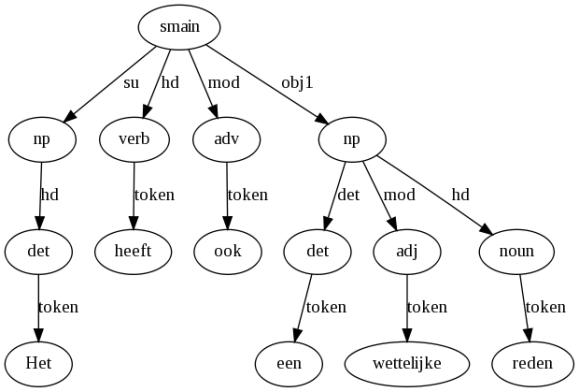

Figure 1: A tree from the Europarl Dutch corpus. (Koehn, 2005) It has been parsed and labeled automatically by the Alpino parser. (van Noord, 2006) A word-for-word translation is "*It also has a legal reason.*" (≈ "*There is also a legal reason (for that).*")

In this paper, we are concerned with identifying and counting *frequent induced unordered subtrees* in treebanks. The term *subtree* has a number of definitions, but this paper will follow the terminology of Chi et al. (2004). Figure 2 contains three examples of *induced unordered subtrees* of the tree in Figure 1. Note that the ordering of the vertices in the subtrees is different from that of Figure 1. This is what makes them *unordered subtrees*. *Induced subtrees* are more formally described in Section 4.

3.1 Apriori

The research builds on frequent subtree discovery algorithms based on the well-known *Apriori* algorithm, which is used to discover frequent itemsets in databases. (Agrawal et al., 1993) As a brief summary of *Apriori*, consider a collection of ordered itemsets $\mathbb{C} = \{\{a,b,c\},\{a,b,d\},\{b,c,d,e\}\}$. *Apriori* discovers all the subsets of those elements that appear at least some user-determined θ times. As an example, let us set $\theta = 2$, and then count the number of times each unique item appears in $\mathbb{C}$. Any single element in $\mathbb{C}$ that appears less than two times cannot be a member of a set of elements that appears at least θ times (since $\theta = 2$), so those are rejected. Each of the remaining set elements $\{a,b,c,d\}$ is extended by counting the number of two-element sets that include it and some element to the right in the ordered itemsets in $\mathbb{C}$. For b, these are $\{\{b,c\},\{b,d\},\{b,e\}\}$. Of this set, only those that appear at least θ times are retained: $\{\{b,c\},\{b,d\}\}$. This process is repeated for size three sets, and iterated over and over for increasingly large subsets, until there are no extensions that appear at least θ times. This whole procedure is then repeated for each unique item. Finally, *Apriori* will have extracted and counted all itemsets that appear at least θ times in $\mathbb{C}$.

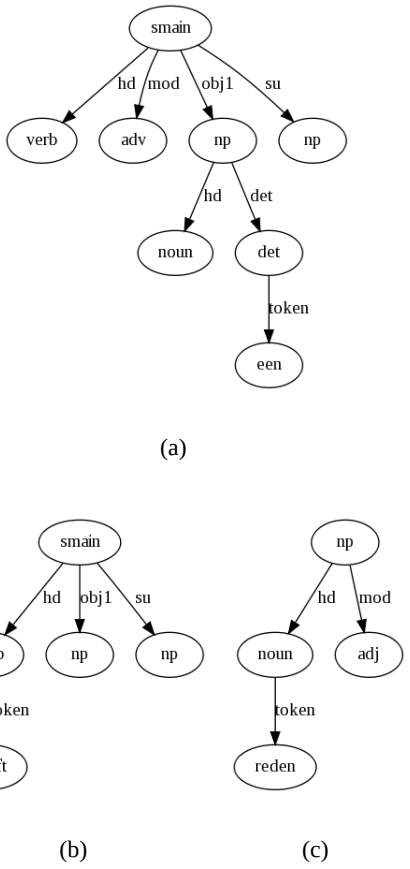

Figure 2: Three induced unordered subtrees of the tree in Figure 1

Extending *Apriori* to frequent subtree discovery dates to the work of Zaki (2002) and Asai et al. (2002). Chi et al. (2004) summarizes much of this line of research. In *Apriori*, larger and less frequent itemsets are discovered

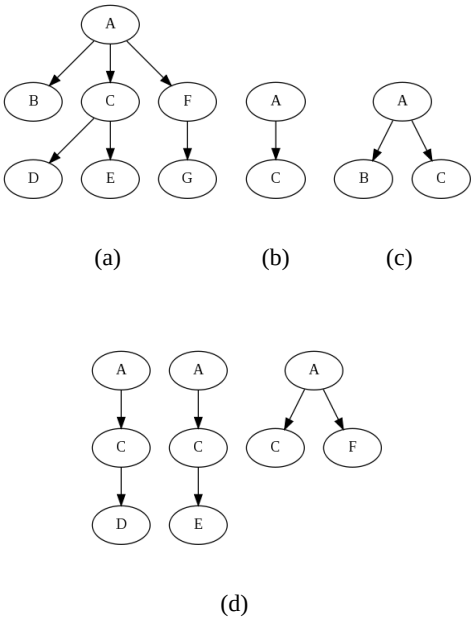

Figure 3: 3(b) and 3(c) are a subtrees of 3(a). The subtrees in 3(d) are possible extensions to 3(b), while 3(c) is not.

and counted by adding items to shorter and more frequent ones. This extends naturally to trees by initially locating and counting all the one-vertex trees in a treebank, and then constructing larger trees by adding vertices and edges to their right sides.

In Figure 3, subtree 3(b) has as valid extensions subtrees 3(d), all of which extend 3(b) to the right. An extension like subtree 3(c), which adds a node to the left of the rightmost node of 3(b), is not a valid extension.

3.2 Treebank applications

Applying these algorithms to natural language treebanks, however, presents a number of challenges.

The approach described above, because it constructs and tests subtrees by moving from left to right, is well-suited to finding *ordered subtrees*. However, this paper will consider *unordered subtrees* as better motivated linguistically. Word order is not completely fixed in any language, and can be very free in many important contexts.

But there are other problems as well. Apriori-style algorithms have the general property that their run-time is proportionate to the size of the output. Given a data-set D and a user-determined minimum frequency threshold θ, this class of solution outputs all the patterns that appear at least θ times in D. If D contains n patterns that appear at least θ times, $\mathbb{P} = \{p_1, p_2, ..., p_n\}; \forall p_i \in \mathbb{P} : freq(p_i) \geq \theta$, then the time necessary to identify and count all the patterns in $\mathbb{P}$ is proportionate to $\sum_{i=1}^{n} freq(p_i)$. In weakly correlated data, this is a very efficient method of finding patterns. In highly correlated data, however, the number of patterns present can become prohibitively large and extend run-time to unacceptable lengths, especially for small θ or large data-sets. Each frequent pattern may have any number of sub-patterns, each of which is also frequent and must be separately counted.

If we identify patterns with subtrees, a subtree with n vertices will, depending on its structure, have a minimum of $n(n-1)$ and a maximum of $(n-1)! + 1$ subtrees. If each of those subtrees is also a pattern that must be counted, then runtime grows very rapidly even for very small data-sets. Since natural language data is highly correlated, simple subtree-discovery extensions of *Apriori*, like those proposed in (Zaki, 2002) and (Asai, 2002), are not feasible for linguistic use. As reported in Martens (2009b), run-times become intractably long very quickly as data size increases for really existing treebanks.

However, there are compact representations of frequent patterns that are better suited to highly-correlated data and which can be efficiently discovered by modified *Apriori* schemes. This paper will only address one such representation: *frequent closures*. (Boulicaut and Bykowski, 2000) Frequent closures are widely used in subtree discovery and have an intuitive meaning when discussing natural language.

Given a treebank D, and a tree T that has a support of $freq(T) = \theta$, then T is *closed* if there is no supertree $T' \supset T$ where $freq(T') = \theta$. In Figure 3, if subtree 3(c) is as frequent in some treebank as 3(b), then 3(b) is not a closed subtree, nor can any further extension of it to the right be a closed subtree.

As a natural language example, given a corpus

of English sentences, let us assume we have found a pattern of the form *"NP make up NP to VP"*, such as in *"He has made up his mind to study linguistics."* If every time this pattern appears in the corpus, the second NP contains *"mind"*, then the pattern is *not* closed. A larger pattern appears just as often and in exactly the same places.

This makes the notion of frequent closed subtree discovery a generalization of *collocation* and *coligation* - well known in corpus-based lexicography - to arbitrary tree structures. (Sinclair, 1991) J.R. Firth famously said, "You shall know a word by the company it keeps." (Firth, 1957) Frequent subtree discovery tells us exactly what company entire linguistic structures keep.

3.3 Efficient closed subtree discovery

Chi et al. (2005a) outlines a general method for efficiently finding frequent closed subtrees without finding all frequent subtrees first. Their approach requires each subtree found to be aligned with its supertree before checking for closure and extensions. However, the alignment between a subtree and its supertree - the map from subtree vertices to supertree vertices - is not necessarily unique. A subtree may have a number of possible alignments with its supertree, even if one or more of the vertex alignments is specificed, as shown in Figure 4, which uses an example from the hand-corrected Alpino Treebank of Dutch.[2]

This can only be avoided by adding a restriction to trees: the combination of edge and vertex labels for each child of a vertex must be unique. This guarantees that specifying just one vertex in the alignment of a subtree to its supertree is enough to determine the entire unique mapping, but it is incompatible with most linguistic theories. Processes like tree binarization can meet this requirement, but only with some loss of generality: Some frequent closed subtrees in a collection of trees like Figure 4(a) will no longer be frequent, or will be less frequent, in a collection of binary trees.

Martens (2009a) describes an alternative method of checking for closure which does not require alignment and can, consequently, be much faster. It has, however, two drawbacks: First, it does not find all frequent closed unordered subtrees. Figure 5 shows the kind of tree where that approach is unable to correctly identify and count an unordered subtree. Second, it requires a great deal more memory than solutions that align each subtree discovered and check directly for closure, and is therefore of limited use with very large corpora.

[2] http://www.let.rug.nl/vannoord/trees/

4 Definitions

A *fully-labeled rooted tree* is a rooted tree in which each vertex and each edge has a label: $T := \langle V, E, L_V, L_E \rangle$, where V is the set of vertices, E is the set of edges, L_V is a map $L_V : V \to \mathbb{L}_V$ from the vertices to a set of labels; and similarly L_E maps the edges to labels $L_E : E \to \mathbb{L}_E$. We will designate an edge e connecting vertex v_1 to its child v_2 by the notation $e = \langle v_1, v_2 \rangle$. $\mathbb{L}_V$ and $\mathbb{L}_E$ constitute collectively the *lexicon*. Figure 1 is an example of a fully-labelled, rooted tree from a Dutch-language treebank. This formalization is broadly applicable to all linguistic formalisms whose structures are *tree-based* or can be converted one-to-one into trees without loss of generality. This may require some degree of restructuring of the tree formats used in particular linguistic theories. For example, in many formal linguistic theories, labels are not atomic symbols, but may have many parts or even whole structured feature sets. In general, these can be mapped to trees with atomic labels by inserting additional vertices, or by taking advantage of edge labelling.

The algorithm described here is insufficient for formal structures that require more powerful graph formalisms like directed acyclic graphs.

The relations *parent*, *child* and *sibling* are taken here in their ordinary sense in discussing trees. In Figure 1, the vertex labeled *adv* is a *child* of the vertex labeled *smain*, the *parent* of the vertex labeled *ook*, and a sibling of the vertex labeled *verb* and the two vertices labeled *np*. To simplify definitions, the operator $label(x)$ will indicate the label of vertex or edge x.

An *induced unordered subtree* is a connected subset of the vertices of some tree that preserves the vertex and edge labels and the parent-child relations of that tree but need not preserve the ordering of siblings. Given a fully-labeled tree $T := \langle V_T, E_T, L_{V_T}, L_{E_T} \rangle$, an *induced subtree* S of T is

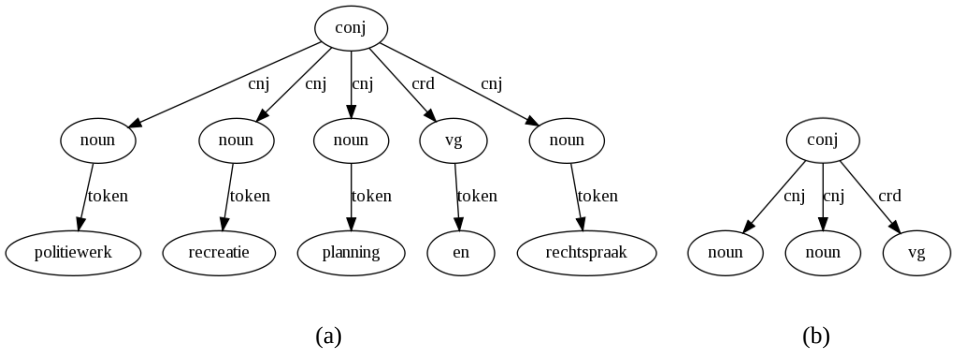

Figure 4: In 4(a) is a Dutch phrase conjoining multiple nouns. It translates as *"police work, recreation, planning and court activities"*. 4(b) has six unique unordered alignments with 4(a).

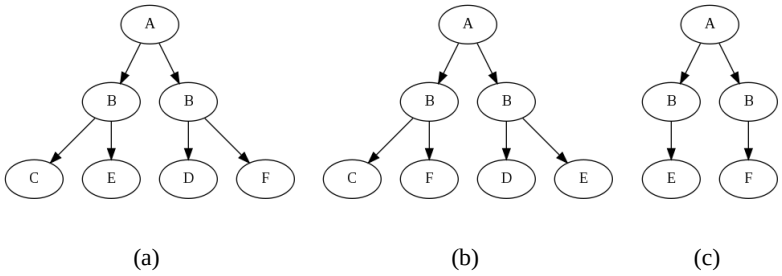

Figure 5: Subtree 5(c) is an unordered subtree of both 5(a) and 5(b), but the algorithm described in Martens (2009a) is unable to capture this in all cases.

a fully-labeled tree $S := \langle V_S, E_S, L_{V_S}, L_{E_S} \rangle$ for which there is an injection $M : V_S \rightarrow V_T$ from the vertices of S to some subset of the vertices of T, and for which:

$\forall v \in V_S$:

a. $label(v) = label(M(v))$
b. $e = \langle parent(v), v \rangle \in E_S \rightarrow$
   $e' = \langle M(parent(v)), M(v) \rangle \in E_T$
c. $label(e) = label(e')$

See Figures 1 and 2 for examples of subtrees of a particular tree.

We will further define all subtrees that are identical except in the ordering of their vertices to be *unordered isomorphic*. If a tree T is a subtree of tree T', we will follow set notation by denoting this relation as $T \subseteq T'$.

4.1 Canonical Ordering

Using canonical orderings to solve frequent unordered subtree problems was first proposed in Luccio et al. (2001) and expanded by other researchers in frequent subtree discovery techniques, notably in Chi et al. (2005b). Since the *Apriori*-style approaches described in Section 3.1 are suited only to finding subtrees whose vertices appear in a particular order, this paper will describe a mechanism for converting fully-labeled trees into canonical forms that guarantee that all instances of any unordered subtree will have an identical order to their vertices.

We must first define a strict total ordering over vertex and edge labels. Given lexica for the edge and vertex labels, $\mathbb{L}_E$ and $\mathbb{L}_V$ respectively, we define a strict total ordering on each such that $\forall l_i, l_j \in \mathbb{L}$ either $l_i \prec l_j$ or $l_i \succ l_j$ or $l_i = l_j$ and if $l_i \prec l_j$ and $l_j \prec l_k$, then $l_i \prec l_k$.

In a collection of fully-labeled trees, every vertex v that is not the root of some tree can be associated with a *full label* which is the pair $fullLabel(v) = \langle label(\langle parent(v), v \rangle), label(v) \rangle$, containing the label of the edge leading to its parent and the label of the vertex itself. For any pair of vertices where the edge to their parent is different, we

order the vertices by the order of those edges. Where the edges are the same, we order them by the ordering of their vertex labels. Where we have two sibling vertices v_i and v_j such that $fullLabel(v_i) = fullLabel(v_j)$, we recursively order the descendants of v_i and v_j, and then compare them. In this way, two nodes can only have an undefined order if they have both exactly the same full labels and identical descendants.

A *canonically ordered tree* is a tree $T := \langle V_T, E_T, L_{V_T}, L_{E_T} \rangle$, where for each $v \in V_T$, the children of v are ordered in just that fashion.

4.2 Condensed trees

A *condensed tree* is a fully-labeled tree $T := \langle V_T, E_T, L_{V_T}, L_{E_T} \rangle$ with two additional properties:

a. Each vertex $v \in V$ is associated to a list of indices $parentIndex(v) = \{i_1, i_2, ..., i_n\}$, which we will call its *parent index*. Each entry $i_1, i_2, ..., i_n$ is a non-negative integer.
b. No vertex $v \in V$ has two children with the same full label.

Condensed trees are constructed from non-condensed trees as follows:

Given a tree $T := \langle V, E, L_V, L_E \rangle$, we first canonically order it, as described in the previous section. Then, we attach a parent index to each vertex $v \in V$ which is not the root of T. The initial parent index of each node consists of a single zero.

We then traverse the vertices of the now ordered tree T in breadth-first order from the the root downwards and from left to right. Given some $v_j \in V$, if it has no sibling to its right, or if the sibling to its immediate right has a different vertex label or a different edge label on the edge to its parent, we do nothing. Otherwise, if v_j has a sibling to its immediate right v_i with the same full label, we set ℓ_i to the size of $parentIndex(v_i)$, and then we append the $parentIndex(v_j)$ to $parentIndex(v_i)$. Then, we take the children of v_j, and for each one, we increment each value in its parent index by ℓ_i, and then insert it under v_i as one of v_i's children. We delete v_j and then we reorder the children of v_i into the canonical order defined in Section 4.1.

This is performed in breadth-first order over T. The result is guaranteed to be a tree where each vertex never has two children with the same edge and vertex labels. Figure 6 shows how the trees in Figure 5 look after they are converted into condensed trees. We will denote condensed trees as $\mathfrak{T} = cond(T)$, to indicate that $\mathfrak{T}$ has been constructed from T.

If two non-condensed trees are unordered isomorphic, then their condensed forms will be identical, including in their vertex orderings and parent indexes. If two condensed trees are identical, then the non-condensed trees from which they are constructed are always unordered isomorphic.

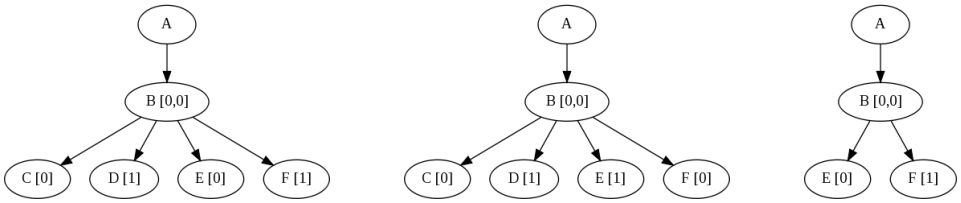
Each vertex $\mathfrak{v}$ of a condensed tree $\mathfrak{T} = cond(T)$ has a parent index containing some number of entries corresponding to a set of vertices in non-condensed tree T. We will designate that set as $orig(\mathfrak{v})$, a subset of the vertices in T. Given a condensed tree vertex $\mathfrak{v}$ and its parent $\mathfrak{p}$, if the size of $orig(\mathfrak{p})$ is larger than one, then the vertices in $\mathfrak{v}$ may have different parents in T. We can interpret the integers in the parent index of each condensed tree vertex as indicating which parent each member of $orig(\mathfrak{v})$ has.

In this way, given $\mathfrak{T} = cond(T)$, there is a one-to-one mapping from the vertices of T to a pair $\langle \mathfrak{v}, i \rangle$ consisting of some vertex in $\mathfrak{T}$ and an index to an entry in its parent index. If some vertex v in T maps to $\langle \mathfrak{v}, i \rangle$, then all the children of v, $c \in children(v)$ map to pairs $\langle \mathfrak{c}, j \rangle$ such that $parent(\mathfrak{c}) = \mathfrak{v}$ and the jth entry in $parentIndex(\mathfrak{c})$ is i. We can use this to define parent-child operations over condensed trees that perfectly match parent-child operations in non-condensed ones.

We will define a *skeleton tree* as a condensed tree stripped of its parent indices, and denote it as $skel(\mathfrak{T})$. Note that for any non-condensed tree T and any non-condensed subtree $S \subseteq T$, $skel(cond(T))$ will always contain $skel(cond(S))$ as an *ordered* subtree, including in cases like Figure 5, as shown in Figure 6.

4.3 Alignment

An alignment of a condensed subtree $\mathfrak{S}$ with a condensed tree $\mathfrak{T}$ has two parts:



(a) (b) (c)

Figure 6: The trees in Figure 5 transformed into their condensed equivalents, with their parent arrays. Note that 6(c) is visibly an ordered subtree of both 6(a) and 6(b) if you ignore the parent arrays.

a. Skeleton Alignment:
   An injection $M : V_{\mathfrak{S}} \rightarrow V_{\mathfrak{T}}$ from the vertices of $\mathfrak{S}$ to the vertices of $\mathfrak{T}$.
b. Index Alignment:
   For each vertex $v_{\mathfrak{S}} \in V_{\mathfrak{S}}$, a bipartite mapping from the vertices in $orig(v_{\mathfrak{S}})$ to the vertices in $orig(M(v_{\mathfrak{S}}))$.

The first part is an alignment of $skel(\mathfrak{S})$ with $skel(\mathfrak{T})$. Given an alignment from the root of $\mathfrak{S}$ to some vertex in $\mathfrak{T}$, this can be performed in time proportionate, in the worst case, to the number of vertices in $skel(\mathfrak{T})$. If all the parent indices of the aligned vertices in the subtree and supertree have only one index in them, then the index alignment is trivial and the alignment of $\mathfrak{S}$ to $\mathfrak{T}$ is complete.

In other cases, index alignment is non-trival. The method here draws on the procedure for unordered subtree alignment proposed by Kilpeläinen (1992). In the worst case, it resolves to the same algorithm, but can perform better on the average because of the structure of condensed trees.

Alignment proceeds from the bottom-up, starting with the leaves of $\mathfrak{S}$. If vertex $\mathfrak{s}$ is a leaf of $\mathfrak{S}$ and is aligned to some vertex $\mathfrak{t}$ in $\mathfrak{T}$, then we initially assume any member of $orig(\mathfrak{s})$ can map to any member of $orig(\mathfrak{t})$. We then proceed upwards in $\mathfrak{S}$, checking each vertex $\mathfrak{s}$ in $\mathfrak{S}$ to find a mapping from $orig(\mathfrak{s})$ to $orig(\mathfrak{t})$ such that if some $s \in orig(\mathfrak{s})$ can be mapped to some $t \in orig(\mathfrak{t})$, then the children of s can be mapped to children of t.

Once we reach the root of $\mathfrak{S}$, we proceed back downwards, removing those mappings from each $orig(\mathfrak{s})$ to its corresponding $orig(\mathfrak{t})$ that are impossible because their parents do not align.

The remaining index alignments must still be checked to verify that each one can form a part of a one-to-one mapping from $orig(\mathfrak{s})$ to $orig(\mathfrak{t})$. This is equivalent to finding a maximal bipartite matching from $orig(\mathfrak{s})$ to $orig(\mathfrak{t})$ for each possible alignment from $orig(\mathfrak{s})$ to $orig(\mathfrak{t})$. Bipartite matching is a problem with a number of well-documented solutions. (Dijkstra (1959), Lovász (1986), among others)

5 Algorithm

Having outlined condensed trees and how to align them, we can build an algorithm for extracting all frequent closed unordered subtrees from a treebank of condensed trees, given a minimum frequency threshold θ. Space restrictions preclude a full formal description of the algorithm, but it closely follows the general outline for closed tree discovery schemes advanced by Chi et al. (2005a):

1. Pass through the treebank collecting all the subtrees that consist of a single vertex label and all their locations.
2. Remove those that appear less than θ times.
3. Loop over each remaining subtree, aligning it to each place it appears in the treebank
4. Collect all the possible extensions, creating a new list of two vertex subtrees and all their locations.
5. Use the extensions to the left of the rightmost vertex in each alignment to check if the subtree is closed to the left, and reject it if it is not.
6. Use the extensions to the right of the rightmost vertex to check if the subtree is closed to the right, and output it if it is.

7. Retain the extensions to the right of the rightmost vertex and their locations if those extensions appear at least θ times.
8. Repeat for those subtrees.

6 Implementation and Performance

The *Varro* toolkit implements condensed trees and the algorithm described above in Python 3.1 and has been applied to treebanks as large as several hundred thousand sentences. The software and source code is available from sourceforge.net[3] and includes a small treebank of parsed Latin texts provided by the Perseus Digital Library. (Bamman and Crane, 2007)

The worst case memory performance of this algorithm is $O(nm)$ where n is the number of vertices in the treebank and m is the largest frequent subtree found in it. However, only the most pathologically structured treebank could come close to this ceiling, and in practice, the current implementation has so far never used as much twice the memory required to store the original treebank.

The runtime performance is, as described in Section 3.2, proportionate to the size of the output. However, aligning each occurrence of each subtree adds an additional factor. Given a condensed subtree $\mathfrak{S}$ and its condensed supertree $\mathfrak{T}$ containing $size(\mathfrak{T})$ vertices, and one already aligned vertex, the worst case alignment time is $O(size(\mathfrak{T})^{2.5})$, but only a highly pathological tree structure would approach this. The best case alignment time is $O(size(\mathfrak{S}))$. Therefore, it always takes more time to align larger subtrees, and since larger subtrees are less frequent than smaller ones, setting lower minimum frequency thresholds increases the average time required to process a subtree.

Processing even the small Alpino Treebank produces very large numbers of frequent closed subtrees. After removing punctuation and the tokens themselves, leaving just parts-of-speech and consituency labels - the Alpino treebank's 7137 sentences are reduced to 206,520 vertices. Within this small set, *Varro* took 1252 seconds to find 7307 frequent closed subtrees that appear at least 100 times. This is both considerably more subtrees than reported by Martens (2009b) on the same data and considerably more time.

Speed and memory performance are the major practical issues in this line of research. Choosing to design *Varro* with memory footprint minimization in mind is a source of some performance bottlenecks. Using Python also takes a heavy toll on speed and a C++ implementation is planned. The fast alignment-free closure checking scheme in Martens (2009b) can also be implemented using condensed trees. On small treebanks this will improve speed without loss of precision, but has limited applicability to large treebanks.

7 Conclusions

The trade-off between memory usage, run-time and completeness for this kind of algorithm is *punitive*. The user must balance *very* long runtimes against excessive memory usage if they want to accurately count all frequent unordered induced subtrees. The *Varro* toolkit is designed to make it possible to choose what tradeoffs to make. Since any subtree can be extended and checked for closure independently of other subtrees, *Varro* can easily implement heuristics designed to further reduce the number of subtrees extracted. We believe the future of this line of research lies in large part in that direction and hope that public release of *Varro* will aid in its development.

We have also discovered that there is a very strong relationship between the concision and consistency of linguistic formalisms and *Varro*'s performance. We restructured the Alpino data by promoting the head of each constituent, creating dependency-style trees along the lines described by Tesnière (1959) and Mel'čuk (1988). This reduced the number of subtrees found by 50%-60% and reduced run-times consistently by 60%-70% across a range of minimum frequency thresholds and treebank sizes. As a general rule, increasing the degree of linguistic abstraction increases the number of frequent subtrees, and consequently slows *Varro* down dramatically. Identifying linguistic formalisms that lend themselves to efficient and productive subtree discovery is another significant direction for this research, and one with immediate impact on other areas in linguistics.

Abstract

This paper investigates the new problem of automatic sense induction for instance names using automatically extracted attribute sets. Several clustering strategies and data sources are described and evaluated. We also discuss the drawbacks of the evaluation metrics commonly used in similar clustering tasks. The results show improvements in most metrics with respect to the baselines, especially for polysemous instances.

1 Introduction

Recent work on information extraction increasingly turns its attention to the automatic acquisition of open-domain information from large text collections (Etzioni et al., 2008). The acquired information typically includes instances (e.g. *barack obama* or *hillary clinton*), class labels (e.g. *politician* or *presidential candidate*) and relations and attributes of the instances (e.g. *president-country* or *date-of-birth*) (Sekine, 2006; Banko et al., 2007).

Within the larger area of relation extraction, the acquisition of instance attributes (e.g. *president* for instances of countries, or *side effects* for instances of drugs) plays an important role, since attributes may serve as building blocks in any knowledge base constructed around open-domain classes of instances. Thus, a variety of attribute extraction methods mine textual data sources ranging from unstructured (Tokunaga et al., 2005) or structured (Cafarella et al., 2008) text within Web documents, to human-compiled encyclopedia (Wu et al., 2008; Cui et al., 2009) and Web search query logs (Paşca and Van Durme, 2007), attempting to extract, for a given class, a ranked list of attributes that is as comprehensive and accurate as possible.

Previous work on attribute extraction, however, does not capture or address attributes of polysemous instances. An instance may have different meanings, and the extracted attributes may not apply to all of them. For example, the most salient meanings of *darwin* are the scientist *Charles Darwin*, an Australian city, and an operating system, plus many less-known meanings. For these ambiguous instances, it is common for the existing procedures to extract mixed lists of attributes that belong to incompatible meanings, e.g. {*biography, population, hotels, books*}.

This paper explores the problem of automatically inducing instance senses from the learned attribute lists, and describes several clustering solutions based on a variety of data sources. For that, it brings together research on attribute acquisition and on word sense induction. Results show that we can generate meaninful groupings of attributes for polysemous instance names, while not harming much the monosemous instance names by generating unwanted clusters for them. The results are much better than for a random baseline, and are superior to the one-in-all and the all-singleton baselines.

2 Previous Work

Previous work on **attribute extraction** uses a variety of types of textual data as sources for mining attributes. Some methods take advantage of structured and semi-structured text available within Web documents. Examples of this are the use of markup information in HTML documents to ex-

Coling 2008: Poster Volume, pages 819–827,
Beijing, August 2010

tract patterns and clues around attributes (Yoshinaga and Torisawa, 2007; Wong and Lam, 2009; Ravi and Paşca, 2008), or the use of articles within online encyclopedia as sources of structured text for attribute extraction (Suchanek et al., 2007; Nastase and Strube, 2008; Wu and Weld, 2008). Regarding unstructured text in Web documents, the method described in (Tokunaga et al., 2005) takes various class labels as input, and applies manually-created lexico-syntactic patterns to document sentences to extract candidate attributes ranked using several frequency statistics. In (Bellare et al., 2007), the extraction is guided by a set of seed instances and attributes rather than handcrafted patterns, with the purpose of generating training data and extract new instance-attribute pairs from text.

Web search queries have also been used as a data source for attribute extraction, using lexico-syntactic patterns (Paşca and Van Durme, 2007) or seed attributes (Paşca, 2007) to guide the extraction, and leading to attributes of higher accuracy than those extracted with equivalent techniques from Web documents (Paşca et al., 2007).

Another related area to this work is the field of **word sense induction**: the task of identifying the possible senses of a word in a corpus using unsupervised methods (Yarowsky, 1995), as opposed to traditional disambiguation methods which rely on the availability of a finite and static list of possible meanings. In (Agirre and Soroa, 2007) a framework is proposed for evaluating such systems. Word sense induction can be naturally formulated as a clustering task. This introduces the complication of choosing the right number of possible senses, hence a Bayesian approach to WSI was proposed which deals with this problem within a principled generative framework (Brody and Lapata, 2009). Another related line of work is the disambiguation of people names (Mann and Yarowsky, 2003). In SEMEVAL-1, a shared task was introduced dedicated to this problem, the Web People Search task (Artiles et al., 2007; Artiles et al., 2009). Disambiguating names is also often approached as a clustering problem. One challenge shared by word sense induction and name disambiguation (and most unsupervised settings), is the evaluation. In both tasks, simple baselines such as predicting one single cluster tend to outperform more sophisticated approaches (Agirre and Soroa, 2007; Artiles et al., 2007).

3 Instance Sense Induction

3.1 Problem description

This paper assumes the existence of an attribute extraction procedure. Using those attributes, our aim is to identify the coarse-grained meanings with which each attribute is associated. As an example, Table 1 shows the top 16 attributes extracted using the procedure described in (Paşca and Van Durme, 2007). Salient meanings for *turkey* are the country name (labeled as 1 in the table), and the bird name (labeled as 2). Some attributes are applicable to both meanings (*pictures* and *facts*). The second example, *darwin*, can refer to a city (sense 1), the Darwin Awards (sense 2), the person (sense 3), and an operating system (sense 4).

Examples of applications that need to discriminate between the several meanings of instances are user-facing applications requiring the attributes to be organized logically and information extraction pipelines that depend on the extracted attributes to find values in documents.

The problem we are addressing is the automatic induction of instance senses from the attribute sets, by grouping together the attributes that can be applied to a particular sense. As in related work on sense induction (Agirre and Soroa, 2007; Artiles et al., 2007), we approach this as a clustering problem: finding the right similarity metrics and clustering procedures to identify sets of related attributes in an instance. We propose a clustering based on the Expectation-Maximization (EM) algorithm (Dempster et al., 1977), exploring different parameters, similarity sources, and prior distributions.

3.2 Instance and attributes input data

The input data of instances and attributes has been obtained, in a fully automated way, following the method described in (Paşca and Van Durme, 2007). The input dataset is a set of fully anonymized set of English queries submitted to a popular (anonymized) search engine. The set contains millions of unique isolated, individual queries that are independent from one another. Each query is accompanied by its frequency of occurrence in the query logs. The sum of frequencies of all queries in the dataset is hundreds of millions. Other sources of similar data are available publicly for research purposes (Gao et al., 2007). This extraction method applies a few patterns (e.g., *the* $\mathcal{A}$ *of* $\mathcal{I}$, or $\mathcal{I}$*'s* $\mathcal{A}$, or $\mathcal{A}$ *of* $\mathcal{I}$) to queries within query logs, where an instance $\mathcal{I}$ is one of the most frequent 5 million queries from the repository of isolated queries, and $\mathcal{A}$ is a candidate attribute. For each instance, the method extracts ranked lists containing zero, one or more attributes, along with frequency-based scores. For this work, only the top 32 attributes of each instance were used, in order to have an input set for the clustering with a reasonable size, but to keep precision at high levels.

3.3 Per-attribute clustering information

For each (instance, attribute) pair, the following information is collected:

Search results: The top 20 search results (including titles and snippets) returned by a popular search engine for a query created by concatenating the instance and the attribute. The motivation for this data source is that the attributes that refer to the same meaning of the instance should help the search engine in selecting web pages that refer to that meaning. The titles and snippets of these search results are expected to contain other terms related to that meaning. For example, for the queries *[turkey maps]* and *[turkey culture]* the search results will contain information related to the country, whereas *[turkey recipes]* and *[turkey nutritional value]* should share many terms about the poultry.

Query sessions: A query session is a series of queries submitted by a single user within a small range of time (Silverstein et al., 1999). Information stored in the session logs may include the text of the queries and metadata, such as the time, the type of query (e.g., using the normal or the advance form), and user settings such as the Web browser used (Silverstein et al., 1999).

For each (instance, attribute) pair:

- Retrieve all the sessions that contained the query *[instance attribute]*.
- Collect the set of all the queries that appeared in the same session and which are a superstring of *instance*.
- Remove *instance* from each of those queries, and output the resulting set of query words.

Figure 1: Algorithm to collect session phrases associated to attributes.

Users often search for related queries within a session: queries on the *culture* of the country Turkey will tend to be surrounded by queries about topics related to the country; similarly, queries about turkey *recipes* will tend to be surrounded by other queries on recipes. Therefore, if two attributes refer to the same meaning of the instance, the distributions of terms that co-occur with them in the same search sessions is expected to be similar. To ensure that the user did not change intent during the session, we also require the queries from which we extract phrases to contain the instance of interest. The pseudocode of the procedure is shown in Figure 1.

Class labels: As described in (Paşca and Van Durme, 2008), we collect for each instance (e.g., *turkey*), a ranked list of class labels (e.g., *country, location, poultry, food*). The procedure uses a collection of Web documents and applies some IsA extraction patterns selected from (Hearst, 1992). Using the (instance, ranked-attributes) and the (instance, ranked-class labels) lists, it is possible to aggregate the two datasets to obtain, for each attribute, the class labels that are most strongly associated to it (Figure 2).

3.4 EM clustering

We run a set of EM clusterings separately for the attributes of each instance. The model implemented is the following: given an instance, let $\mathcal{A} = \{a_1, a_2, ..., a_n\}$ be the set of attributes associated with that instance. Let $\mathcal{T}$ be the vocabulary for the terms found in the search results, $\mathcal{S}$ the vocabulary of session log terms co-occurring with

For each attribute:

- Collect all the instances that contain that attribute.
- For each class label, average its ranks for those instances. If an instance does not contain a particular class label, use as rank the size of the longest list of class labels plus one.
- Rank the class labels from smaller to larger average rank.

Figure 2: Algorithm to collect class labels associated to attributes.

the attribute, and $\mathcal{C}$ be the set of all the possible class labels. Let $\mathcal{K}$ be the cluster function which assigns cluster indexes to the attributes.

We assume that the distributions for snippet terms, session terms and class labels are conditionally independent given the clustering. Furthermore, we assume that the distribution of terms for queries in a cluster are also conditionally independent given the cluster assignments:

$$p_\theta(\mathcal{T}|\mathcal{K},\mathcal{A}) \approx \prod_j p_\theta(t_j|\mathcal{K},\mathcal{A})$$
$$p_\theta(\mathcal{S}|\mathcal{K},\mathcal{A}) \approx \prod_k p_\theta(s_k|\mathcal{K},\mathcal{A})$$
$$p_\theta(\mathcal{C}|\mathcal{K},\mathcal{A}) \approx \prod_l p_\theta(c_l|\mathcal{K},\mathcal{A})$$

The clustering model for each instance (the expectation step) is, therefore:

$$p_\theta(\mathcal{K}\mathcal{T}\mathcal{S}\mathcal{C}|\mathcal{A},\Theta) =$$
$$\prod_i^N p_\theta(\mathcal{K}|\mathcal{A})p_\theta(\mathcal{T}|\mathcal{K},\mathcal{A})p_\theta(\mathcal{S}|\mathcal{K},\mathcal{A})p_\theta(\mathcal{C}|\mathcal{K},\mathcal{A})$$

To estimate the parameters of the model, we must be able to estimate the following distributions during the maximization step:

- $p_\theta(t_j|\mathcal{K},\mathcal{A}) = \frac{E_\theta(t_j,\mathcal{K}|\mathcal{A})}{E_\theta(\mathcal{K}|\mathcal{A})}$
- $p_\theta(s_k|\mathcal{K},\mathcal{A}) = \frac{E_\theta(s_k,\mathcal{K}|\mathcal{A})}{E_\theta(\mathcal{K}|\mathcal{A})}$
- $p_\theta(c_l|\mathcal{K},\mathcal{A}) = \frac{E_\theta(c_l,\mathcal{K}|\mathcal{A})}{E_\theta(\mathcal{K}|\mathcal{A})}$

One advantage of this approach is that it allows using a subset of the available data sources to evaluate their relative influence on the clustering quality. In the experiments we have tried all possible combinations of the three data sources to find the settings that give the best results.

3.5 Initialization strategies

The initial assignment of attributes to clusters is important, since a bad seed clustering can lead EM to local optima. We have tried the following two strategies:

Random assignment: the attributes are assigned to clusters randomly. To make the results repeatable, for each instance we use the instance name as the seed for the random number generator.

K-means: the initial assignments of attributes to clusters is performed using K-means. In this model, we use a simple vector-space-model in the following way:

1. Each attribute is represented with a bag-of-words of the snippets of the search results for a concatenation of the instance name and the attribute. This is the same data already collected for EM.
2. Each of the snippet terms in these bag-of-words is weighted using the $tf \times idf$ score, with inverse document frequencies estimated from an English web corpus with hundreds of millions of documents.
3. The cosine of the angle of the vectors is used as the similarity metric between each pair of attributes.

Several values of K have been tried in our experiments, as mentioned in Section 4.

3.6 Post-processing

EM works with a fixed set of clusters. In order to decide which is the optimal number of clusters, we have run all the experiments with a number of clusters K that is large enough to accommodate most of the queries in our dataset, and we run a post-processing step that merges clusters for instances that have less than K meanings.

Since we have, for each attribute, a distribution of the most likely class labels (Section 3.3), the post-processing performs as follows:

1. Generate a list of class labels per cluster, by combining the ranked lists of per-attribute class labels as was done in Section 3.3.
2. Merge together all the clusters such that their sets of top k class labels are the same.

The values of K and k are chosen by doing several runs with different values on the development set, as described in Section 4.

4 Evaluation and Results

4.1 Evaluation metrics

There does not exist a fully agreed evaluation metric for clustering tasks in NLP (Geiss, 2009; Amigó et al., 2009). Each metric has its own idiosyncrasies, so we have chosen to compute six different evaluation metrics as described in (Amigó et al., 2009). Empirical results show they are highly correlated, i.e., tuning a parameter by hill-climbing on F-score typically also improves the B^3 F-score.

Purity (Zhao and Karypis, 2002): Let C be the clusters to evaluate, L the set of categories (the clusters in the gold-standard), and N the number of clustered items. Purity is the average of the precision values: Purity $= \sum_i \frac{|C_i|}{N} \max_j \text{Prec}(C_i, L_j)$, where the precision for cluster C_i with respect to category L_j is $\text{Prec}(C_i, L_j) = \frac{|C_i \cap L_j|}{|C_i|}$. Purity is a precision metric. Inverting the roles of the categories L and the clusters C gives a recall metric, **inverse purity**, which rewards grouping items together. The two metrics can be combined in an F-score.

B^3 Precision (Bagga and Baldwin, 1998): Let $L(e)$ and $C(e)$ denote the gold-standard-category and the cluster of an item e. The correctness of the relation between e and other element e' is defined as

$$\text{Correctness}(e, e') = \begin{cases} 1 & \text{iff} L(e) = L(e') \Leftrightarrow C(e) = C(e') \\ 0 & \text{otherwise} \end{cases}$$

The B^3 Precision of an item is the proportion of items in its cluster which belong to its category, including itself. The total precision is the average of the item precisions: B^3 Prec $= \text{avg}_e[\text{avg}_{e':C(e)=C(e')}\text{Correctness}(e, e')]$

B^3 Recall: is calculated in a similar way, inverting the roles of clusters and categories. The **B^3 F-score** is obtained by combining B^3 precision and B^3 recall.

4.2 Gold standards

We have built two annotated sets, one to be used as a development set for adjusting the parameters, and a second one as a test set. The evaluation settings were chosen without knowledge of the test set. Each of the two sets contains 75 instances chosen randomly from the complete set of instances with ranked attributes (Section 3.2 described the input data). For the random sampling, the instances were weighted with their frequency in the query logs as full queries, so that more frequent instances have higher chance to be chosen. This ensures that uncommon instances are not overrepresented in the gold-standard.

The annotators contributed 50 additional instances (25 for development and 25 for testing) that they considered interesting to study, e.g., because of having several salient meanings.

Five human annotators were shown the top 32 attributes for each instance, and they were asked to cluster them. We decided to start with a simplified version of the problem by considering it a hard clustering task.

Table 2 shows that the average agreement scores between judge pairs, measured with the same evaluation metrics used for the system output, are quite high. In the first three metrics, the F-score is not an average of precision and recall, but a weighted average calculated separately for each cluster, so it may have a value that is not between the values of precision and recall.

The annotated instances were classified as monosemous/polysemous, depending on wether or not they had more than one cluster with enough (five) attributes. This classification allows to report separate results for the whole set (where instances with just one major sense dominate) and for the subset of polysemous instances. Table 3 shows examples of polysemous instances. Exam-

Purity	Inv. Purity	F-score	B^3 Precision	B^3 Recall	B^3 F-score
0.94	0.95	0.92	0.90	0.92	0.91

Table 2: Inter-judge agreement scores.

Polysemous	Main meanings
airplane	machine, movie
apple	fruit, company
armstrong	unit, company, person
chain reaction	company, film, band, chemistry
chf	airport, currency, heart attack
darwin	person, city
david copperfield	book, performer, movie
delta	letter, airways

Table 4: Scores over all instances and over polysemous instances.

ples of monosemous instances are *activision*, *amctheaters*, *american airlines*, *ask.com*, *bebo*, *disney* or *einstein*. 22% of the instances in the development set and 13% of the instances in the test set are polysemous.

4.3 Parameter tuning

We tuned the different parameters of the algorithm using the development set. We performed several EM runs including all three data sources, modifying the following parameters: the smoothing ϵ added to the cluster soft-assignment in the Maximization step (Manning et al., 2008), the number K of clusters for K-Means and EM, and the number k of top ranked class labels that two clusters need to have in common in order to be merged at the post-processing step. The best results were obtained with $\epsilon = 0.4$, $K = 5$ and $k = 1$. These are the values used in the experiments mentioned from now on.

4.4 EM initialization and data sources

Table 4 shows the results after running EM over the development set, using every possible combination of data sources, and the two initialization strategies (random and K-Means). Several observations can be drawn from this table:

First, as mentioned in Section 2, the evaluation metrics are biased towards the all-in-one solution. This is worsened by the fact that the majority of the instances in our dataset are monosemous. Therefore, the highest F-scores and B^3 F-scores are obtained by the all-in-one baseline, although it is not the most useful clustering.

When using only class labels, EM tends to produce results similar to the all-in-one baseline This can be explained by the limited class vocabulary which makes most of the attributes share class labels. The bad results when using only sessions are caused by the presence of attributes with no session terms, due to insufficient data.

The random clustering baseline (third line in Table 4) tends to give smaller clusters than EM, because it distributes instances uniformly across the clusters. This leads to better precision scores, and much worse recall and F-score metrics.

From these results, we conclude that snippet terms are the most useful resource for clustering. The other data sources do not provide a significant improvement over it. The best results overall for the polysemous instances, and the highest results for the whole dataset (excluding the outliers that are too similar to the all-in-one baseline) are obtained using snippet terms. For these configurations, as we expected, the K-Means initialization does a better job in avoiding local optima during EM than the random one.

4.5 Post-processing

Table 5 includes the results on the development set after post-processing, using the best configuration for EM (K-Means initialization and snippet terms for EM). Post-processing slightly hurts the B^3 F-score for polysemous terms, but it improves results for the whole dataset, as it merges many clusters for the monosemous instances.

Data	Method	Purity	Inv. Purity	F-score	B^3 Prec.	B^3 Recall	B^3 F-score
All instances	All-in-one	0.797	1.000	0.766	0.700	1.000	0.797
	All-singletons	1.000	0.145	0.187	1.000	0.145	0.242
	K-Means + EM (snippets)	0.844	0.765	0.700	0.771	0.654	0.675
	K-Means + EM (snippets) + postprocessing	0.825	0.837	0.728	0.743	0.761	0.722
Polysemous	All-in-one	0.558	1.000	0.540	0.410	1.000	0.573
	All-singletons	1.000	0.205	0.266	1.000	0.205	0.333
	K-Means + EM (snippets)	0.671	0.806	0.587	0.556	0.719	0.611
	K-Means + EM (snippets) + postprocessing	0.644	0.846	0.592	0.518	0.777	0.607

Table 5: Scores only over all and polysemous instances, without and with postprocessing.

definition, religion, slogan, books	definition, religion, slogan, books	

Table 6: Attributes extracted for the monosemous instance *obama*, using snippet terms for EM.

4.6 Clustering examples

Tables 6 and 7 show examples of clustering results for three instances chosen as representatives of the monosemous and the polysemous subsets. These show that the output of the K-Means initialization can uncover some meaningful clusters, but tends to generate a dominant cluster and a few small or singleton clusters. EM distributes the attributes more evenly across clusters, combining attributes that are closely related.

For monosemous instances like *obama*, EM generates small clusters of highly related attributes (e.g, *family*, *kids* and *daughters*). Postprocessing merges some of the clusters together, but it fails to merge all into a single cluster.

For *darwin*, two of the small clusters given by K-Means are actually good, as *ports* is the only attribute of the operating system, and *lyrics* is one of the two attributes referring to a song titled Darwin. EM again redistributes the attributes, creating two large and mostly correct clusters.

For *david copperfield*, EM creates two clusters for the performer, one for the book, one for the movie, and one for *tattoo* (off-topic for this instance). The two clusters referring to the performer are merged in the post-processing, with some errors remaining, e.g, *trailer* and *second wife* are in the wrong cluster.

4.7 Results on the test set

Table 8 show the results of the EM clustering and the postprocessing step when executed on the test set. The settings are those that produced the best results on the development set: using EM initialized with K-Means, and using only snippet terms for the generative model.

As mentioned above, the test set has a higher proportion of monosemous queries than the development set, so the all-in-one baseline produces better results than before. Still, we can see the same trend happening: for the whole dataset the F-score metrics are somewhat worse than the best baseline, given that the evaluation metrics all overvalue the all-in-one baseline, but this can be considered an artifact of the metrics. As with the development set, using EM produces the best precision scores (except for the all-singletons baseline), and the postprocessing improves precision and F-score over the all-in-one baseline. The whole system improves considerably the F-score for the polysemous terms.

5 Conclusions

This paper investigates the new task of inducing instance senses using ranked lists of attributes as input. It describes a clustering procedure based on the EM model, capable of integrating differ-

Instance	K-Means output	EM output	Post-processing

	EM+postprocessing	0.675	0.894	0.650	0.564	0.842	0.661

Table 8: Scores in the test set.

ent data sources, and explores cluster initialization and post-processing strategies. The evaluation shows that the most important of the considered data sources is the snippet terms obtained from search engine results to queries made by concatenating the instance and the attribute. A simple post-processing that merges attribute clusters that have common class labels can improve recall for monosemous queries. The results show improvements across most metrics with respect to a random baseline, and F-score improvements for polysemous instances.

Future work includes extending the generative model to be applied across the board, linking the clustering models of different instances with each other. We also intend to explore applications of the clustered attributes in order to perform extrinsic evaluations on these data.

A Power Mean Based Algorithm for Combining Multiple Alignment Tables

Sameer Maskey, Steven J. Rennie, Bowen Zhou
IBM T.J. Watson Research Center
{smaskey, sjrennie, zhou}@us.ibm.com

Abstract

Most existing techniques for combining multiple alignment tables can combine only two alignment tables at a time, and are based on heuristics (Och and Ney, 2003), (Koehn et al., 2003). In this paper, we propose a novel mathematical formulation for combining an arbitrary number of alignment tables using their power mean. The method frames the combination task as an optimization problem, and finds the optimal alignment lying between the intersection and union of multiple alignment tables by optimizing the parameter p: the affinely extended real number defining the order of the power mean function. The combination approach produces better alignment tables in terms of both F-measure and BLEU scores.

1 Introduction

Machine Translation (MT) systems are trained on bi-text parallel corpora. One of the first steps involved in training a MT system is obtaining alignments between words of source and target languages. This is typically done using some form of Expectation Maximization (EM) algorithm (Brown et al., 1993), (Och and Ney, 2003), (Vogel et al., 1996). These unsupervised algorithms provide alignment links between english words e_i and the foreign words f_j for a given $e-f$ sentence pair. The alignment pairs are then used to extract phrases tables (Koehn et al., 2003), hierarchical rules (Chiang, 2005), or tree-to-string mappings (Yamada and Knight, 2001). Thus, the accuracy of these alignment links has a significant impact in overall MT accuracy.

One of the commonly used techniques to improve the alignment accuracy is combining alignment tables obtained for source to target ($e2f$) and target to source ($f2e$) directions (Och and Ney, 2003). This combining technique involves obtaining two sets of alignment tables A_1 and A_2 for the same sentence pair $e - f$, and producing a new set based on union $A_\cup = A_1 \cup A_2$ or intersection $A_\cap = A_1 \cap A_2$ or some optimal combination A_o such that it is subset of $A_1 \cup A_2$ but a superset of $A_1 \cap A_2$. How to find this optimal A_o is a key question. $A_\cup$ has high precision but low recall producing fewer alignments and $A_\cap$ has high recall but low precision.

2 Related Work

Most existing methods for alignment combination (symmetrization) rely on heuristics to identify reliable links (Och and Ney, 2003), (Koehn et al., 2003). The method proposed in (Och and Ney, 2003), for example, interpolates the intersection and union of two asymmetric alignment tables by adding links that are adjacent to intersection links, and connect at least one previously unaligned word. Another example is the method in (Koehn et al., 2003), which adds links to the intersection of two alignment tables that are the diagonal neighbors of existing links, optionally requiring that any added links connect two previously unaligned words.

Other methods try to combine the tables during alignment training. In (Liang et al., 2006), asymmetric models are jointly trained to maximize the similarity of their alignments, by opti-

Coling 2008: Poster Volume, pages 828–836,
Beijing, August 2010

mizing an EM-like objective function based on agreement heuristics. In (Ayan et al., 2004), the authors present a technique for combining alignments based on various linguistic resources such as parts of speech, dependency parses, or bilingual dictionaries, and use machine learning techniques to do alignment combination. One of the main disadvantages of (Ayan et al., 2004)'s method, however, is that the algorithm is a supervised learning method, and so requires human-annotated data. Recently, (Xiang et al., 2010) proposed a method that can handle multiple alignments with soft links which are defined by confidence scores of alignment links. (Matusov et al., 2004) on the other hand, frame symmetrization as finding a set with minimal cost using use a graph based algorithm where costs are associated with local alignment probabilities.

In summary, most existing alignment combination methods try to find an optimal alignment set A_o that lies between $A_\cap$ and $A_\cup$ using heuristics. The main problems with methods based on heuristics are:

1. they may not generalize well across language pairs
2. they typically do not have any parameters to optimize
3. most methods can combine only 2 alignments at a time
4. most approaches are ad-hoc and are not mathematically well defined

In this paper we address these issues by proposing a novel mathematical formulation for combining an arbitrary number of alignment tables. The method frames the combination task as an optimization problem, and finds the optimal alignment lying between the intersection and union of multiple alignment tables by optimizing the parameter p of the power mean function.

3 Alignment combination using the power mean

Given an english-foreign sentence pair (e_1^I, f_1^J) the alignment problem is to determine the presence of absence of alignment links a_{ij} between the words e_i and f_j, where $i \leq I$ and $j \leq J$. In this paper we will use the convention that when $a_{ij} = 1$, words e_i and f_j are linked, otherwise $a_{ij} = 0$. Let us define the alignment tables we obtain for two translation directions as A_1 and A_2, respectively. The union of these two alignment tables $A_\cup$ contain all of the links in A_1 and A_2, and the intersection $A_\cap$ contain only the common links. Definitions 1 and 2 below define $A_\cup$ and $A_\cap$ more formally. Our goal is to find an alignment set A_o such that $|A_\cap| \leq |A_o| \leq |A_\cup|$ that maximizes some objective function. We now describe the power mean (PM) and show how the PM can represent both the union and intersection of alignment tables using the same formula.

The power mean:
The power mean is defined by equation 1 below, where p is a real number in $(-\infty, \infty)$ and a_n is a positive real number.

$$S_p(a_1, a_2, ..., a_n) = (\frac{1}{n}\sum_{k=1}^{n} a_k^p)^{\frac{1}{p}} \quad (1)$$

The power mean, also known as the generalized mean, has several interesting properties that are relevant to our alignment combination problem. In particular, the power mean is equivalent to the geometric mean G when $p \to 0$ as shown in equation 2 below:

$$\begin{aligned} G(a_1, a_2, ..., a_n) &= (\prod_{i=1}^{n} a_i)^{\frac{1}{n}} \\ &= \lim_{p\to 0}(\frac{1}{n}\sum_{k=1}^{n} a_k^p)^{\frac{1}{p}} \quad (2) \end{aligned}$$

The power mean, furthermore, is equivalent to the maximum function M when $p \to \infty$:

$$\begin{aligned} M(a_1, a_2, ..., a_n) &= \max(a_1, a_2, ..., a_n) \\ &= \lim_{p\to \infty}(\frac{1}{n}\sum_{k=1}^{n} a_k^p)^{\frac{1}{p}} \quad (3) \end{aligned}$$

Importantly, the PM S_p is a non-decreasing function of p. This means that S_p is lower bounded by G and upper-bounded by M for $p \in [0, \infty]$:

$$G < S_p < M, \quad 0 < p < \infty. \quad (4)$$

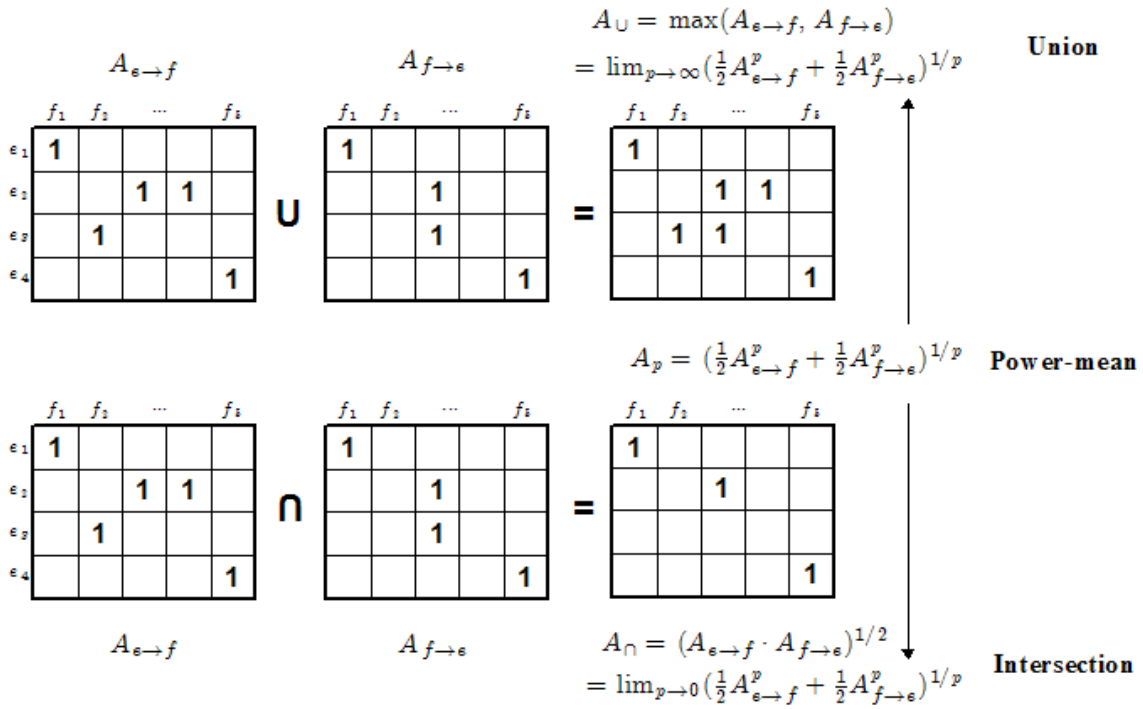

Figure 1: The power-mean is a principled way to interpolate between the extremes of union and intersection when combining multiple alignment tables.

They key insight underpinning our mathematical formulation of the alignment combination problem is that the geometric mean of multiple alignment tables is equivalent to their intersection, while the maximum of multiple alignment tables is equivalent to their union.

Let A_q be an alignment with elements a^q_{ij} such that $a^q_{ij} = 1$ if words e_i and f_j are linked, and $a^q_{ij} = 0$ otherwise. The union and intersection of a set of n alignment tables can then be formally defined as follows:

Definition 1: The union of alignments $A_1, A_2, ..., A_n$ is a set $A_\cup$ with $a^\cup_{ij} = 1$ if $a^q_{ij} = 1$ for *any* $q \in \{1, 2, ..., n\}$.

Definition 2: The intersection of alignments $A_1, A_2, ..., A_n$ is a set $A_\cap$ with $a^\cap_{ij} = 1$ if $a^q_{ij} = 1$ for *all* $q \in \{1, 2, ..., n\}$.

Figure 1 depicts a simple example of the alignment combination problem for the common case of alignment symmetrization. Two alignments tables, $A_{e\to f}$ and $A_{f\to e}$ (one-to-many alignments), need to be combined. The result of taking the union $A_\cup$ and intersection $A_\cap$ of the tables is shown. $A_\cup$ can be computed by taking the element-wise maximum of $A_{e\to f}$ and $A_{f\to e}$, which in turn is equal to the power mean A_p of the elements of these tables in the limit as $p \to \infty$. The intersection of the two tables, $A_\cap$, can similarly be computed by taking the geometric mean of the elements of $A_{e\to f}$ and $A_{f\to e}$, which is equal to the power mean A_p of the elements of these tables in the limit as $p \to 0$. For $p \in (0, \infty)$, equation 4 implies that A_p has elements with values between $A_\cap$ and $A_\cup$. We now provide formal proofs for these results when combining an arbitrary number of alignment tables.

3.1 The intersection of alignment tables $A_1..A_n$ is equivalent to their element-wise geometric mean $G(A_1, A_2, ..., A_n)$, as defined in (2).

Proof : Let $A_\cap$ be the intersection of all A_q where $q \in \{1, 2, .., n\}$. As per our definition of intersection $\cap$ between alignment tables, $A_\cap$ contains links where $a^q_{ij} = 1 \; \forall \; q$.

Let A_g be the set that contains the elements

of $G(A_1, A_2, ..., A_n)$. Then a_{ij}^g is the geometric mean of the elements a_{ij}^q where $q \in \{1, 2, .., n\}$, as defined in equation 2, that is, $a_{ij}^g = (\prod_{q=1}^{n} a_{ij}^g)^{\frac{1}{n}}$. This product is equal to 1 iff $a_{ij}^q = 1 \,\forall\, q$ and zero otherwise, since $a_{ij}^q \in \{0, 1\} \,\forall\, q$. Hence $A_g = A_\cap$. Q.E.D.

3.2 The union of alignment tables $A_1..A_n$ is equivalent to their element-wise maximum $M(A_1, A_2, ..., A_n)$, as defined in (3).

$Proof$: Let $A_\cup$ be the union of all A_q for $q \in \{1, 2, .., n\}$. As per our definition of the union between alignments $A_\cup$ has links where $a_{ij}^q = 1$ for some q.

Let A_m be the set that contain the elements of $M(A_1, A_2, ..., A_n)$. Let a_{ij}^m be the maximum of the elements a_{ij}^q where $q \in \{1, 2, .., n\}$, as defined in equation (3). The max function is equal to 1 iff $a_{ij}^q = 1$ for some q and zero otherwise, since $a_{ij}^q \in \{0, 1\} \,\forall\, q$. Hence $A_m = A_\cup$. Q.E.D.

3.3 The element-wise power mean $S_p(A_1, A_2, ..., A_n)$ of alignment tables $A_1..A_n$ has entries that are lower-bounded by the intersection of these tables, and upper-bounded by their union for $p \in [0, \infty]$.

$Proof$: We have already shown that the union and intersection of a set of alignment tables are equivalent to the maximum and geometric mean of these tables, respectively. Therefore given that the result in equation 4 is true (we will not prove it here), the relation holds. In this sense, the power mean can be used to interpolate between the intersection and union of multiple alignment tables. Q.E.D.

4 Data

We evaluate the proposed method using an English-Pashto translation task, as defined by the DARPA TransTac program. The training data for this task consists of slightly more than 100K parallel sentences. The Transtac task was designed to evaluate speech-to-speech translation systems, so all training sentences are conversational in nature. The sentence length of these utterances varies greatly, ranging from a single word to more than 50 words. 2026 sentences were randomly sampled from this training data to prepare held out development set. The held out Transtac test set consists of 1019 parallel sentences.

Method	F-measure
I	0.5979

PM$_n$	0.7276
U	0.6589

Table 1: F-measure Based on Various Alignment Combination Methods

5 Experiments and Discussion

We have shown in the previous sections that union and intersection of alignments can be mathematically formulated using the power mean. Since both combination operations can be represented with the same mathematical expression, we can search the combination space "between" the intersection and union of alignment tables by optimizing p w.r.t. any chosen objective function. In these experiments, we define the optimal alignment as the one that maximizes the objective function $f(\{a_{ijt}\}, \{\hat{a}_{ijt}\}, p)$, where f is standard F-measure, $\{\hat{a}_{ijt}\}$ is the set of all estimated alignment entries on some dataset, $\{a_{ijt}\}$ is the set of all corresponding human-annotated alignment entries, and p is the order of the power mean function. Instead of attempting to optimize the F-measure using heuristics, we can now optimize it by finding the appropriate power order p using any suitable numerical optimization algorithm. In our experiments we used the general simplex algorithm of amoeba search (Nelder and Mead, 1965), which attempts to find the optimal set of parameters by evolving a simplex of evaluated points in the direction that the F-measure is increasing.

In order to test our alignment combination formulation empirically we performed experiments on English-Pashto language with data described in Section 4. We first trained two sets of alignments, the e2f and f2e directions, based on GIZA++ (Och and Ney, 2003) algorithm. We then combined these alignments by performing intersec-

tion (I) and union (U). We obtained F-measure of 0.5979 for intersection (I), 0.6589 for union (U). For intersection the F-measure is lower presumably because many alignments are not shared by the input alignment tables so the number of links is under-estimated. We then also re-produced the two commonly used combination heuristic methods that are based on growing the alignment diagonally (GDF) (Koehn et al., 2003), and adding links based on refined heuristics (H) (Och and Ney, 2003), respectively. We obtained F-measure of 0.6891 for H, and 0.6712 for GDF as shown in Table 1.

We then used our power mean formulation for combination to maximize the F-measure function with the aforementioned simplex algorithm for tuning the power parameter p, where F-measure is computed with respect to the hand aligned development data, which contains 150 sentences. This hand aligned development set is different than the development set for training MT models. While doing so we also optimized table weights $W_q \in (0,\ 1), \sum_q W_q = 1$, which were applied to the alignment tables before combining them using the PM. The W_q allow the algorithm to weight the two directions differently. We found that the F-measure function had many local minima so the simplex algorithm was initialized at several values of p and $\{W_q\}$ to find the globally optimal F-measure.

After obtaining power mean outputs for the alignment entries, they need to be converted into binary valued alignment links, that is, $S_p(a^1_{ij}, a^2_{ij}, ...a^n_{ij})$ needs to be converted into a binary table. There are many ways to do this conversion such as simple thresholding or keeping best N% of the links. In our experiments we used the following simple selection method, which appears to perform better than thresholding. First we sorted links by PM value and then added the links from the top of the sorted list such that e_i and f_j are linked if e_{i-1} and e_{i+1} are connected to f_j, or f_{j-1} and f_{j+1} is linked to e_i, or both e_i and f_j are not connected. After tuning power mean parameter and the alignment weights the best parameter gave an F-measure of 0.6984 which is higher than commonly used GDF by 2.272% and H by 0.93% absolute respectively. We observe in Figure 2 that even though PM has higher F-measure compared with GDF it has significantly fewer number of alignment links suggesting that PM has improved precision on the finding the alignment links. The presented PM based alignment combination can be tuned to optimize any chosen objective, so it is not surprising that we can improve upon previous results based on heuristics.

One of the main advantages of the combining alignment tables using the PM is that our statements are valid for any number of input tables, whereas most heuristic approaches can only process two alignment tables at a time. The presented power mean algorithm, in contrast, can be used to combine any number of alignments in a single step, which, importantly, makes it possible to jointly optimize all of the parameters of the combination process.

In the second set of experiments the PM approach, which we call PM_n, is applied simultaneously to more than two alignments. We obtained four more sets of alignments from the Berkeley aligner (BA) (Liang et al., 2006), the HMM aligner (HA) (Vogel et al., 1996), the alignment based on partial words (PA), and alignment based on dependency based reordering (DA) (Xu et al., 2009). Alignment I was obtained by using Berkeley aligner as an off-the-shelf alignment tool. We built the HMM aligner based on (Vogel et al., 1996) and use the HMM aligner for producing Alignment II. Producing different sets of alignments using different algorithms could be useful because some alignments that are pruned by one algorithm may be kept by another giving us a bigger pool of possible links to chose from.

We produced Alignment III based on partial words. Pashto is morphologically rich language with many prefixes and suffixes. In lack of a morphological segmenter it has been suggested that keeping only first 'n' characters of a word can effectively reduce the vocabulary size and may produce better alignments. (Chiang et al., 2009) used partial words for alignment training in English and Urdu. We trained such alignments using using GIZA++ on parallel data with partial words for Pashto sentences.

The fourth type of alignment we produced, Alignment IV, was motivated by the (Xu et al.,

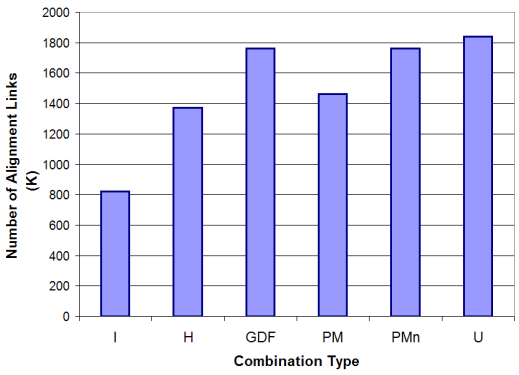

Figure 2: Number of Alignments Links for Different Combination Types

2009). (Xu et al., 2009) showed that translation between subject-verb-object (English) and subject-object-verb (Pashto) languages can be improved by reordering the source side of the parallel data. They obtained dependency tree of the source side and used high level human generated rules to reorder source side using precedence-based movement of dependency subtrees. The rules were particularly useful in reordering of verbs that moved to the end of the sentence. Making the ordering of source and target side more similar may produce better alignments for language pairs which differ in verb ordering, as many alignment algorithms penalize or fail to consider alignments that link words that differ greatly in sentence position. A Pashto language expert was hired to produce similar precedence-based rules for the English-Pashto language pair. Using the rules and algorithm described in (Xu et al., 2009) we reordered all of the source side and used GIZA++ to align the sentences.

The four additional alignment sets just described, including our baseline alignment, Alignment V, were combined using the presented PM$_n$ combination algorithm, where n signifies the number of tables being combined. As seen on Table 1, we obtained an F-measure of 0.7276 which is 12.97% absolute better than intersection and 6.87% better than union. Furthermore PM$_n$, which in these experiments utilizes 5 alignments, is better than PM by 2.92% absolute. This is an encouraging result because this not only shows that we are finding better alignments than intersection and union, but also that combining more than two alignments is useful. We note that PM$_n$ performed 3.85% absolute better than H (Och and Ney, 2003), and 5.64% better than GDF heuristics.

In the above experiments the parameters of the power mean combination method were tuned on development data to optimize alignment F-measure, and the performance of several alignment combination techniques were compared in terms of F-measure. However, it is not clear how correlated alignment F-measures are with BLEU scores, as explained in (Fraser and Marcu, 2007).

While there is no mathematical problem with optimizing the parameters of the presented PM-based combination algorithm w.r.t. BLEU scores, computationally it is not practical to do so because each iteration would require a complete training phase. To further evaluate the quality of the alignments methods being compared in this paper, we built several MT models based on them and compared the resulting BLEU scores.

E2F	Dev	Test
I	0.1064	0.0941
H	0.1028	0.0894
GDF	0.1256	0.1091
PM	0.1214	0.1094
PM$_n$	0.1378	0.1209
U	0.1062	0.0897

Table 2: E2F BLEU: PM Alignment Combination Based MT Model Comparision

We built a standard phrase-based translation system (Koehn et al., 2003) that utilizes a stack-based decoder based on an A^* search. Based on the combined alignments, we extracted phrase tables with a maximum phrase length of 6 for English and 8 for Pashto, respectively. We then trained the lexicalized reordering model that produced distortion costs based on the number of words that are skipped on the target side, in a manner similar to (Al-Onaizan and Papineni, 2006). Our training sentences are a compilation of sentences from various domains collected by DARPA, and hence we were able to build interpolated language model which weights the domains differently. We built an interpolated LM for both

English and Pashto, but for English we had significantly more monolingual sentences (1.4 million in total) compared to slightly more than 100K sentences for Pashto. We tuned our MT model using minimum error rate (Och, 2003) training.

F2E	Dev	Test
I	0.1145	0.1101
H	0.1262	0.1193
GDF	0.1115	0.1204
PM	0.1201	0.1155
PM_n	0.1198	0.1196
U	0.1111	0.1155

Table 3: F2E BLEU : PM Alignment Combination Based MT Model Comparision

We built five different MT models based on Intersection (I), Union (U), (Koehn et al., 2003) Grow Diagonal Final (GDF), (Och and Ney, 2003) H refined heuristics and Power Mean (PM_n) alignment sets where $n = 5$. We obtained BLEU (Papineni et al., 2002) scores for E2F direction as shown in Table 2. As expected MT model based on I alignment has the low BLEU score of 0.1064 on the dev set and 0.0941 on the test set on E2F direction. Intersection, though, has higher precision, but throws away many alignments, so the overall number of alignments is too small to produce a good phrase translation table. Similarly the U alignment also has low scores (0.1062 and 0.0897) on the dev and test sets, respectively. The best scores for E2F direction for both dev and test set is obtained using the model based on PM_n algorithm. We obtained BLEU scores of 0.1378 on the dev set and 0.1209 on the test set which is better than all heuristic based methods. It is better by 1.22 absolute BLEU score on the dev set and 1.18 on a test compared to commonly used GDF (Koehn et al., 2003) heuristics. The above BLEU scores were all computed based on 1 reference. Note that for the e2f direction PM, which combines only 2 alignments, is not worse than any of the heuristic based methods. Also note that the difference in the BLEU score of PM and PM_n is quite large, which indicates that combining more than two alignments using the power mean leads to substantial gains in performance.

Although we saw significant gains on E2F direction we did not see similar gains on F2E direction unfortunately. Matching our expectation Intersection (I) produced the worse results with BLEU scores of 0.1145 and 0.1101 on the dev and test set respectively, as shown in Table 3. Our PM_n algorithm obtained BLEU score of 0.1198 on the dev set and 0.1196 on test set which is better by 0.83 absolute in dev set over GDF. On the test set though performance between PM_n and GDF is only slightly different with 0.1196 for PM_n and 0.1204 for GDF. The standard deviation on test set BLEU scores for F2E direction is only 0.0042 which is one third of the standard deviation in E2F direction at 0.013 signifying that the alignment seems to make less difference in F2E direction for our models. One possible explanation for such results is that the Pashto LM for the E2F direction is trained on a small set of sentences available from training corpus while English LM for F2E direction was trained on 1.4 million sentences. Therefore the English LM, which is trained on significantly more data, is probably more robust to translation model errors.

Type	PT Size (100K)
I	182.17
H	30.73
GDF	27.65
PM	60.87
PM_n	25.67
U	24.54

Table 4: E2F Phrase Table Size

Type	PT Size (100K)
I	139.98
H	56.76
GDF	22.96
PM	47.50
PM_n	21.24
U	20.33

Table 5: F2E Phrase Table Size

Note that different alignments lead to different phrase table (PT) sizes (Figure 2). The intersection (I) method has the least number of alignment links, and tends to produce the largest phrase tables, because there are less restrictions on the

phrases to be extracted. The Union (U) method, on the other hand, tends to produce the least number of phrases, because the phrase extraction algorithm has more constraints to satisfy. We observe that PT produced by intersection is significantly larger than others as seen in Tables 4 and 5. The PT size produced by PM_n as shown in Table 4 is between I and U and is significantly smaller than the other heuristic based methods. It is 7.1% smaller than GDF heuristic based phrase table. Similarly in F2E direction as well (Table 5) we see the similar trend where PM_n PT size is smaller than GDF by 4.2%. The decrease in phrase table size and increase in BLEU scores for most of the dev and test sets show that our PM based combined alignments are helping to produce better MT models.

6 Conclusion and Future Work

We have presented a mathematical formulation for combining alignment tables based on their power mean. The presented framework allows us to find the optimal alignment between intersection and union by finding the best power mean parameter between 0 and ∞, which correspond to intersection and union operations, respectively. We evaluated the proposed method empirically by computing BLEU scores in English-Pashto translation task and also by computing an F-measure with respect to human alignments. We showed that the approach is more effective than intersection, union, the heuristics of (Och and Ney, 2003), and the grow diagonal final (GDF) algorithm of (Koehn et al., 2003). We also showed that our algorithm is not limited to two tables, which makes it possible to jointly optimize the combination of multiple alignment tables to further increase performance.

In future work we would like to address two particular issues. First, in this work we converted power mean outputs to binary alignment links by simple selection process. We are currently investigating ways to integrate the binary constraint into the PM-based optimization algorithm. Second, we do not have to limit ourselves to alignments tables that are binary. PM based algorithm can combine alignments that are not binary, which makes it easier to integrate other sources of information such as posterior probability of word translation into the alignment combination framework.

Abstract

Traditional 1-best translation pipelines suffer a major drawback: the errors of 1-best outputs, inevitably introduced by each module, will propagate and accumulate along the pipeline. In order to alleviate this problem, we use compact structures, *lattice* and *forest*, in each module instead of 1-best results. We integrate both lattice and forest into a single tree-to-string system, and explore the algorithms of lattice parsing, lattice-forest-based rule extraction and decoding. More importantly, our model takes into account all the probabilities of different steps, such as segmentation, parsing, and translation. The main advantage of our model is that we can make global decision to search for the best segmentation, parse-tree and translation in one step. Medium-scale experiments show an improvement of +0.9 BLEU points over a state-of-the-art forest-based baseline.

1 Introduction

Statistical machine translation (SMT) has witnessed promising progress in recent years. Typically, conventional SMT is characterized as a 1-best pipeline system (Figure 1(a)), whose modules are independent of each other and only take as input 1-best results from the previous module. Though this assumption is convenient to reduce the complexity of SMT systems. It also bring a major drawback of error propagation. The errors of 1-best outputs, introduced inevitably in each phase, will propagate and accumulate along the pipeline. Not recoverable in the final decoding step. These errors will severely hurt the translation quality. For example, if the accuracy of each module is 90%, the final accuracy will drop to 73% after three separate phases.

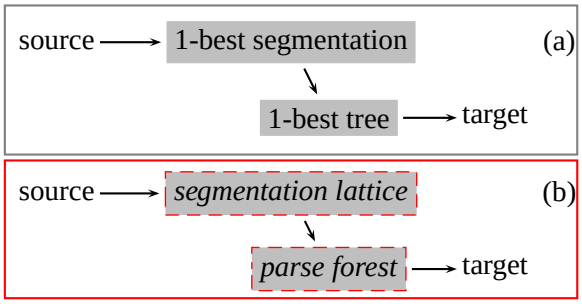

Figure 1: The pipeline of tree-based system: (a) 1-best (b) lattice-forest.

To alleviate this problem, an obvious solution is to widen the pipeline with *k*-best lists rather than 1-best results. For example Venugopal et al. (2008) use *k*-best alignments and parses in the training phase. However, with limited scope and too many redundancies, it is inefficient to search separately on each of these similar lists (Huang, 2008).

Another efficient method is to use compact data structures instead of *k*-best lists. A *lattice* or *forest*, compactly encoded exponentially many derivations, have proven to be a promising technique. For example, Mi and Huang (2008), Mi et al. (2008), Liu et al. (2009) and Zhang et al. (2009) use forests in rule extraction and decoding phases to extract more general rules and weaken the influence of parsing errors; Dyer et al. (2008) use word lattice in Chinese word segmentation and Arabic morphological variation phases to weaken the influence of segmentation errors; Huang (2008) and

Coling 2008: Poster Volume, pages 837–845,
Beijing, August 2010

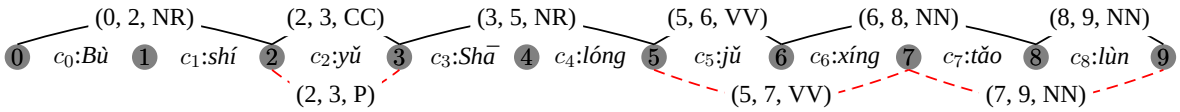

Figure 2: The lattice of the example:“ *Bù shí yǔ Shā lóng jǔ xíng tǎo lùn*.” The solid lines show the 1-best result, which is wrong.

Jiang et al. (2008b) stress the problems in reranking phase. Both lattices and forests have become popular in machine translation literature.

However, to the best of our knowledge, previous work only focused on one module at a time. In this paper, we investigate the combination of lattice and forest (Section 2), as shown in Figure 1(b). We explore the algorithms of lattice parsing (Section 3.2), rule extraction (Section 4) and decoding (Section 5). More importantly, in the decoding step, our model can search among not only more parse-trees but also more segmentations encoded in the lattice-forests and can take into account all the probabilities of segmentations and parse-trees. In other words, our model postpones the disambiguition of segmentation and parsing into the final translation step, so that we can do global search for the best segmentation, parse-tree and translation in one step. When we integrate a lattice into a forest system, medium-scale experiments (Section 6) show another improvement of +0.9 BLEU points over a state-of-the-art forest-based system.

2 Compact Structures

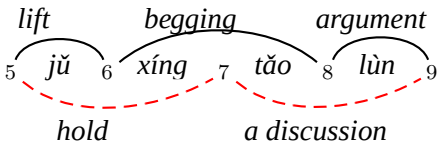
A **word lattice** (Figure 2) is a compact representation of all the possible of segmentations and POS tags, while a **parse forest** (Figure 5) is a compact representation of all parse trees.

2.1 Word Lattice

For a given input sentence $C = c_0..c_{n-1}$, where c_i denotes a character at position i, and n is the length of the sentence.

A word lattice (Figure 2), or **lattice** in short, is a set of **edges** L, where each edge is in the form of (i, j, X), which denotes a word of tag X, covering characters c_i through c_{j-1}. For example, in Figure 2, (7, 9, NN) is a noun “*tǎolùn*” of two characters.

The lattice in Figure 2 shows result of the example:“ *Bù shí yǔ Shā lóng jǔ xíng tǎo lùn* ”. One ambiguity comes from the POS tag of word “*yǔ*” (preposition (P) or conjunction (CC)). The other one is the segmentation ambiguity of the last four characters, we can segment into either “*jǔ xíngtǎo lùn*” (solid lines), which means *lift*, *begging* and *argument* separately for each word or “*jǔxíng tǎolùn*” (dashed lines), which means *hold a discussion*.



The solid lines above (and also in Figure 2) show the 1-best result, which is obviously wrong. If we feed it into the next modules in the SMT pipeline, parsing and translation will be become much more difficult, since the segmentation is not recoverable. So it is necessary to postpone error segmentation decisions to the final translation step.

2.2 Parse Forest

In parsing scenario, a parse forest (Figrure 5), or **forest** for short, can be formalized as a hypergraph H, a pair $\langle V, E \rangle$, where node $v \in V$ is in the form of $X_{i,j}$, which denotes the recognition of nonterminal X spanning the substring $c_{i:j-1}$ from positions c_i through c_{j-1}. Each hyperedge $e \in E$ is a pair $\langle tails(e), head(e) \rangle$, where $head(e) \in V$ is the **consequent node** in an instantiated deductive step, and $tails(e) \in (V)^*$ is the list of **antecedent nodes**.

For the following deduction:

$$\frac{\mathrm{NR}_{0,2} \quad \mathrm{CC}_{2,3} \quad \mathrm{NR}_{3,5}}{\mathrm{NP}_{0,5}} \qquad (*)$$

its hyperedge e^* is notated:

$$\langle(\text{NR}_{0,2},\ \text{CC}_{2,3},\ \text{NR}_{3,5}),\ \ \text{NP}_{0,5}\rangle.$$

where

$$head(e^*) = \{\text{NP}_{0,5}\}, \text{ and}$$
$$tails(e^*) = \{\text{NR}_{0,2}, \text{CC}_{2,3}, \text{NR}_{3,5}\}.$$

We also denote $IN(v)$ to be the set of **incoming hyperedges** of node v, which represents the different ways of deriving v. For simplicity, we only show a tree in Figure 5(a) over 1-best segmentation and POS tagging result in Figure 2. So the $IN(\text{NP}_{0,5})$ is $\{e^*\}$.

3 Lattice Parsing

In this section, we first briefly review the conventional CYK parsing, and then extend to lattice parsing. More importantly, we propose a more efficient parsing paradigm in Section 3.3.

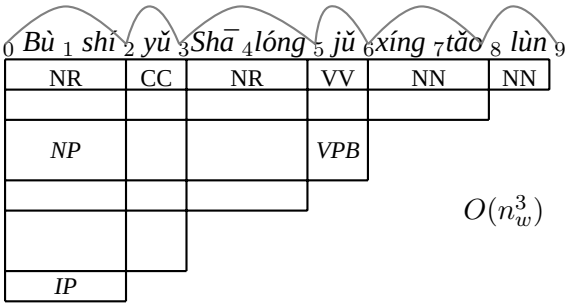
3.1 Conventional Parsing

The conventional CYK parsing algorithm in Figure 3(a) usually takes as input a single sequence of words, so the CYK cells are organized over words. This algorithm consists of two steps: initialization and parsing. The first step is to initialize the CYK cells, whose span size is one, with POS tags produced by a POS tagger or defined by the input string[1]. For example, the top line in Figure 3(a) is initialized with a series of POS tags in 1-best segmentation. The second step is to search for the best syntactic tree under a context-free grammar. For example, the tree composed by the solid lines in Figure 5(a) shows the parsing tree for the 1-best segmentation and POS tagging results.

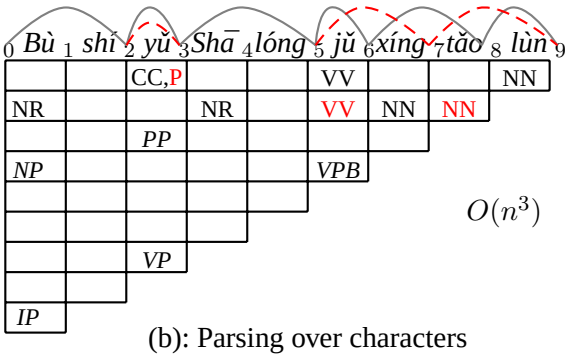
3.2 Lattice Parsing

The main differences of our lattice parsing in Figure 3(b) from conventional approach are listed in following: First, the CYK cells are organized over characters rather than words. Second, in the initialization step, we only initialize the cells with all edges L in the lattice. Take the edge (7, 9, NN) in Figure 2 for example, the corresponding cell should be $(7, 9)$, then we add a leaf node $v = \text{NN}_{7,9}$ with a word *tǎolùn*. The final initialization is shown in Figure 3(b), which shows that

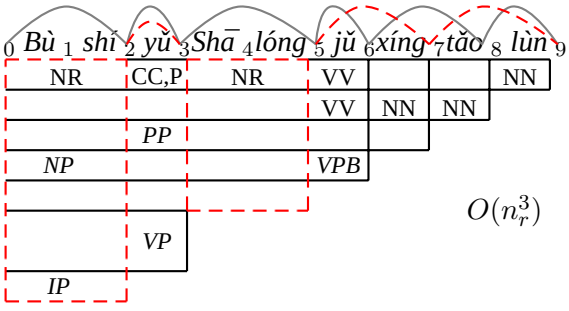
[1]For simplicity, we assume the input of a parser is a segmentation and POS tagging result



(a): Parsing over 1-best segmentation



(b): Parsing over characters



(c): Parsing over most-refined segmentation

Figure 3: CKY parsing charts (a): Conventional parsing over 1-best segmentation. (b): Lattice parsing over characters of input sentence. (c): Lattice parsing over most-refined segmentation of lattice. n_w and n_r denotes the number of tokens over the 1-best segmentation and the most-refined segmenation respectively, and $n_w \leq n_r \leq n$.

lattice parsing can initialize the cells, whose span size is larger than one. Third, in the deduction step of the parsing algorithm *i*, *j*, *k* are the indexes between characters rather than words.

We formalize our lattice parser as a deductive proof system (Shieber et al., 1994) in Figure 4.

Following the definitions of the previous Sec-

tion, given a set of edges L of a lattice for an input sentence $C = c_0..c_{n-1}$ and a PCFG grammar: a 4-tuple $\langle N, \Sigma, P, S\rangle$, where N is a set of non-terminals, Σ is a set of terminal symbols, P is a set of inference rules, each of which is in the form of $X \rightarrow \alpha : p$ for $X \in N$, $\alpha \in (N \cup \Sigma)^*$ and p is the probability, and $S \in N$ is the start symbol. The deductive proof system (Figure 4) consists of **axioms**, **goals** and **inference rules**. The axioms are converted by edges in L. Take the (5, 7, NN) associated with a weight p_1 for example, the corresponding axiom is NN $\rightarrow$ *tǎolùn* : p_1. All axioms converted from the lattice are shown in Figure 3(b) exclude the italic non-terminals. Please note that all the probabilities of the edges L in a lattice are taken into account in the parsing step. The goals are the recognition $X_{0,n} \in S$ of the whole sentence. The inference rules are the deductions in parsing. Take the deduction (*) for example, it will prove a new item $NP_{0,5}$ (italic NP in Figure 3(b)) and generate a new hyper-edge e^* (in Figure 5(b)). So the parsing algorithm starts with the axioms, and then applies the inference rules to prove new items until a goal item is proved. The final whole forest for the input lattice (Figure 2) is shown in Figure 5(b). The extra hyper-edges of lattice-forest are highlighted with dashed lines, which can inference the input sentence correctly. For example: "*yǔ*" is tagged into P rather than CC.

3.3 Faster Parsing with Most-refined Lattice

However, our statistics show that the average number of characters n in a sentence is 1.6 times than the number of words n_w in its 1-best segmentation. As a result, the parsing time over the characters will grow more than 4 times than parsing over the 1-best segmentation, since the time complexity is $O(n^3)$. In order to alleviate this problem, we reduce the parsing time by using **most-refined segmentation** for a lattice, whose number of tokens is n_r and has the property $n_w \leq n_r \leq n$.

Given a lattice with its edges L over indexes $(0, .., n)$, a index i is a **split point**, if and only if there exists some edge $(i, j, X) \in L$ or $(k, i, X) \in L$. The **most-refined segmentation**, or **ms** for short, is the segmentation result by using all split points in a lattice. For example, the corresponding **ms** of the example is "*Bùshí yǔ Shālóng jǔ xíng tǎo lùn*" since points 1 and 4 are *not* split points.

Item form: $X_{i,j}$

Axioms: $\dfrac{}{X_{i,j} : p(i,j,X)}\ (i,j,X) \in L$

Infer. rules: $\dfrac{X_{i,k} : p_1\ Y_{k,j} : p_2}{Z_{i,j} : pp_1p_2} Z \rightarrow XY : p \in P$

Goals: $X_{0,n}$

Figure 4: Lattice parsing as deductive proof system. The i, j, k are the indexes between characters.

Figure 3(c) shows the CKY parsing cells over most-refined segmentation, the average number of tokens n_r is reduced by combining columns, which are shown with red dashed boxes. As a result, the search space is reduced without losing any derivations. Theoretically, the parsing over *fs* will speed up in $O((n/n_r)^3)$. And our experiments in Section 6 show the efficiency of our new approach.

It turns out that the parsing algorithm developed in lattice-parsing Section 3.2 can be used here without any change. The non-terminals inducted are also shown in Figure 3(c) in italic style.

4 Rule Extraction with Lattice & Forest

We now explore the extraction algorithm from aligned source lattice-forest and target string[2], which is a tuple $\langle F, \tau, a\rangle$ in Figure 5(b). Following Mi and Huang (2008), we extract minimal rules from a lattice-forest also in two steps:

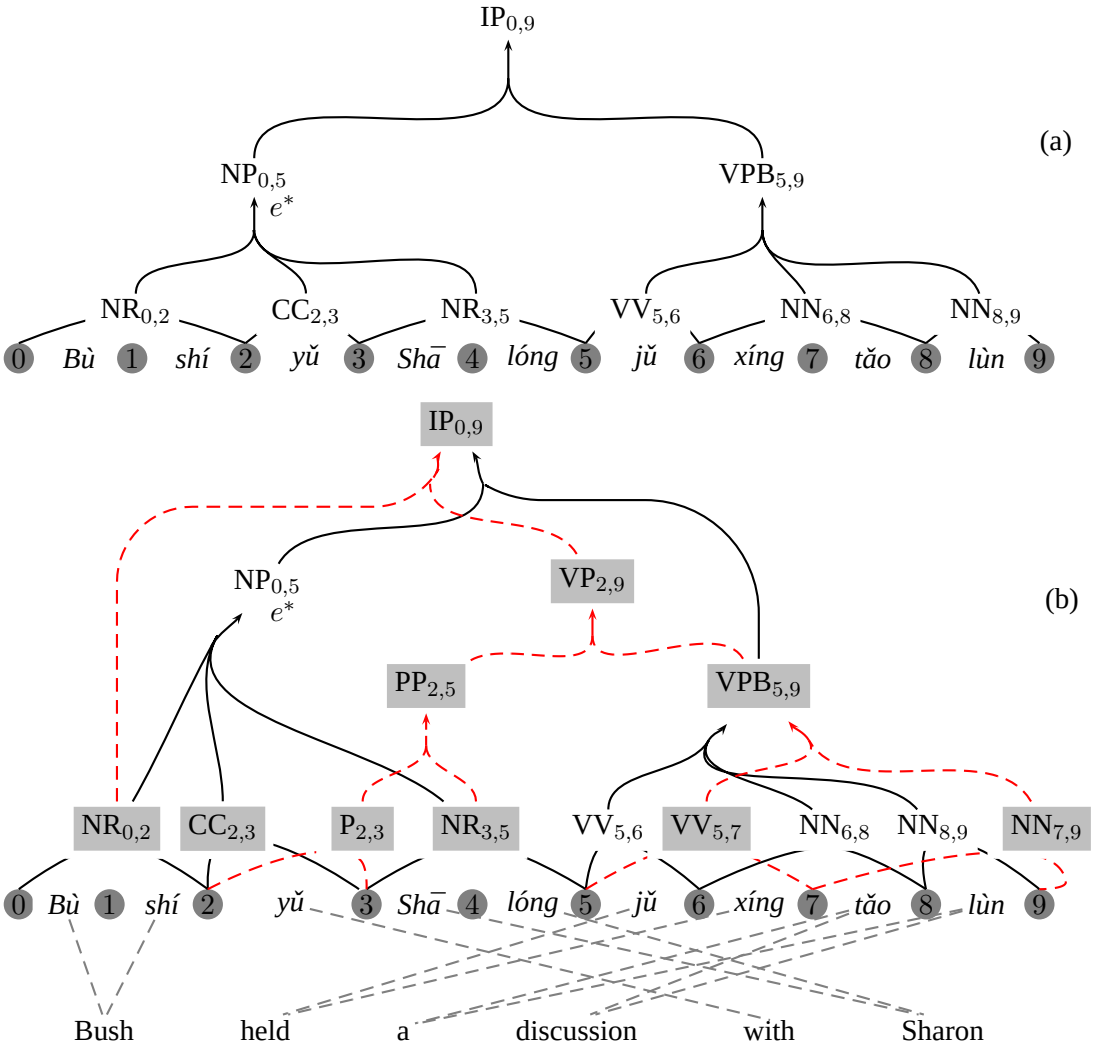
(1) frontier set computation

(2) fragmentation

Following the algorithms developed by Mi and Huang (2008) in Algorithm 1, all the nodes in *frontier set* (*fs*) are highlighted with gray in Figure 5(b).

Our process of fragmentation (lines 1- 13) is to visit each frontier node v and initial a queue ($open$) of growing fragments with a pair of empty fragment and node v (line 3). Each fragment is associated with a list of *expansion sites* ($front$) being

[2]For simplicity and consistency, we use character-based lattice-forest for the running example. The "*Bù*" and "*shí*" are aligned to the same word "*Bush*". In our experiment, we use most-refined segmentation to run lattice-parsing and word alignment.



Forest only (Minimal rules)	Lattice & forest (Extra minimal rules)
IP(NP(x_1:NR x_2:CC x_3:NR) x_4:VPB)	IP(x_1:NR x_2:VP) $\rightarrow x_1\ x_2$
$\rightarrow x_1\ x_4\ x_2\ x_3$	VP(x_1:PP x_2:VPB) $\rightarrow x_2\ x_1$
CC(*yǔ*) $\rightarrow$*with*	PP(x_1:P x_2:NR) $\rightarrow x_1\ x_2$
NR(*Shālóng*) $\rightarrow$*Sharon*	P(*yǔ*) $\rightarrow$*with*
NR(*Bùshí*) $\rightarrow$*Bush*	VPB(x_1:VV x_2:NN) $\rightarrow x_1\ x_2$
VPB(VV(*jǔ*) NN(*xíngtǎo*) NN(*lùn*))	VV(*jǔxíng*) $\rightarrow$*held*
$\rightarrow$*held a discussion*	NN(*tǎolùn*) $\rightarrow$*a discussion*

(c)

Figure 5: (a): The parse forest over the 1-best segmentation and POS tagging result. (b): Word-aligned tuple $\langle F, \tau, a\rangle$: the lattice-forest F, the target string τ and the word alingment a. The solid hyperedges form the forest in (a). The dashed hyperedges are the extra hyperedges introduced by the lattice-forest. (c): The minimal rules extracted on forest-only (left column), and the extra minimal rules extracted on lattice-forest (right column).

the subset of leaf nodes of the current fragment that are *not* in the *fs* except for the initial node v. Then we keep expanding fragments in $open$ in following way. If current fragment is complete, whose expansion sites is empty, we extract rule corresponding to the fragment and its target string

Code 1 Rule Extraction (Mi and Huang, 2008).

Input: lattice-forest F, target sentence τ, and alignment a
Output: minimal rule set $\mathcal{R}$

1: $fs \leftarrow \text{FROSET}(F, \tau, a)$ ▷ frontier set
2: **for** each $v \in fs$ **do**
3: $open \leftarrow \{\langle \varnothing, \{v\}\rangle\}$ ▷ initial queue
4: **while** $open \neq \varnothing$ **do**
5: $\langle frag, front\rangle \leftarrow open.pop()$
6: **if** $front = \varnothing$ **then** ▷ finished?
7: generate a rule r using $frag$
8: $\mathcal{R}$.append(r)
9: **else** ▷ incomplete: further expand
10: $u \leftarrow front$.pop() ▷ expand frontier
11: **for** each $e \in IN(u)$ **do**
12: $f \leftarrow front \cup (tails(e) \setminus fs)$
13: $open$.append($\langle frag \cup \{e\}, f\rangle$)

(line 7) . Otherwise we pop one expansion node u to grow and spin-off new fragments by $IN(u)$, adding new expansion sites (lines 11- 13), until all active fragments are complete and $open$ queue is empty.

The extra minimal rules extracted on lattice-forest are listed at the right bottom of Figure 5(c). Compared with the forest-only approach, we can extract smaller and more general rules.

After we get all the minimal rules, we compose two or more minimal rules into composed rules (Galley et al., 2006), which will be used in our experiments.

For each rule r extracted, we also assign a fractional count which is computed by using inside-outside probabilities:

$$c(r) = \frac{\alpha(root(r)) \cdot P(lhs(r)) \cdot \prod_{v \in yield(root(r))} \beta(v)}{\beta(\text{TOP})}, \quad (1)$$

where $root(r)$ is the root of the rule, $lhs(r)$ is the left-hand-side of rule, $rhs(r)$ is the right-hand-side of rule, $P(lhs(r))$ is the product of all probabilities of hyperedges involved in $lhs(r)$, $yield(root(r))$ is the leave nodes, TOP is the root node of the forest, $\alpha(v)$ and $\beta(v)$ are outside and inside probabilities, respectively.

Then we compute three conditional probabilities for each rule:

$$P(r \mid lhs(r)) = \frac{c(r)}{\sum_{r': lhs(r')=lhs(r)} c(r')} \quad (2)$$

$$P(r \mid rhs(r)) = \frac{c(r)}{\sum_{r': rhs(r')=rhs(r)} c(r')} \quad (3)$$

$$P(r \mid root(r)) = \frac{c(r)}{\sum_{r': root(r')=root(r)} c(r')}. \quad (4)$$

All these probabilities are used in decoding step (Section 5). For more detail, we refer to the algorithms of Mi and Huang (2008).

5 Decoding with Lattice & Forest

Given a source-side lattice-forest F, our decoder searches for the best derivation d^* among the set of all possible derivation D, each of which converts a tree in lattice-forest into a target string τ:

$$d^* = \underset{d \in D, T \in F}{\text{argmax}} P(d|T)^{\lambda_0} \cdot e^{\lambda_1 |d|} \cdot LM(\tau(d))^{\lambda_2} \cdot e^{\lambda_3 |\tau(d)|}, \quad (5)$$

where $|d|$ is the penalty term on the number of rules in a derivation, $LM(\tau(d))$ is the language model and $e^{\lambda_3|\tau(d)|}$ is the length penalty term on target translation. The $P(d|T)$ decomposes into the product of rule probabilities $P(r)$, each of which is decomposed further into

$$P(d|T) = \prod_{r \in d} P(r). \quad (6)$$

Each $P(r)$ in Equation 6 is decomposed further into the production of five probabilities:

$$\begin{aligned} P(r) = & P(r|lhs(r))^{\lambda_4} \\ & \cdot P(r|rhs(r))^{\lambda_5} \\ & \cdot P(r|root(lhs(r))^{\lambda_6} \\ & \cdot P_{lex}(lhs(r)|rhs(r))^{\lambda_7} \\ & \cdot P_{lex}(rhs(r)|lhs(r))^{\lambda_8}, \end{aligned} \quad (7)$$

where the last two are the lexical probabilities between the terminals of $lhs(r)$ and $rhs(r)$. All the weights of those features are tuned by using Minimal Error Rate Training (Och, 2003).

Following Mi et al. (2008), we first convert the lattice-forest into *lattice translation forest* with the conversion algorithm proposed by Mi et al. (2008),

and then the decoder finds the best derivation on the lattice translation forest. For 1-best search, we use the *cube pruning* technique (Chiang, 2007; Huang and Chiang, 2007) which approximately intersects the translation forest with the LM. For k-best search after getting 1-best derivation, we use the lazy Algorithm 3 of Huang and Chiang (2005) to incrementally compute the second, third, through the kth best alternatives.

For more detail, we refer to the algorithms of Mi et al. (2008).

6 Experiments

6.1 Data Preparation

Our experiments are on Chinese-to-English translation. Our training corpus is FBIS corpus with about 6.9M/8.9M words in Chinese/English respectively.

We use SRI Language Modeling Toolkit (Stolcke, 2002) to train a 4-gram language model with Kneser-Ney smoothing on the first 1/3 of the Xinhua portion of Gigaword corpus.

We use the 2002 NIST MT Evaluation test set as development set and the 2005 NIST MT Evaluation test set as test set. We evaluate the translation quality using the case-insensitive BLEU-4 metric (Papineni et al., 2002). We use the standard MERT (Och, 2003) to tune the weights.

6.1.1 Baseline Forest-based System

We first segment the Chinese sentences into the 1-best segmentations using a state-of-the-art system (Jiang et al., 2008a), since it is not necessary for a conventional parser to take as input the POS tagging results. Then we parse the segmentation results into forest by using the parser of Xiong et al. (2005). Actually, the parser will assign multiple POS tags to each word rather than one. As a result, our baseline system has already postponed the POS tagging disambiguition to the decoding step. Forest is pruned by using a marginal probability-based pruning algorithm similar to Huang (2008). The pruning threshold are $p_f = 5$ and $p_f = 10$ at rule extraction and decoding steps respectively.

We word-align the strings of 1-best segmentations and target strings with GIZA++ (Och and Ney, 2000) and apply the refinement method "grow-diag-final-and" (Koehn et al., 2003) to get the final alignments. Following Mi and Huang (2008) and Mi et al. (2008), we also extract rules from forest-string pairs and translate forest to string.

6.1.2 Lattice-forest System

We first segment and POS tag the Chinese sentences into word lattices using the same system (Jiang et al., 2008a), and prune each lattice into a reasonable size using the marginal probability-based pruning algorithm.

Then, as current GIZA++ (Och and Ney, 2000) can only handle alignment between string-string pairs, and word-alingment with the pairs of Chinese characters and target-string will obviously result in worse alignment quality. So a much better way to utilize GIZA++ is to use the most-refined segmentation for each lattice instead of the character sequence. This approach can be viewed as a compromise between character-string and lattice-string word-alignment paradigms. In our experiments, we construct the most-refined segmentations for lattices and word-align them against the English sentences. We again apply the refinement method "grow-diag-final-and" (Koehn et al., 2003) to get the final alignments.

In order to get the lattice-forests, we modified Xiong et al. (2005)'s parser into a lattice parser, which produces the pruned lattice forests for both training, dev and test sentences. Finally, we apply the rule extraction algorithm proposed in this paper to obtain the rule set. Both lattices and forests are pruned using a marginal probability-based pruning algorithm similar to Huang (2008). The pruning threshold of lattice is $p_l = 20$ at both the rule extraction and decoding steps, the thresholds for the latice-forests are $p_f = 5$ and $p_f = 10$ at rule extraction and decoding steps respectively.

6.2 Results and Analysis

Table 1 shows results of two systems. Our lattice-forest (LF) system achieves a BLEU score of 29.65, which is an absolute improvement of 0.9 points over the forest (F) baseline system, and the improvement is statistically significant at $p < 0.01$ using the *sign-test* of Collins et al. (2005).

The average number of tokens for the 1-best and most-refined segmentations are shown in second column. The average number of characters is 46.7, which is not shown in Table 1. Com-

Sys	Avg # of		Rules		BLEU
	tokens	links	All	dev&tst	
F	28.7	35.1	29.6M	3.3M	28.75
LF	37.1	37.1	23.5M	3.4M	29.65

Table 1: Results of forest (F) and lattice-forest (LF) systems. Please note that lattice-forest system only extracts 23.5M rules, which is only 79.4% of the rules extracted by forest system. However, in decoding step, lattice-forest system can use more rules after filtered on dev and test sets.

pared with the characters-based lattice parsing, our most-refined lattice parsing speeds up parsing by $(37.1/46.7)^3 \approx 2$ times, since parsing complexity is $O(n^3)$.

More interestingly, our lattice-forest model only extracts 23.5M rules, which is 79.4% percent of the rules extracted by the baseline system. The main reason lies in the larger average number of words for most-refined segmentations over lattices being 37.1 words vs 28.7 words over 1-best segmentations. With much finer granularity, more word aligned links and restrictions are introduced during the rule extraction step by GIZA++. However, more rules can be used in the decoding step for the lattice-forest system, since the lattice-forest is larger than the forest over 1-best segmentation.

We also investigate the question of how often the non 1-best segmentations are picked in the final translation. The statistic on our dev set suggests 33% of sentences choose non 1-best segmentations. So our lattice-forest model can do global search for the best segmentation and parse-tree to direct the final translation. More importantly, we can use more translation rules in the translation step.

7 Related Works

Compactly encoding exponentially many derivations, lattice and forest have been used in some previous works on SMT. To alleviate the problem of parsing error in 1-best tree-to-string translation model, Mi et al. (2008) first use forest to direct translation. Then Mi and Huang (2008) use forest in rule extraction step. Following the same direction, Liu et al. (2009) use forest in tree-to-tree model, and improve 1-best system by 3 BLEU points. Zhang et al. (2009) use forest in tree-sequence-to-string model and also achieve a promising improvement. Dyer et al. (2008) combine multiple segmentations into word lattice and then use lattice to direct a phrase-based translation decoder. Then Dyer (2009) employ a single Maximum Entropy segmentation model to generate more diverse lattice, they test their model on the hierarchical phrase-based system. Lattices and forests can also be used in Minimal Error Rate Training and Minimum Bayes Risk Decoding phases (Macherey et al., 2008; Tromble et al., 2008; DeNero et al., 2009; Kumar et al., 2009; Li and Eisner, 2009). Different from the works listed above, we mainly focus on how to combine lattice and forest into a single tree-to-string system.

8 Conclusion and Future Work

In this paper, we have proposed a lattice-forest based model to alleviate the problem of error propagation in traditional single-best pipeline framework. Unlike previous works, which only focus on one module at a time, our model successfully integrates lattice into a state-of-the-art forest tree-to-string system. We have explored the algorithms of lattice parsing, rule extraction and decoding. Our model postpones the disambiguition of segmentation and parsing into the final translation step, so that we can make a more global decision to search for the best segmentation, parse-tree and translation in one step. The experimental results show that our lattice-forest approach achieves an absolute improvement of +0.9 points in term of BLEU score over a state-of-the-art forest-based model.

For future work, we would like to pay more attention to word alignment between lattice pairs and forest pairs, which would be more principled than our current method of word alignment between most-refined segmentation and string.

Abstract

In this paper, an automatic method for Persian WordNet construction based on Prenceton WordNet 2.1 (PWN) is introduced. The proposed approach uses Persian and English corpora as well as a bilingual dictionary in order to make a mapping between PWN synsets and Persian words. Our method calculates a score for each candidate synset of a given Persian word and for each of its translation, it selects the synset with maximum score as a link to the Persian word. The manual evaluation on selected links proposed by our method on 500 randomly selected Persian words, shows about 76.4% quality respect to precision measure. By augmenting the Persian WordNet with the un-ambiguous words, the total accuracy of automatically extracted Persian WordNet is about 82.6% which outperforms the previously semi-automated generated Persian WordNet by about 12.6%.

1 Introduction

In Natural Language Processing (NLP) wide coverage lexical databases are used in different area such as information retrieval and cross-language information retrieval. WordNet is an example for a lexical database that groups words into sets of synonyms and categorizes them in four categories: noun, verb, adjective and adverb and records various relations between synonym sets. A broad overview of the different PWN applications such as "Machine Translation", "Information Retrieval", "Document Classification", "Query Answering" and "Conceptual Identification" have been presented in (Morato et al., 2004).

PWN was created and maintained since 1990s. After this WordNet for other languages have been under development and new projects start every year. PWN database contains about 150000 words organized in over 115000 synsets.

Manual construction of WordNet is a time consuming task and requires linguistic knowledge. A number of automatic methods were proposed for constructing WordNet for other languages that use PWN and other existing lexical resources. In order to help the development of WordNets for other languages rather than English, especially for European one, a project named EuroWordNet was found (Vossen, 1999), in which a number of automatic methods for construction of such databases were proposed (Farreres et al., 1998).

There have been some other efforts to create a WordNet for Persian language (Famian, 2007; Rouhizadeh et al., 2008; Shamsfard, 2008) but there exists no Persian WordNet yet that covers all Persian words in dictionary and comparable with PWN. These projects have tried to construct Persian WordNet in the manually or semi automatic manner. In (Shamsfard, 2008) a semi automatic method is proposed in which for each Persian word a number of PWN synsets are suggested by system in order to be supervised by a human annotator to select a relevant synset. Based on experiments mentioned by Shamsfard (2008), the proposed WordNet extracted automatically by the system, retrieved about 70% accuracy.

In this paper a fully automatic method for constructing a large-scale Persian WordNet from available resource such as PWN, MRDs and corpora has been proposed. Our approach uses different word similarity metrics like mutual information and WordNet similarity to map Persian words to appropriate PWN synsets.

2 Related Works

In the related field of automatic and semi automatic WordNet construction, several efforts

Coling 2008: Poster Volume, pages 846–850,
Beijing, August 2010

have been made. In (Shamsfard, 2008) a semi automatic method has been used for developing a lexical ontology called FarsNet for Persian language. About 1500 verbs and 1500 nouns have been gathered manually to make WorldNet's core. Then some heuristics and Word Sense Disambiguation (WSD) methods have been used to find the most likely related Persian synsets.

According to the first heuristic, a Persian word has only one synset if it's be translated to a single English word. In this case no ambiguity exists for the Persian word whose one of synsets will be equivalent with that of English word. In other cases, second heuristic is used: if two translations of a Persian word have only one common synset then for the Persian word this common synset is selected. The existence of a single common synset in fact implies the existence of a single common sense between the two words and therefore their Persian translations shall be connected to this synset (Shamsfard, 2008). For words whose English translations have more than one synset and second heuristic cannot find the appropriate synset, WSD methods have been used to select correct synset. For each candidate synset, a score is calculated using the measure of semantic similarity and synset gloss words. Manual evaluation of the proposed automatic method in this research shows 70% correctness and covers about 6500 Entries on WordNet.

In (Sathapornrungkij and Pluempitiwiriyawej, 2005) a semi-automatic approach has been described to construct the Thai WordNet lexical database from WordNet and LEXiTRON machine readable dictionaries. Thai WordNet synsets have been derived from the PWN. The candidate links between Thai words and synsets have been derived from semantic links which are obtained from WordNet and the translation links which are obtained from LEXiTRON. In order to derive links between Thai words and PWN synsets, 13 criteria have been used which are categorized into three groups: monosemic, polysemic and structural criteria. Monosemic criteria focus on an English word which has only one meaning. Such English word has one synset in PWN. Polysemic criteria focus on an English word which has multiple meaning. Such English word has multiple synset in PWN. Structural criteria focus on the structural relations among synsets with respect to WordNet 1.7. In order to verify links that constructed using these 13 criteria, stratified sampling technique has been applied and for each criterion 400 links have been verified manually. The results of verification show that the best criterion has 92% correctness and the lowest correctness is equal 49.25%.

In PWN, there is a gloss for each synset that can be used in automatic WordNet construction. In (Kaji and Watanabe, 2006) this information has been used for automatic construction of Japanese WordNet. Given an English synset, it calculates the score for each of its Japanese translation candidates according to the gloss appended to the synset. A pair of words is called associated if mutual information between them be larger than a threshold. The score is defined as the sum of correlations between the translation candidate and the associated words appearing in the gloss. Whereas availability of bilingual corpora is limited, for calculating pair wise correlation between the Japanese translations of an English word and its associated words an iteratively approach has been proposed that calculate this correlation without using bilingual corpora.

In (Lee et al., 2000) a set of automatic WSD techniques have been described for linking Korean words collected from a bilingual MRD to PWN synsets. For a given synset, 6 individual heuristic scores are calculated and then a decision tree is used to combine these scores to classify the synset as linking or discarding. In order to make the decision tree, a set of synsets have been labeled manually as linking or discarding and corresponding heuristic scores have been calculated and then used for training data set. To evaluate the accuracy of proposed method the candidate synsets of 3260 senses of Korean words have been classified manually as linking or discarding. This test set has been used to calculate precision of each heuristic. The results of experiments show that the precision of all heuristics is better than random mapping and the best heuristic have 75.21% precision. The combination of heuristics using decision tree shows 93.59% precision.

3 Automatic Persian WordNet Construction

Each Persian word can have several English translations and each English translation has also

several PWN synsets. For a given Persian word, a bilingual dictionary is used to extract English equivalent words, and then a set of candidate synset is generated using PWN that contains all synsets of English translations of Persian word. As in (Shamsfard, 2008), if the English translation of a given Persian word has only one synset in PWN, then the Persian word is linked to this PWN synset directly, or if for a candidate synset at least two English translations belong to it, then Persian word is linked to this PWN synset.

In other cases, a score is calculated for each remaining candidate synset and the synset with maximum score is selected as an appropriate synset of the Persian word. Note that after selecting a synset, all synsets that share English words are removed from candidate synsets.

The following resources have been used in the process of score calculation:

- PWN: synset words, synset definition and hypernymy relations have been used.
- Bilingual dictionary (Persian – English)
- Raw Persian text corpus for extracting related words of a given Persian word
- Raw English text corpus for extracting mutual information between English words

Text corpora have been used to extract the related words of any given word. To do this, Mutual Information (MI) metric between any words in corpus and given Persian word are calculated and n-best words with higher MI values are selected. Mutual Information of pair x and x' is defined as follows:

$$MI(x,x') = \frac{n(x,x')}{n(x) * n(x')} * N \qquad (1)$$

In formula 1, n(x, x') is co-occurrence frequency of x and x' in corpus. This frequency is calculated using a window with specific size. n(x) is the frequency of word x in corpus and N is the number of unique words in corpus.

So, in order to select the most related words for a given Persian word, an additional step is considered. For each Persian word *w*, other related Persian words with highest mutual information are selected and considered as a set $R = \{r_1, r_2, \ldots, r_n\}$. Then for each Persian word r_i a similar process is used and a set of words is extracted that is called R_i. If R_i contains the word *w*, then r_i is selected as the related word for *w* and otherwise discarded.

After extracting the related words of the given Persian word, a Persian to English dictionary has been used to find equivalent translation of each related word. These words are referred as Related Translation Set (RTS). In scoring algorithm words that appear in gloss of each synset and words that appear in hypernym synset are called Gloss Words (GW). These words are considered as related words to the candidate synset and distinguish each synset from other.

Now for each candidate synset of a given Persian word a score is calculated that is based on the idea that two related words in the two-side languages share the same words in the correlation set. That is, if Persian word *w* relates to English synset *e*, then other co-related Persian words $r_1, r_2, \ldots, r_n$ which have gotten the best MI respect to *w*, should be related to the same synset *e* again.

Based on the above notion, the score of each candidate synset S can be estimated as follow:

$$Score(S) = \sum_{w_i \in RTS} \sum_{e_i \in GW} Sim(w_i, S) * MI(w_i, e_i) \qquad (2)$$

The score of synset S is defined as summation on product of semantic similarity between words in RTS and synset S, and mutual information between words in RTS and words in GW. In (Pedersen et al., 2004) several methods for calculating semantic similarity based on WordNet's structure have been presented. Some of these methods are based on path lengths between concepts and some of them are based on information content. One of these methods is named path in which for each word *w* and synset *s* is defined as inverse of shortest path length between any synset of *w* and *s*. In our experiments the measure path has been used and calculated using formula 3.

$$Sim(w,S) = \frac{1}{\min_{s_i \in \text{ synsets of w}}(path(s_i,S))} \qquad (3)$$

In formula 2 the words from RTS which has less similarity to synset *s* has little effect on the amount of score in synset.

4 Experiments and Evaluations

Persian WordNet constructor components are Word Translator, Related Word Extractor, Synset Extractor and Synset Selector. Persian words and their selected synsets are input and output of this system. Persian word is given as input to the Word Translator and Related Word Extractor components. In our experiment, 10 words with highest MI to the given Persian word are extracted using Related Word Extractor. For this purpose, 3000 documents of IRNA[1] newspaper text corpus have been used. IRNA is a news agency published their news on different languages, mainly on Persian. In order to count the number of co-occurrences of words x and x', a window with the size of 20 words was considered. Translations of related words and candidate synsets are given to Synset Selector and appropriate synsets for the given Persian word are selected. In this step PWN is used for semantic similarity calculation and an English text corpus (USENET corpus) is used to calculate mutual information. Table 1 shows the number of words and documents in the Persian and English text corpora. About 30698 Persian words from Aryanpour[2] Persian to English dictionary has been used for constructing Persian WordNet.

	Num of documents	Num of Unique Words
Persian	3000	32197
English	3000	32899

Table 1: number of documents and unique words in Persian and English corpuses

As it was mentioned in the previous section, Persian words were linked to PWN synsets in the two different ways. Some links was selected directly without calculating their score by using some heuristics. We call these links as unambiguous links. Some of these links are shown in table 2. As it shown in the table, unambiguous links are wrong in some cases. For example in the case of '<barchasb>tag', a verb synset is selected while the Persian word is noun, so the selection is judged as incorrect. If the part of speech tag information of word is used in this example the correct synset would be selected.

Another type of links are ambiguous links, in which a scoring method is used for selecting the appropriate synset. Examples of these links are shown in table 3. As it's shown in the table, the word '<karmozd>commission' has been linked to 6th sense of word 'commission' that is wrong. In constructed Persian WordNet also word '<farman>commission' has been linked to this sense of word 'commission' but the word '<karmozd>commission' and the word '<farman>commission' have less similarity together. In this example link between '<farman>commission' and 6th sense of word 'commission' is an unambiguous link. Therefore we can avoid of selecting this synset for '<karmozd>commission' using this information.

In order to evaluate the quality of the selected links, 500 Persian words have been randomly selected and the accuracy of selected synsets has been evaluated manually. Table 4 summarizes the results of this evaluation. As it's shown in the table, the precision of unambiguous links is about 95.8% while this precision is 76.4% for the ambiguous links. The weighted average precision of the whole links in our automatically generated Persian WordNet is 82.6%, which outperforms the only comparable semi-automated Persian WordNet which was previously presented by (Shamsfard, 2008), about 12.5%. Also, by comparing the PWN coverage rate of these Persian WordNets, it reveals that our result covered 29716 entries on PWN which it is about 4 times more than the previously generated Persian WordNet.

	Precision
Unambiguous links	95.8%
Ambiguous links	76.4%
All links	82.6%

Table 4: accuracy of selected links for 500 words

The experimental results reveal that in PWN there is a short gloss for some synsets which makes the calculated score for those synsets to be lower than other candidate synsets of a given Persian word. This problem can be overcome by normalizing the scores of candidate synset of a given Persian word, i.e. by dividing the score of each synset by the number of words in GW. Another solution of this problem is proposed by (Kaji and Watanabe, 2006). In (Kaji and Wata-

[1] Islamic Republic News Agency (http://www.irna.ir)
[2] http://www.aryanpour.com/

Persian word	English translation	Selected synset	Gloss	Correct /incorrect
<mosen> aged	aged, elderly, old	aged, elderly	people who are old collectively	correct
<barchasb> tag	tag, label, mark	tag, label, mark	attach a tag or label to	incorrect

Table 2: Examples of unambiguous links

Persian word	English translation	Selected synset	Gloss	Correct /incorrect
<enteshar> publication	publication	publication	the communication of something to the public; making information generally known	correct
<karmozd> commission	commission	commission, charge, direction	a formal statement of a command or injunction to do something	incorrect

Table 3: Examples of ambiguous links

nabe, 2006), the gloss is given as a query to text retrieval engine and the words that appear as the answer of this query are used instead of the words of gloss. In our experiments, the first solution is chosen which retrived the results shown in table 4.

5 Conclusion

This paper explored a method for automatically linking WordNet synsets to Persian words using pre-existing lexical resources such as Persian and English text corpora and PWN. The proposed method calculates a score for each candidate synset of a given Persian word and selects the synset with maximum score to be linked to the Persian word. This score is calculated considering related words of Persian word and words that appear in gloss of synset. A preliminary experiment shows that this method can be used to construct Persian WordNet. In the proposed method for each Persian word synsets with maximum calculated score are selected without considering other Persian words. In future work we intend to adapt our method and contribute other Persian word in order to select a synset for a given Persian word.

Abstract

Entity sense disambiguation becomes difficult with few or even zero training instances available, which is known as imbalanced learning problem in machine learning. To overcome the problem, we create a new set of reliable training instances from dictionary, called dictionary-based prototypes. A hierarchical classification system with a tree-like structure is designed to learn from both the prototypes and training instances, and three different types of classifiers are employed. In addition, supervised dimensionality reduction is conducted in a similarity-based space. Experimental results show our system outperforms three baseline systems by at least 8.3% as measured by macro F_1 score.

1 Introduction

Ambiguities in terms and named entities are a challenge for automatic information extraction (IE) systems. The problem is particularly acute for IE systems targeting the biomedical domain, where unambigiously identifying terms is of fundamental importance. In biomedical text, a term (or its abbreviation (Okazaki et al., 2010)) may belong to a wide variety of semantic categories (e.g., gene, disease, etc.). For example, *ER* may denote protein *estrogen receptor* in one context, but cell subunit *endoplasmic reticulum* in another, not to mention it can also mean emergency room. In addition, same terms (e.g., protein) may belong to many model organisms, due to the nomenclature of gene and gene products, where genes in model organisms other than human are given, whenever possible, the same names as their human orthologs (Wain et al., 2002). On the other hand, public biological databases keep species-specific records for the same protein or gene, making species disambiguation an inevitable step for assigning unique database identifiers to entity names in text (Hakenberg et al., 2008; Krallinger et al., 2008).

One way to entity disambiguation is classifying an entity into pre-defined semantic categories, based on its context (e.g., (Bunescu and Paşca, 2006)). Existing classifiers, such as maximum entropy model, achieved satisfactory results on the "majority" classes with abundant training instances, but failed on the "minority" ones with few or even zero training instances, i.e., the knowledge acquisition bottleneck (Agirre and Martinez, 2004). Furthermore, it is often infeasible to create enough training data for all existing semantic classes. In addition, too many training instances for certain majority classes lead to increased computational complexity for training, and a biased system ignoring the minority ones. These correspond to two previously addressed difficulties in imbalanced learning: *"... either (i) you have far more data than your algorithms can deal with,*

Coling 2008: Poster Volume, pages 851–859,
Beijing, August 2010

and you have to select a sample, or (ii) you have no data at all and you have to go through an involved process to create them" (Provost, 2000). Given an entity disambiguation task with imbalanced data, this paper explores how to create more informative training instances for minority classes and how to improve the large-scale training for majority classes.

Previous research has shown that words denoting class information in the surrounding context of an entity can be an informative indicator for disambiguation (Krallinger et al., 2008; Wang et al., 2010). Such words are refered to as "cue words" throughout this paper. For example, to disambiguate the type of an entity, that is, whether it is a protein, gene, or RNA, looking at words such as *protein*, *gene* and *RNA* are very helpful (Hatzivassiloglou et al., 2001). Similarly, for the task of species disambiguation (Wang et al., 2010), the occurrence of *mouse p53* strongly suggests that *p53* is a *mouse* protein. In many cases, cue words are readily available in dictionaries. Thus, for the minority classes, instead of creating artificial training instances by commonly used sampling methods (Haibo and Garcia, 2009), we propose to create a new set of real training instances by modelling cue words from a dictionary, called dictionary-based prototypes. To learn from both the original training instances and the dictionary-based prototypes, a hierarchical classification system with a tree-like structure is designed. Furthermore, to cope with the large number of features representing each instance, supervised orthogonal locality preserving projection (SOLPP) is conducted for dimensionality reduction, by simultaneously preserving the intrinsic structures constructed from both the features and labels. A new set of lower-dimensional embeddings with better discriminating power is obtained and used as input to the classifier. To cope with the large number of training instances in some majority classes, we propose a committee machine scheme to accelerate training speed without sacrificing classification accuracy. The proposed method is evaluated on a species disambiguation task, and the empirical results are encouraging, showing at least 8.3% improvement over three different baseline systems.

2 Related Work

Construction of a classification model using supervised learning algorithms is popular for entity disambiguation. A number of researchers have tackled entity disambiguation in general text using wikipedia as a resource to learn classification models (Bunescu and Paşca, 2006). Hatzivassiloglou et al. (2001) studied disambiguating proteins, genes, and RNA in text by training various classifiers using entities with class information provided by adjacent cue words. Wang et al. (2010) proposed a "hybird" system for species disambiguation, which heuristically combines results obtained from classifying the context, and those from modeling relations between cue words and entities. Although satisfactory performance was reported, their system incurs higher computational cost due to syntactic parsing and the binary relation classifier.

Many imbalanced learning techniques, as reviewed by Haibo and Garcia (2009), can also be used to achieve the same purpose. However, to our knowledge, there is little research in applying these machine learning (ML) techniques to entity disambiguation. It is worth mentioning that although these ML techniques can improve the learning performance to some extent, they only consider the information contained in the original training instances. The created instances do not add new information, but instead utilize the original training information in a more sophisticated way. This motivates us to pursue a different method of creating new training instances by using information from a related and easily obtained source (e.g., a dictionary), similar to transfer learning (Pan and Yang, 2009).

3 Task and Corpus

In this work, we develop an entity disambiguation technique with the use of cue words, as well as a general ML algorithm for imbalanced classification using a set of newly created dictionary-based prototypes. These prototypes are represented with different features from those used by the original training instances. The proposed method is evaluated on a species disambiguation task: given a text, in which mentions of biomedical named en-

tities are annotated, we assign a *s*pecies identifier to every entity mention. The types of entities studied in this work are genes and gene products (e.g., proteins), and we use the NCBI Taxonomy[1] (taxon) IDs as species tags and to build the prototypes. Note that this paper focuses on the task of species disambiguation and makes the assumption that the named entities are already recognised.

Consider the following sentence as an example: if one searches the proteins (i.e., the underlined term) in a protein database, he/she will find they belong to many model organisms. However, in this particular context, CD200R-CD4d3+4 is *human* and *mouse* protein, while *r*CD4d3+4 is a *rat* one.[2] We call such a task of assigning species identifiers to entities, according to context, as species disambiguation.

> The amounts of *human* and *mouse* CD200R-CD4d3+4 and *r*CD4d3+4 protein on the microarray spots were similar as visualized by the red fluorescence of OX68 mAb recognising the CD4 tag present in each of the recombinant proteins.

The informative cue words (e.g., *mouse*) used to help species disambiguation are called species words. In this work, species words are defined as any word that indicates a model organism and also appears in the organism dictionaries we use. They may have various parts-of-speech, and may also contain multiple tokens (despite the name species *word*). For example, "human", "mice", "bovine" and "E. Coli" are all species words. We detect these words by automatic dictionary lookup: a word is annotated as a species word if it matches an entry in a list of organism names. Each entry in the list contains a species word and its corresponding taxon ID, and the list is merged from two dictionaries: the NCBI Taxonomy and the UniProt controlled vocabulary of species.[3] The NCBI portion is a flattened NCBI Taxonomy (i.e., without hierarchy) including only the identifiers of *genus* and *species* ranks. In total, the merged list contains 356,387 unique species words and 272,991 unique species IDs. The ambiguity in species words is low: 3.86% of species words map to multiple IDs, and on average each word maps to 1.043 IDs.

The proposed method was evaluated on the corpus developed in (Wang et al., 2010), containing $6,223$ genes and gene products, each of which was manually assigned with either a taxon ID or an "Other" tag, with *human* being the most frequent at 50.30%. With the extracted features and the species ID tagged by domain experts, each occurrence of named entities can be represented as a d-dimensional vector with a label. Species disambiguation can be modelled as a multi-classification task: Given n training instances $\{\boldsymbol{x}_i\}_{i=1}^n$, their $n \times d$ feature matrix $\mathbf{X} = [x_{ij}]$ and n-dimensional label vector $\boldsymbol{y} = [y_1, y_2, \ldots, y_n]^T$ are used to train a classifier $\mathfrak{C}(\cdot)$, where $\boldsymbol{x}_i = [x_{i1}, x_{i2}, \ldots, x_{id}]^T$, $y_i \in \{1, 2, \ldots, c\}$, and c denotes the number of existing species in total. Given m different query instances $\{\hat{\boldsymbol{x}}_i\}_{i=1}^m$, their $m \times d$ feature matrix $\hat{\mathbf{X}} = [\hat{x}_{ij}]$ are used as the input to the trained classifier, so that their labels can be predicted by $\{\mathfrak{C}(\hat{\boldsymbol{x}}_i)\}_{i=1}^m$.

We used relatively simple contextual features because this work was focused on developing a ML framework. In more detail, we used the following features: 1) 200 words surrounding the entity in question; 2) two nouns and two adjectives at the entity's left and right; 3) 5 species words at the entity's left and right. In addition, function words and words that consist of only digits and punctuations are filtered out. The final numerical dataset consists of 6,227 instances, each represented by 16,851 binary features and belonging to one of the 13 classes. The dataset is highly imbalanced: among the 13 classes, the numbers of instances in the four majority classes vary from 449 to 3,220, while no more than 20 instances are contained in the eight minority classes (see Table 1).

4 Proposed Method

4.1 Dictionary-based Prototypes

For each existing species, we create a b-dimensional binary vector, given as $\boldsymbol{p}_i = [p_{i1}, p_{i2}, \ldots, p_{ib}]^T$, using b different species words listed in the dictionary as features, which is called dictionary-based prototype. The binary value p_{ij} denotes whether the jth species word belongs to the ith species in the dictionary. This leads to a $c \times b$ feature matrix $\mathbf{P} = [p_{ij}]$ for c species.

Considering that the species words preceding and appearing in the same sentence as an entity can be informative indicators for the possible species of this entity, we create two more $m \times b$ binary feature matrices for the query instances with the same b species words as features: $\hat{\mathbf{X}}_1 = [\hat{x}_{ij}^{(1)}]$ and $\hat{\mathbf{X}}_2 = [\hat{x}_{ij}^{(2)}]$, where $\hat{x}_{ij}^{(1)}$ denotes whether the jth species word is the preceding word of the ith entity, and $\hat{x}_{ij}^{(2)}$ denotes whether the jth species word appears in the same sentence as the ith entity but is not preceding word. Thus, the similarity between each query entity and existing species can be simply evaluated by calculating the inner-product between the entity instance and the corresponding prototype. This leads to the following $m \times c$ similarity matrix $\hat{\mathbf{S}} = [\hat{s}_{ij}]$:

$$\hat{\mathbf{S}} = \theta \hat{\mathbf{X}}_1 \mathbf{P}^T + (1-\theta)\hat{\mathbf{X}}_2 \mathbf{P}^T, \qquad (1)$$

where $0 \leq \theta \leq 1$ is a user-defined parameter controlling the degree of indicating reliability of the preceding word and the same-sentence word. The $n \times c$ similarity matrix $\mathbf{S} = [s_{ij}]$ between the training instances and the species can be constructed in exactly the same way. Based on empirical experience, the preceding word indicates the entity's species more accurately than the same-sentence word. Thus, θ is preferred to be set as greater than 0.5. The obtained similarity matrix will be used in the nearest neighbour classifier (see Section 4.2.1).

Both the original training instances $\mathbf{X}$ and the newly created prototypes $\mathbf{P}$ are used to train the proposed hierarchical classification system. Subject to the nature of the classifier employed, it is convenient to construct one single feature matrix instead of using $\mathbf{X}$ and $\mathbf{P}$ individually. Aiming at keeping the same similarity values between each entity instance and the species prototype, we construct the following $(n+c) \times (d+b)$ feature matrix for both the training instances and prototypes:

$$\mathbf{F} = \begin{bmatrix} \mathbf{X} & \theta\mathbf{X}_1 + (1-\theta)\mathbf{X}_2 \\ \mathbf{0} & \mathbf{P} \end{bmatrix}, \qquad (2)$$

where $\mathbf{X}_1$ and $\mathbf{X}_2$ are constructed in the same way as $\hat{\mathbf{X}}_1$ and $\hat{\mathbf{X}}_2$ but for training instances. Their corresponding label vector is $\boldsymbol{l} = [\boldsymbol{y}^T, 1, 2, \ldots, c]^T$.

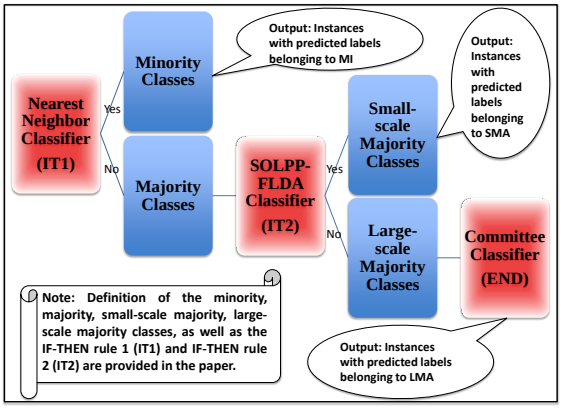

Figure 1: Structure of the proposed hierarchical classification system

4.2 Hierarchical Classification

Multi-stage or hierarchical classification (Giusti et al., 2002; Podolak, 2007; Kurzyński, 1988) is widely used in many complex multi-category classification tasks. Existing research shows such techniques can potentially achieve right trade-off between accuracy and resource allocation (Giusti et al., 2002; Podolak, 2007). Our proposed hierarchical system has a tree-like structure with three different types of classifier at nodes (see Figure 1). Different classes are organized in a hierarchical order to be classified based on the corresponding numbers of available training instances. Letting n_i denote the number of training instances available in the $i$the class excluding the created prototypes, we categorize the classes as follows:

- **Minority Classes (MI):** Classes with less training instances than the threshold: MI $= \{i : \frac{n_i}{n} < \sigma_1, i \in \{1, 2 \ldots, c\}\}$.

- **Majority Classes (MA):** Classes with more training instances than the threshold: MA $= \{i : \frac{n_i}{n} \geq \sigma_1, i \in \{1, 2 \ldots, c\}\}$.
- **Small-scale Majority Classes (SMA):** Majority Classes with less training instances than the threshold: SMA $= \{i : \frac{n_i}{n} < \sigma_2, i \in \text{MA}\}$.
- **Large-scale Majority Classes (LMA):** Majority Classes with more training instances than the threshold: LMA $= \{i : \frac{n_i}{n} \geq \sigma_2, i \in \text{MA}\}$.

Here, $0 < \sigma_1 < 1$ and $0 < \sigma_2 < 1$ are size thresholds set by users. We have MI $\cap$ MA $= \emptyset$, SMA $\cap$ LMA $= \emptyset$, and SMA $\cup$ LMA $=$ MA.

The tree-like hierarchical structure of our system is determined by MI, MA, SMA, and LMA. We propose two IF-THEN rules to control the system: Given a query instance $\hat{\boldsymbol{x}}_i$, the level 1 classifier $\mathfrak{C}_1$ is used to predict whether $\hat{\boldsymbol{x}}_i$ belongs to MA or a specific class in MI, which wer call IF-THEN rule 1 (IT1). If $\hat{\boldsymbol{x}}_i$ belongs to MA, the level 2 classifier $\mathfrak{C}_2$ is used to predict whether $\hat{\boldsymbol{x}}_i$ belongs to LMA or a specific class in SMA, called IF-THEN rule 2 (IT2). If $\hat{\boldsymbol{x}}_i$ belongs to LMA, the level 3 classifier $\mathfrak{C}_3$ finally predicts the specific class in LMA $\hat{\boldsymbol{x}}_i$ belongs to. We explain in the following sections how the classifiers $\mathfrak{C}_1$, $\mathfrak{C}_2$, and $\mathfrak{C}_3$ work in detail.

4.2.1 Nearest Neighbour Classifier

The goal of the nearest neighbour classifier, denoted by $\mathfrak{C}_1$, is to decide whether the nearest-neighbour prototype of the query instance belongs to MI. The only used training instances are our created dictionary-based prototypes $\{\boldsymbol{p}_i\}_{i=1}^{c}$ with the label vector $[1, 2, \ldots, c]^T$. The nearest-neighbour prototype of the query instance $\hat{\boldsymbol{x}}_i$ possesses the maximum similarity to $\hat{\boldsymbol{x}}_i$:

$$NN(\hat{\boldsymbol{x}}_i) = \arg \max_{j=1,2,\ldots,c} \hat{s}_{ij}, \tag{3}$$

where $\hat{s}_{ij}$ is obtained by Eq. (1). Consequently, the output of the classifier $\mathfrak{C}_1$ is given as

$$\mathfrak{C}_1(\hat{\boldsymbol{x}}_i) = \begin{cases} NN(\hat{\boldsymbol{x}}_i), & \text{If } NN(\hat{\boldsymbol{x}}_i) \in \text{MI}, \\ 0, & \text{Otherwise.} \end{cases} \tag{4}$$

The IF-THEN rule 1 can then be expressed as

$$\text{Action}^{(\text{IT1})} = \begin{cases} \text{Go to } \mathfrak{C}_2, & \text{If } \mathfrak{C}_1(\hat{\boldsymbol{x}}_i) = 0, \\ \text{Stop}, & \text{Otherwise.} \end{cases}$$

4.2.2 SOLPP-FLDA Classifier

The goal of the SOLPP-FLDA classifier, denoted by $\mathfrak{C}_2$, is to predict whether the query instance belongs to LMA or a specific class in SMA. In this classifier, the used training instances are the original training entities and the dictionary-based prototypes, both belonging to MA. The feature matrix $\mathbf{F}$ and the label vector $\boldsymbol{l}$ defined in Section 4.1 are used, but with instances from MI removed (we use $\tilde{n}$ to denote the number of remaining training instances, and the same symbol $\mathbf{F}$ for feature matrix). The used label vector $\tilde{\boldsymbol{l}}$ to train $\mathfrak{C}_2$ should be re-defined as $\tilde{l}_i = l_i$ if $l_i \in$ SMA, and 0 otherwise.

First, we propose to implement orthogonal locality preserving projection (OLPP) (Kokiopoulou and Saad, 2007) in a supervised manner, leading to SOLPP, to obtain a smaller set of more powerful features for classification. Also, we conduct SOLPP in a similarity-based feature space computed from $(d + 2b)$ original features by employing dot-product based similarity, given by $\mathbf{F}\mathbf{F}^T$. As explained later, to compute the new features from $\mathbf{F}\mathbf{F}^T$ instead of the original features $\mathbf{F}$ achieves reduced computational cost. An $\tilde{n} \times k$ projection matrix $\mathbf{V} = [v_{ij}]$ is optimized in this n-dimensional similarity-based feature space. The optimal projections are obtained by minimizing the weighted distances between the lower-dimensional embeddings so that "similar" instances are mapped together in the projected feature space. Mathematically, this leads to the following constrained optimization problem:

$$\min_{\substack{\mathbf{V} \in R^{\tilde{n} \times k}, \\ \mathbf{V}^T\mathbf{V} = \mathbf{I}_{k \times k}}} \text{tr}[\mathbf{V}^T\mathbf{F}^T\mathbf{F}(\mathbf{D} - \mathbf{W})\mathbf{F}\mathbf{F}^T\mathbf{V}], \tag{5}$$

where $\mathbf{W} = [w_{ij}]$ denotes the $n \times n$ weight matrix with w_{ij} defining the degree of "closeness" or "similarity" between the ith and jth instances, $\mathbf{D}$ is a diagonal matrix with $\{d_i = \sum_{j=1}^{\tilde{n}} w_{ij}\}_{i=1}^{\tilde{n}}$ as the diagonal elements.

Usually, the weight matrix $\mathbf{W}$ is defined by an adjacency graph constructed from the original

data, e.g. for OLPP. One common way to define the adjacency is by including the K-nearest neighbors (KNN) of a given node to its adjacency list, which is also called the KNN-graph (Kokiopoulou and Saad, 2007). There are two common ways to define the weight matrix: constant value, where $w_{ij} = 1$ if the ith and jth samples are adjacent, while $w_{ij} = 0$ otherwise, and Gaussian kernel. We will denote in the rest of the paper such a weight matrix computed only from the features as $\mathbf{W}_X$. Ideally, if the features can accurately describe all the discriminating characteristics, the samples that are close or similar enough to each other should have the same label vectors. However, when processing real dataset, what may happen is that, in the d-dimensional feature space, the data points that are close to each other may belong to different categories, while on the contrary, the data points that are in a distant to each other may belong to the same category. In the k-dimensional projected feature space obtained by OLPP, one may have the same problem. Because OLPP solves the constrained optimization problem in Eq. (5) using $\mathbf{W}_X$: if two instances are close or similar to each other in the original feature space, they will be the same close or similar to each other in the projected space. To solve this problem, we decide to modify the "closeness" or "similarity" between instances in the projected feature space by considering the label information. The following computation of a supervised weight matrix is used for our SOLPP:

$$\mathbf{W} = (1-\alpha)\mathbf{W}_X + \alpha\mathbf{L}\mathbf{L}^T, \tag{6}$$

where $0 \leq \alpha \leq 1$ is a user-defined parameter controlling the tradeoff between the label-based and feature-based neighborhood structures, and $\mathbf{L} = [l_{ij}]$ is an $\tilde{n} \times c$ binary label matrix with $l_{ij} = 1$ if the ith instance belongs to the jth class, and $l_{ij} = 0$ otherwise.

The optimal solution of Eq. (5) is the top $(k+1)$th eigenvectors of the $\tilde{n} \times \tilde{n}$ symmetric matrix $\mathbf{F}^T\mathbf{F}(\mathbf{D} - \mathbf{W})\mathbf{F}\mathbf{F}^T$, corresponding to the $k+1$ smallest eigenvalues, but with the top one eigenvector removed, denoted by $\mathbf{V}^*$. It is worth to mention that if the original feature matrix $\mathbf{F}$ is used as the input of SOLPP, one needs to compute the eigen-decomposition of the $(d+b) \times (d+b)$ symmetric matrix $\mathbf{F}^T(\mathbf{D} - \mathbf{W})\mathbf{F}$. The corresponding computation complexity increases in $O((d+b)^3)$, which is unacceptable in practical when $d + b \gg \tilde{n}$. The projected features for the training instances are computed by

$$\mathbf{Z} = \mathbf{F}\mathbf{F}^T\mathbf{V}^*. \tag{7}$$

Given a different set of m query instances with an $m \times (d+b)$ feature matrix,

$$\hat{\mathbf{F}} = [\hat{\mathbf{X}},\ \theta\hat{\mathbf{X}}_1 + (1-\theta)\hat{\mathbf{X}}_2], \tag{8}$$

their embeddings can be easily obtained by

$$\hat{\mathbf{Z}} = \hat{\mathbf{F}}\hat{\mathbf{F}}^T\mathbf{V}^*. \tag{9}$$

Then, the projected feature matrix $\mathbf{Z}$ and label vector $\tilde{\boldsymbol{l}}$ are used to train a multi-class classifier. By employing the one-against-all scheme, different binary classifiers $\{\mathfrak{C}_i^{(2)}\}_{i \in \text{SMA} \cup \{0\}}$ with label space $\{+1, -1\}$ are trained. For the ith class ($i \in \text{SMA} \cup \{0\}$), the training instances belonging to it are labeled as positive, otherwise negative. In each binary classifier $\mathfrak{C}_i^{(2)}$, a separating function

$$f_i^{(2)}(\boldsymbol{x}) = \boldsymbol{x}^T\boldsymbol{w}_i^{(2)} + b_i^{(2)} \tag{10}$$

is constructed, of which the optimal values of the weight vector $\boldsymbol{w}_i^{(2)}$ and bias $b_i^{(2)}$ are computed using Fisher's linear discriminant analysis (FLDA) (Fisher, 1936; Mu, 2008). Finally, the output of the classifier $\mathfrak{C}_2$ can be obtained by assigning the most confident class label to the query instance $\hat{\boldsymbol{x}}_i$, with the confidence value indicated by the value of separating function:

$$\mathfrak{C}_2(\hat{\boldsymbol{x}}_i) = \arg \max_{j \in \text{SMA} \cup \{0\}} f_j^{(2)}(\hat{\boldsymbol{x}}_i). \tag{11}$$

The IF-THEN rule 2 can then be expressed as

$$\text{Action}^{(\text{IT2})} = \begin{cases} \text{Go to } \mathfrak{C}_3, & \text{If } \mathfrak{C}_2(\hat{\boldsymbol{x}}_i) = 0, \\ \text{Stop}, & \text{Otherwise.} \end{cases}$$

4.2.3 Committee Classifier

The goal of the committee classifier, denoted by $\mathfrak{C}_3$, is to predict the specific class in LMA the query instance belongs to. The used training

instances are entities and dictionary-based prototypes only belonging to LMA. With the same one-against-all scheme, there are large number of positive and negative training instances to train a binary classifier for a class in LMA. To accelerate the training procedure without sacrificing the accuracy, the following scheme is designed.

Letting n_e denote the number of experts in committee, all the training instances are averagely divided into n_e+1 groups each containing similar numbers of training instances from the same class. The instances in the ith and the $(i+1)$th groups are used to train the ith expert classifier. This achieves overlapped training instances between expert classifiers. The output value of $\mathfrak{C}_i^{(3)}$ is not the class index as used in $\mathfrak{C}_2$, but the value of the separating function of the most confident class, denoted by $f_i^{(3)}$. Different from the commonly used majority voting rule, we only trust the most confident expert. Thus, the output of $\mathfrak{C}_3$ for a query instance $\hat{\boldsymbol{x}}_i$ can be obtained by

$$\mathfrak{C}_3(\hat{\boldsymbol{x}}_i) = \arg \max_{j=1,2,...,n_e} f_j^{(3)}(\hat{\boldsymbol{x}}_i). \qquad (12)$$

By using $\mathfrak{C}_3$, different expert classifiers can be trained in parallel. The total training time is equal to that of the slowest expert classifier. The more expert classifiers are used, the faster the system is, however, the less accurate the system may become due to the decrease of used training instances for each expert, especially the positive instances in the case of imbalanced classification. This is also the reason we do not apply the committee scheme to SMA classes.

5 Experiments

5.1 System Evaluation and Baseline

We evaluate the proposed method using 5-fold cross validation, with around 4,980 instances for training, and 1,245 instances for test in each trial. We compute the F_1 score for each species, and employ macro- and micro- average scheme to compute performance for all species. Three baselines for comparison include:

- **Baseline 1 (B1)** : A maximum entropy model trained with training data only.
- **Baseline 1 (B2)** : Combination of B1 and the species dictionary using rules employed in Wang et al. (2010).
- **Baseline 2 (B3)**: The "hybrid" system combining B1, the dictionary and a relation model [4] using rules (Wang et al., 2010).

Our hierarchical classification system were implemented in two ways:

- **HC**: Only the training data on its own is used to train the system.
- **HC/D**: Both the training data and the dictionary-based prototypes are used to train the system.

5.2 Results and Analysis

The proposed system was implemented with $\theta = 0.8$, $\alpha = 0.8$, $n_e = 4$, and $k = 1000$. The species 9606, 10090, 7227, and 4932 were categorized as LMA, the species 10116 as SMA, and the rest species as MI. To compute the supervised weight matrix, the percentage of the used KNN in the KNN-graph was 0.6. Parameters were not fine tuned, but set based on our empirical experience on previous classification research. As shown in Table 1: HC and B1 were trained with the same instances and features, and HC outperformed B1 in both macro and micro F1. Both HC and B1 obtained zero F_1 scores for most minority species, showing that it is nearly impossible to correctly label the query instances of minority classes, due to lack of training data. By learning from a related resource, HC/D, B2, and B3 yielded better macro performance. In particular, while HC/D and B2 learned from the same dictionary and training data, HC/D outperformed B2 by 19.1% in macro and 2.5% in micro F1. B3 aimed at improving the macro performance by employing computationally expensive syntactic parsers and also by training an extra relation classifier. With the same goal, HC/D integrated the cue word information into the ML classifier in a more general way, and yielded an 8.3% improvement over B3, as measured by macro-F1.

[4] This is an SVM model predicting relations between entities and nearby species words with positive output indicates species words bear the semantic label of entities.

Species Name	Cat.	No.	HC	HC/D	B1	B2	B3
Homo sapiens (9606)	LMA	3220	87.39	**87.48**	86.06	85.43	86.48

6 Conclusions and Future Work

Disambiguating bio-entities presents a challenge for traditional supervised learning methods, due to the high number of semantic classes and lack of training instances for some classes. We have proposed a hierarchical framework for imbalanced learning, and evaluated it on the species disambiguation task. Our method automatically builds training instances for the minority or missing classes from a cue word dictionary, under the assumption that cue words in the surrounding context of an entity strongly indicate its semantic category. Compared with previous work (Wang et al., 2010; Hatzivassiloglou et al., 2001), our method provides a more general way to integrate the cue word information into a ML framework without using deep linguistic information.

Although the species disambiguation task is specific to bio-text, the difficulties caused by imbalanced frequency of different senses are common in real application of sense disambiguation. The proposed technique can also be applied to other domains, providing the availability of a cue word dictionary that encodes semantic information regarding the target semantic classes. Building such a dictionary from scratch can be challenging, but may be easier compared to manual annotation. In addition, such dictionaries may already exist in specialised domains.

Abstract

The goal of this work is to produce a classifier that can distinguish subjective sentences from objective sentences for the Urdu language. The amount of labeled data required for training automatic classifiers can be highly imbalanced especially in the multilingual paradigm as generating annotations is an expensive task. In this work, we propose a co-training approach for subjectivity analysis in the Urdu language that augments the positive set (subjective set) and generates a negative set (objective set) devoid of all samples close to the positive ones. Using the data set thus generated for training, we conduct experiments based on SVM and VSM algorithms, and show that our modified VSM based approach works remarkably well as a sentence level subjectivity classifier.

1 Introduction

Subjectivity tagging involves distinguishing sentences that express opinions from sentences that present factual information (Banfield 1982; Wiebe, 1994). A wide variety of affective nuances can be used while delivering a message pertaining to an event. Although the factual content remains the same, lexical selections and grammatical choices can considerably influence the affective nature of the text. Recognizing sentences that exhibit affective behavior will require, at the least, recognizing the structure of the sentence and the emotion bearing words.

To date, much of the research in this area is focused on English. A variety of reliable resources that facilitate effective sentiment analysis and opinion mining, such as polarity lexicons (Senti-WordNet [1]) and contextual valence shifters (Kennedy and Inkpen, 2005) are available for English. The MPQA corpus of 10,000 sentences (Wiebe *et al.,* 2005) provides detailed annotations for sources of opinions, targets, speech events and fragments that indicate attitudes for the English newswire data. The IMDB corpus contains 10,000 sentences categorized as subjective and objective in the movie review domain. Clearly, English is well supported with resources. There are other widely spoken resource poor languages that are not as privileged. When we consider social media, limiting our analysis to a language like English, however universal, will lead to loss of information. With the advent of virtual keyboards and extended Unicode support, the internet is rapidly getting flooded by users who use their native language in textual communication. There is a pressing need to perform non-topical text analysis in the multilingual paradigm.

Subjectivity analysis is a precursor to numerous applications performing non-topical text analysis like sentiment analysis, emotion detection, and opinion extraction (Liu *et al.*, 2005; Ku *et al.,* 2006; Titov and McDonald, 2008). Creating the state-of-the-art subjectivity classifier using machine learning techniques require access to large amounts of annotated data. For less commonly taught languages like

[1] http://swn.isti.cnr.it/download_1.0/

Coling 2008: Poster Volume, pages 860–868,
Beijing, August 2010

Urdu, Hindi, Bengali, Spanish and Romanian, the resources required to automate subjectivity analysis are either very sparse or unavailable. Generating annotated corpus for subjectivity detection is laborious and time consuming.

However, several innovative techniques have been proposed by researchers in the past to generate annotated data and lexical resources for subjectivity analysis in resource poor languages. Mihalcea *et al.,* (2007) and Banea *et al.,* (2008) used machine translation technique to leverage English resources for analysis in Romanian and Spanish languages. Wan (2009) proposed a co-training technique that leveraged an available English corpus for Chinese sentiment classification. Wan (2008) focused on improving Chinese sentiment analysis by using both Chinese and English lexicons.

Unfortunately, not much work has been done in the area of subjectivity analysis for the Urdu language. This language lacks annotated resources required to generate even the basic NLP tools (POS tagger, NE tagger etc.) needed for text analysis. In order to facilitate subjectivity analysis in Urdu language, we annotated a small set of Urdu newswire articles for emotions (§2). The sentence level annotations provided in this dataset follow the annotation guidelines proposed by Wiebe *et al.,* (2003). Although tremendous effort was put into generating this corpus, the data set is not very comprehensive and contains only about 500 sentences marked subjective. This is definitely insufficient to train a suitable subjectivity classifier.

1.1 Issue with unbalanced data set

A subjectivity classifier is a binary classifier. A traditional binary classifier is trained using universal representative sets for positive and negative categories. But in subjectivity analysis, especially for languages like Urdu that have no annotated data, generating universal representative sets is extremely difficult and almost an impossible task. Assimilating the negative set is especially a delicate task as the set should be carefully pruned of all the positive samples. Also, detecting subjectivity in a sentence is highly personalized. Annotators are sometimes prejudiced while marking samples. This bias, however small, produces errors with some true positive samples being unintentionally missed and categorized as negative. Traditionally, research in machine learning has assumed the class distribution in the training data to be reasonably balanced. However, when the training data is highly imbalanced, i.e., the number of positive examples is very small, the performance of text classification algorithms such as linear support vector machine (SVM) (Brank and Grobelnik, 2003), naïve Bayes and decision trees (Kubat and Matwin, 1997) are adversely affected.

In order to achieve a balanced training set, Japkowicz (2000) duplicates positive examples (oversampling) and discards negative ones (downsizing). Kubat and Matwin (1997) discard all samples that are close to the positive set to avoid misclassification. Chan and Stalfo (1998) have trained several classifiers on different balanced data subsets, each constructed to include all positive training samples and a set of negative samples of comparable size. The predictions are combined through stacking.

For the task of subjectivity analysis, especially in the multilingual paradigm where the data set is highly unbalanced, using one of the techniques proposed above will yield benefit. To the best of our knowledge, co-training technique has not been applied before for the subjectivity detection task, in particular, for the Urdu language.

1.2 Contribution

Our first contribution is inspired by the work of Luo *et al.,* (2008). We propose a similar co-training technique that helps to create a likely negative set (objective sentences) and a filtered positive set (subjective sentences) simultaneously from the unlabeled set. We use two learning models trained using the linear SVM algorithm iteratively. In every iteration of co-training, the likely positive samples are filtered. The iterative process terminates when no more positive samples are found. The final negative set is the likely negative set, considered as the universal representative set for the non-subjective category. The likely positive sample set is appended to the already existing positive set (annotated set). The SVM models are trained using part of speech, unigrams and emotion bearing words, as features.

The second contribution of this work includes training a state-of-the-art Vector Space Model

(VSM) for Urdu newswire data using the data sets generated by the co-training method. Experiments that use the SVM classifier are also performed. The results show that the performance of the proposed VSM based approach helps to achieve state-of-the-art sentence level subjectivity classifier. The F-Measure of the VSM subjectivity classifier is 82.72% with 78.7% F-measure for the subjective class and 86.7% F-Measure for the objective class.

2 Data Set

The data set used to generate a subjectivity classifier for Urdu newswire articles is obtained from BBC Urdu[2]. The annotating efforts are directed towards achieving the final goal- *emotion detection* in Urdu newswire data and the annotation guidelines are based on the MPQA standards set for English.

The repository of articles provided by BBC is huge and needs to be filtered intelligently. Two levels of filters are applied. – *date* and *keyword search*. The *date* filter is applied to retrieve articles of three years, starting year 2003. The *keyword* based filter consists of a set of seed words that are commonly used to express emotions in Urdu -*ghussa (~anger), pyar (~love)* etc. Clearly, this list will not cover all possible linguistic expressions that express emotion and opinion. But it is definitely a representative of a wide range of phenomena that naturally occurs in text expressing emotions.

The data retrieved is parsed using an in-house HTML parser to produce clean data. To date, we have 500 articles, consisting of 700 sentences annotated for emotions. There are nearly 6000 sentences that do not contain any emotions making it highly unbalanced. This data set is divided into testing and training sets with 30% and 70% of the data respectively. Co-training is performed only on the 70% training set that consists of 470 subjective sentences and about 4000 objective sentences. The purpose of co-training here is to remove samples that are close to subjective from the objective set and create a likely negative set. The samples removed are the likely positive set. This set of 4000 objective sentences can be considered as the un-annotated set.

[2] http://www.bbc.co.uk/urdu/

3 Co-Training

Identifying sentences that express emotions in Urdu newswire data is not trivial. Subjective sentences do not always contain individual expressions that indicate subjectivity. Analysis is highly dependent on the contextual information. Wiebe *et al.,* (2001) reported that nearly 44% of sentences in the MPQA corpus (English newswire data) are subjective. In newswire data, though most facts are reported objectively, there are cases when the tone of the sentence is very intense indicating the existence of emotion. Consider Example 1.

Example 1:
Political news headline

بھارت کا پاکستان کے ساتھ **جامع مذاکرات** سے انکار ،**بھارتی لیکچر سننے کے خواہاں نہیں**

[bhart ka pakstan kE sath jame mZakrat sE ankar, bharty lykcr snnE kE KwahaN nhyN]

*[India refuses to have a **dialog** with Pakistan, Indians **are not willing to listen to the lecture**]*

Common Urdu

انڈیا نے پاکستان سے **بات چیت** کارنے سے انکار کر دیا ہے

*[India refuses to **talk** to Pakistan]*

Clearly, the news headline is extremely intense and strongly expresses the opinion of India on Pakistan. However, the statement in common Urdu is not as affective.

Example 2:

انصاری نے کہا، میری رائے میں عامر سہیل ایک بد دماغ اور ضدی شخص ہیں

[anSary nE kha "myry ray^E myN eamr shyl ayk bd dmaG awr Zdy XKS hyN"]

[Ansari said, "according to me Aamir Sohail is one crazy and stubborn man"]

Statements in quotes that express emotions are subjective as shown in example 2.

Consider example 3. Here, identifying the words that indicate subjectivity is not straight forward. The phrase, *"found it very difficult to hide his smile"* is indicative of the emotion experienced by *"Habib Miya"*.

Example 3:

رقم کی اس وصولی پر یہ حبیب میاں کے لئے **بہت مشکل** تھا کہ وہ اپنی مسکراہٹ چھپا سکیں

[rqm ky as wSwly pr yh Hbyb myaN kE ly^E bht mXkl t\|ha kh wh apny mskrahT c\|hpa skyN]

[At this event of money collection, Habib Miyan found it very difficult to hide his smile.]

There are also several false positives that make subjective detection hard task. Example 4 is an objective sentence despite the usage of word *"pyar" ~ love*, an emotion bearing word.

Example 4:

انضمام کا نیا پیار کا نام انزی پڑا ہے

[n|Zmam ka nya pyar ka nam anzy pRa hE]

[The new nickname for Inzaman is Inzi]

Expressive elements in Urdu sentences were marked with an inter-annotator agreement of 0.8 kappa score. Though high, there still exists a bias that can influence classification especially when the number of sentences in the positive set is relatively less. In order to obtain a reliable positive and negative set for training a learning algorithm, we adopt a semi-supervised learning technique of co-training. *Co-training* (Blum and Mitchell, 1998) is similar to self-training in that it increases the amount of labeled data by automatically annotating unlabeled data. The intuition here is that if the conditional independence assumption holds, then on an average each selected document will be as informative as a random document, and the learning will progress. Co-training differs from self-training as it uses multiple learners to do the annotation. Each learner offers its own perspective that when combined gives more information. This technique is especially effective when the feature space of a particular type of problem can be divided into distinct groups and each group contains sufficient information to perform the annotation. In other words, co-training algorithm involves training two different learning algorithms on two different feature spaces. The learning of one becomes conditionally independent of the other and the prediction made by each classifier is used on the unlabeled data set to augment the training data of the other.

A traditional co-training classifier is trained and later applied on the same unlabeled data set. Theoretically such classifiers are not likely to assign confident labels. In this work, the proposed co-training method differs from the traditional co-training method in that the two classifiers are based not on two different feature spaces but on two different training data sets with the same feature space.

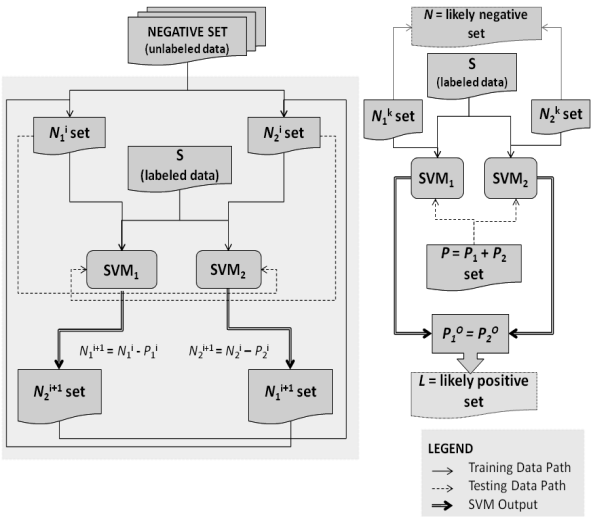

Figure 1: Co-Training model

Figure 1 explains the overall working of the model. The negative set (which can also be the unlabeled set) is split into two equal parts N_1 and N_2. S represents the positive annotated set. Two linear SVM classifiers are trained iteratively to purify the negative data set. SVM_1 is trained using $S+N_1^i$ and SVM_2 is trained using $S+N_2^i$ data sets. In every iteration *i*, N_1^i data set is evaluated using SVM_2 model and N_2^i data set is evaluated using SVM_1 model. The samples that are classified as positive in a given iteration *i* are binned into sets P_1^i and P_2^i respectively. These samples are removed from N_1^i and N_2^i data sets to create new N_1^{i+1} and N_2^{i+1} sets that are used for training in the next iteration *i+1*. The iterations continue until no positive samples are marked by both SVM_1 and SVM_2 models. The final set of likely negatives is $\mathbf{N} = N_1^k + N_2^k$ sets, where N_1^k and N_2^k are sets created in the last *k* iteration of the algorithm. In order to obtain the likely positive set, the final $P_1 = \{P_1^1 + P_1^2 + \ldots. + P_1^k\}$ and $P_2 = \{P_2^1 + P_2^2 + \ldots. + P_2^k\}$ sets are combined and tested using the SVMs modeled in the last *k* iteration of the co-training algorithm. Similar to the traditional co-training method the samples that are marked positive by both classifiers ($P_1^o = P_2^o$) are considered to be the likely positive set **L**.

Several features are used to train the SVM learning models used for co-training. The best performance is obtained when word unigrams, parts of speech and likely emotion words are used as features.

This technique of co-training provides us with a relatively huge set of likely positive samples

(close to 400 sentences). Sentences in this set were examined by the annotators and nearly 60% of the sentences were subjective or near subjective in nature (Example 5 and 6).

Labels	R %	P %	IF %	AF %
Unigram				**52.63**
1	**18.64**	74.57	**29.83**	
-1	95.4	62.35	75.44

1	**14.40**	85	**24.63**	
-1	98.19	61.82	75.87	

Table 1: Performance of the model using un-balanced data set[3]

Labels	R %	P %	IF %	AF %
Annotated positive + likely positive + likely negative				**62.95**
1	**39**	70	**50.09**	
-1	87.28	67.34	79.9	
Annotated positive + likely negative				55.42
1	30	61.2	**40.26**	
-1	86.1	64.23	73.57	

Table 2 – Performance of the model after co-training method

Table 1 shows the performance of the SVM model using the unbalanced data set for training. Table 2 shows the performance of the same model using data generated after co-training.

Example 5:

پوتن نے کہا کہ لوگ دوسروں کی آنکھ میں تنکا دیکھ لیتے ہیں لیکن اپنی آنکھ میں پڑا شہتیر انہیں نظر نہیں آتا ۔

[pwtn nE kha kh lwg dwsrwN ky Ank|h myN tnka dyk|h lytE hyN lykn apny Ank|h myN pRa Xhtyr anhyN n|zr nhyN Ata .]

[Potan said people who see dust in others eyes never realize that it is their eyes that are filled with dirt.]

The above example is a metaphor indicating extreme anger.

Example 6:

عطاء الرحمن شیخ کا کہنا ہے کہ بارہ اگست کو انہیں ان کے بیٹوں کے سامنے مکمل طور پر برہنہ کر کے پریڈ کرائی گئی

[e|ta& alrHmn XyK ka khna hE kh barh agst kw anhyN an kE byTwN kE samnE mkml |twr pr brhnh kr kE pryD kray^y gy^y]

[etlaalrahman said that on 12th Aug they made him parade naked in front of his children.]

Example 6 indicates extreme sad emotion. Such examples were found in the likely positive set.

4 Features

Features that are commonly used to train a subjectivity classifier for English are word unigrams, emotion keywords, part of speech information and noun patterns (Pang *et al.,* 2002). Due to difference in syntactic structure, vocabulary and style, features that work for English may not work for Urdu. Also, Urdu is handicapped by the lack of resources required to perform basic NLP analysis. However, it is worth exploring the English feature set as subjectivity is more a semantic phenomenon. Efforts to generate likely emotion word lexicons and subjectivity patterns for the Urdu language are underway. The sections that follow summarize the experimented features.

4.1 Word Unigrams

Unigram word features are very informative. Three different approaches are tried for selecting the unigrams. The first method involves selecting only those words that occur more than twice in the dataset. This eliminates proper nouns (low frequency named entities do not generally contribute towards subjectivity detection) and spelling errors (Pang *et al.,* 2002). In the second method, only words that are adjectives and verbs along with the surrounding case markers are accounted for as features. This has the advantage of drastically reducing the feature set. The third method involves including the nouns as well to the feature set. A simple list of stop words (common Urdu words – pronouns such as *'us', 'is', 'aap', 'un'*, salutations like *'shabba khair', 'aadab'* and honorifics along with punctuations and special symbols) are eliminated. The features are represented as Boolean features for the SVM model. The value is 1 if the feature word appears in the sentence to be classified and 0 otherwise. The best performance is obtained for the first method that considers all words with frequency greater than 2. This conforms to what is shown by Pang *et al.,* (2002) for classification of English movie reviews.

4.2 Part of Speech (POS) Information

The work done by Mukund and Srihari (2009) provides suitable POS and NE tagger for Urdu.

[3] Convention used across tables - Label 1: subjective sentences Label -1: objective sentences R: Recall P: Precision IF: Individual F-Measure AF: Average F-Measure.

This POS tagger is used to generate parts of speech tags on the acquired data set (§3). The POS tags associated with adjectives, verbs, common nouns and auxiliary words are considered and used as Boolean features for the SVM model. The proper noun words are normalized to one common word *"nnp"* and are assigned the common noun tag. For the English language, when building a subjectivity classifier for review classification, the use of POS information did not benefit the system (Kennedy and Inkpen, 2006). However, for Urdu, the performance of the co-training model with POS information showed 1.2% improvement (table 3).

4.3 Likely Emotion Lexicon

In order to facilitate simple keyword based detection of subjectivity, access to a lexicon consisting of likely emotion words is needed. Unfortunately, no such lexicon is available off the shelf for Urdu. In this work, an Urdu specific emotion list is generated that contains translations from the English emotion list released by SemEval (2007) '*WordNet affect Emotion List*'. Words for each emotion category - sadness (sad), fear, joy (happy), surprise, anger and disgust are obtained for Urdu by using an Urdu-English dictionary. The list is pruned manually and corrected to remove errors. Simple keyword lookup on the Urdu annotated corpus has an emotion detection rate of 29.27%. This shows that although the contribution of the emotion lexicon for subjectivity classification is not significant, it contains information which when used along with other features aid subjectivity detection.

4.4 Patterns

Extracting syntactic patterns contribute towards the affective orientation of a sentence (Riloff *et al.,* 2003). The Apriori algorithm (Agarwal and Srikant, 1994) for learning association rules is used here to mine the syntactic word patterns commonly used in the positive and negative data set. The length of the candidate item set k = 4. Starting from a small set of seed words (likely emotion words) and the associated POS tags, POS sequential patterns like "adverb verb verbtransitive sentencemarker", "noun noun casemarker verbtransitive", etc., that are most commonly found in subjectivity set are extracted. 23 patterns that strongly indicate subjectivity were found by this method and included as features to train the SVM learning algorithm.

4.5 Confidence Words

The confidence word list positively aids the VSM classifier (§5). The words in the likely emotion list are not the only ones that contribute towards the emotion orientation of a sentence and also, not all of these words contribute effectively. There are several stop words (eliminated while accounting for unigrams) (esp. case markers) that contribute significantly for categorization. In order to identify all the keywords that actually contribute to subjectivity categorization, a technique proposed by Soucy and Mineau (2004) is used.

The confidence weight of a given word w, based on the number of documents it is associated with under each category, is measured using the Wilson Proportion Estimate (Wilson, 1927). In order to compute the confidence of w for a specific category, the number of positive and negative documents associated with w has to be determined. A document is positive if it belongs to that category and negative otherwise. Thus, two kinds of word confidence metrics are computed, $C_{POS:w}$ and $C_{NEG:w}$ as given below.

$$C_{POS:w} = \frac{\left(\hat{p}_{POS:w} + \frac{z^2_{\alpha/2}}{2n} \pm z_{\alpha/2} \sqrt{[\hat{p}_{POS:w}(1-\hat{p}_{POS:w}) + z^2_{\alpha/2}/4n]/n} \right)}{(1 + z^2_{\alpha/2}/n)} \quad \text{..... (Eq. 1)}$$

$$C_{NEG:w} = \frac{\left(\hat{p}_{NEG:w} + \frac{z^2_{\alpha/2}}{2n} \pm z_{\alpha/2} \sqrt{[\hat{p}_{NEG:w}(1-\hat{p}_{NEG:w}) + z^2_{\alpha/2}/4n]/n} \right)}{(1 + z^2_{\alpha/2}/n)} \quad \text{..... (Eq. 2)}$$

where n is the total number of positive and negative documents, $\hat{p}_{POS:w}$ is the ratio of the number of positive documents which contain w to the total number of documents, and $\hat{p}_{NEG:w}$ is the ratio of the number of negative documents which contain w to the total number of documents. The normal distribution is used when $n > 30$.

Note that equations 1 and 2 give a range of values for $C_{POS:w}$ and $C_{NEG:w}$. If the lower bound of $C_{POS:w}$ is greater than the upper bound of $C_{NEG:w}$, we say that w is likely to be a word in that category. Now, we compute the strength of a word S_w in a particular category as

$$S_w = \begin{cases} \log(2 \cdot mPRF) & ; \text{if } lb(C_{POS:w}) > ub(C_{NEG:w}) \\ 0 & ; \text{otherwise} \end{cases}$$

..... **(Eq. 3)**

where *mPRF* is given by

$$mPRF = \frac{lb(C_{POS:w})}{lb(C_{POS:w}) + ub(C_{NEG:w})}$$

..... **(Eq. 4)**

and lb(…) and ub(…) are the lower and upper bounds of their arguments, respectively.

Equations 1 through 4 generated a very good set of keywords that are used as category word features in the SVM learning model. For VSM, the strength value is used as a boost factor along with the *tf-idf* weight when calculating the similarity score (table 3).

5 Final Subjectivity Classifier

Wiebe *et al.,* (2005) and Pang *et al.,* (2002) have shown that an SVM based approach works well for subjectivity classification. Riloff *et al.,* (2003) have conducted experiments that use Bag-Of-Words (BoW) as features to generate a Naïve Bayes subjectivity classifier for the MPQA corpus in English. This method has an accuracy of 73.3%. Su and Markert (2008) use BoW features termed as lexical features on the IMDB corpus to generate an accuracy of 60.5%. Das and Bandyopadhyay (2009) use a CRF based approach to generate a subjectivity classifier for Bengali data with a precision of 72.16% for news and 74.6% for blogs domain. The same approach has a precision of 76.08% and 79.9% on the two domains respectively. Impressive results for emotion detection are obtained by Danisman and Alpkocak, (2007) who use a VSM based approach. They show that their approach works much better than a traditional SVM based approach commonly used for emotion detection.

In this work, we conduct subjectivity classification experiments using two different learning algorithms – linear SVM and VSM. The best performance is obtained using the VSM model as shown in table 4. All experiments are conducted on the data set obtained after applying the co-training technique.

5.1 VSM algorithm

The final subjectivity classifier is based on the VSM approach. Inspired by the work done in "*Feeler*" (Danisman and Alpkocak, 2007), a similar technique is used to train the final subjectivity classifier for Urdu. The algorithm is explained in table 3. The similarity metric is modified to include the confidence score for each word (pt.5). In VSM, documents and queries are represented as vectors, and the cosine angle between them indicates the similarity.

1.	$d_i = <w_{1i}, w_{2i}, ... w_{ni}>$ where w_{ki} is the weight of the k^{th} term in document i , d_i is the document vector. w_{ki} is computed using *tf-idf* weighting scheme.
2.	$M_j=\{d_1,d_2,\ldots,d_c\}$ where M_j is each class (subjective and objective)
3.	Model vector for an arbitrary class E_j is created by taking the mean of d_j vectors $$E_j = \frac{1}{M_j}\sum_{d_i \in M_j}^{|M_j|} d_i$$ where $\|M_j\|$ represents number of documents in M_j.
4.	The whole system is represented with a set of model vectors, $D=\{E_1,E_2,...,E_s\}$ where s represents the number of distinct classes to be recognized.
5.	The normalized similarity between a given query text Q, and a class, E_j, is defined as follows: $$sim(Q,E_j) = \sum_{k=1}^{n}(w_{kq} + conf) * E_{kj}$$ *conf* is the confidence factor applied for lexical terms found in the word list.
6.	classification result is, $VSM(Q) = \arg\max(sim(Q,E_j))$

Table 3: VSM Algorithm for subjectivity Classification

Labels	R %	P %	IF %	AF %
Before Co-Training (all data)				**62.95**
1	65.85	70.85	**67.4**

After Co-Training (pruned data)				**86.73**
1	**72.88**	85.57	**78.72**	
-1	91.29	82.60	86.73	

Table 4: VSM approach, using all training data and using pruned training data (L+N+true)

The confidence metric (strength) for each term is calculated using the Wilson proportion estimate (§4.4) and added to the term score as the boost factor. Q is the test set. Model vectors are obtained using the data set that consists of true set (annotated positive samples), likely positive set L and likely negative set N. Sets L and N are obtained from the co-training method. The results are shown in table 4.

The power of SVM cannot be ignored. Pang *et al.,* (2002) use SVM to generate a subjectivity (polarity) classifier for English. Our second set of experiments is conducted to measure the performance of a linear SVM classifier for subjectivity analysis on the Urdu newswire data. The data set used for training is the pruned data set

obtained after applying the co-training technique. The features used and the performance of the model with each feature is documented in table 6.

Labels	R %	P %	IF %	AF %
Unigrams + POS				64.2

1	48.31	70.81	**57.43**	
-1	85.88	70.09	77.19	

Table 6: SVM classifier on Urdu newswire data

In order to provide a better understanding of the power of the VSM technique, we applied this model on the IMDB data set. The training data consists of 4000 positive (subjective) and 4000 negative (objective) samples. Since the data set is already balanced, we skip the co-training method. Our aim here is to test the working of VSM classifier. The test set consists of 1000 positive and 1000 negative samples. The classification result on this data set is shown in table 5. The results are comparable to the state-of-the-art performance of English subjectivity classifier that uses SVM (Wiebe *et al.,* 2005).

Labels	R %	P %	IF %	AF %
Balanced training				**78.01**
1	64	90.57	**75**	
-1	93.18	71.68	81.03	

Table 5: VSM approach on IMDB data set

6 Analysis of results

In this work, experiments were conducted using two different classification approaches; 1. VSM based 2. SVM based. Results in table 4 indicate that the VSM technique when combined with the modified boost factor (confidence measure) can be a very powerful technique for sentence level classification tasks. When model vectors were constructed using the entire training set (highly unbalanced), the performance was at 62% F-Measure with the subjectivity detection rate of 70.85%. Post co-training, using the modified model vectors obtained from the pruned data set generated better scores. The increase in the recall of negative class and the increase in the overall F-Measure can be attributed to (i) increase in the positive samples (~likely positive set), and (ii) cleaner negative set (no near positive samples).

The results in table 6 for the SVM classifier also indicate the benefits of co-training. The subjectivity classification performance show positive improvement. Although the performance of the SVM model is not as good as the VSM model, addition of each feature shows an improvement in the subjectivity recognition rate. This performance indicates that the feature sets explored definitely contain positive information necessary for accurate detection.

The poor performance of SVM (over VSM) can be attributed to 1. lack of balanced data for training a traditional SVM model and, 2. small number of positive samples. In VSM the problem of unbalanced data set in a way is overcome by using the confidence score at the time of calculating similarity. If these factors are compensated, the performance of the SVM model will significantly improve.

7 Conclusion

This research provides interesting insights in modeling a subjectivity classifier for Urdu newswire data. We show that despite Urdu being a resource poor language, techniques like co-training and statistical techniques based on *tf-idf* and word unigrams coupled with confidence measures help model the state-of-the-art subjectivity classifier. We demonstrate the power of the co-training technique in generating likely negative and positive sets. The number of near subjective samples in the likely positive set suggests that this method can be used as an adaptive learning technique to enable the annotators produce more samples. For a task like emotion detection, that requires fine grained analysis, sentences need to be analyzed at the semantic level and this goes beyond simple keyword based approach. Our efforts are now concentrated in this direction.

Support or Oppose? Classifying Positions in Online Debates from Reply Activities and Opinion Expressions

Akiko Murakami[1,2] **Rudy Raymond**[1]

{akikom,raymond}@jp.ibm.com

Abstract

We propose a method for the task of identifying the *general* positions of users in online debates, i.e., support or oppose the main topic of an online debate, by exploiting *local* information in their remarks within the debate. An online debate is a forum where each user post an opinion on a particular topic while other users state their positions by posting their remarks within the debate. The supporting or opposing remarks are made by directly replying to the opinion, or indirectly to other remarks (to express local agreement or disagreement), which makes the task of identifying users' general positions difficult. A prior study has shown that a link-based method, which completely ignores the content of the remarks, can achieve higher accuracy for the identification task than methods based solely on the contents of the remarks. In this paper, we show that utilizing the textual content of the remarks into the link-based method can yield higher accuracy in the identification task.

1 Introduction

Social computing tools, such as a SNS (Social Network Service) or an online discussion board have become very powerful communication tools for discussing topics with people around the world. Many companies use these kinds of social computing tools to understand their customers' requirements and their marketing activities. Social computing tools are very useful not only for aggregating customers' opinions outside the companies, but also for aggregating their employees' ideas. For example, IBM has held Jam[1] sessions, which are short-term online discussions to aggregate ideas from employees and customers. The results of Jam sessions help management decisions, for instance the technology areas to invest.

Not just enterprises, but some nations are trying to aggregate their citizens' ideas in the Internet and provide systems for discussions at the people-to-people levels as part of the movement for open government. The United States government has the *Idea Factory*[2] website for collecting ideas to enhance activities of Department of Homeland Security (DHS) and the *Open For Questions*[3] to collect requests for the US government.

The motivation for creating these kinds of online discussions is not limited to collecting ideas but also to help understand the trends of opinions about the ideas or topics. This means that getting a quick overview of opinions about ideas is a key point for the success of online discussions.

In this paper we propose a method to show quick overview of participants' positions, "Support" or "Oppose" for the main idea or topic in online debates. It is difficult to identify each person's position for a topic directly, since most of opinionative expressions are made not for main topic but for adjacent remarks. This causes a difficulty in building answer sets for classifier. The following example shows opinion expressions for a main topic focused on an adjacent remark in a

Coling 2008: Poster Volume, pages 869–875,
Beijing, August 2010

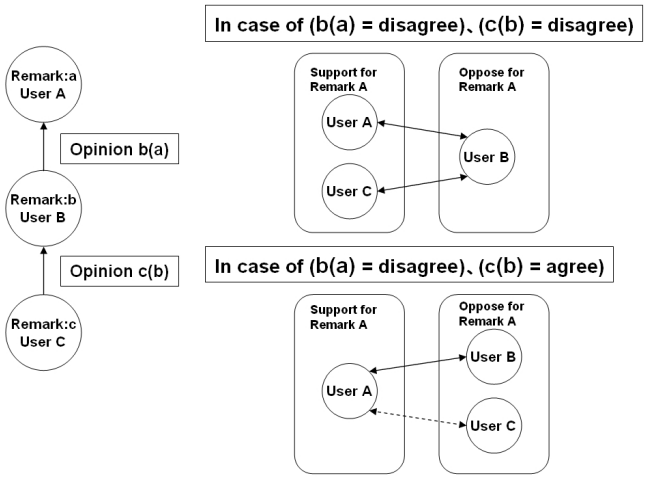

Figure 1: Identifying users' positions from their opinions about previous remarks

debate. In this example, The main topic is "Travel and F2F (face-to-face) meeting is fundamental to business".

Remark A Travel isn't necessary because besides the high cost of travels around the world, today we have a lot of communication tools, for instance web conference, video chat that can easily contribute to join leaders around the world in a cheaper way.

Remark B I disagree. Without travel and F2F meetings global integration does not work as well or as quickly. It doesn't mean that everybody has to travel all the time, but at least some meetings are key to success.

The author of Remark A mentions that travel is not necessary to business. This opinion opposed to the main topic, so that the position for the main topic is "Oppose". In contrast, the opinion expression in Remark B is not an opinion about the main topic, but relates to the previous opinion in Remark A. This opinion expression indicates that the author of Remark B disagrees with the opinion of Remark A, and indirectly implies agreement with the main topic. Thus, although it is hard to infer the global position of Remark B from only the surface expressions, it is straightforward to infer that an opinion in Remark B about Remark A is negative (i.e., Remark B expresses disagreement with Remark A).

In this paper, positions with regards to the main topic (global positions) are classified into two classes: support and oppose, while opinions about the previous remarks (local positions) are classified into three: *agree*, *disagree*, and *neutral*. For example, let us consider the case in Fig. 1, where Remark "a" is the main topic, and Remark "b" is the reply to Remark "a" and Remark "c" is the reply to Remark "b". Here, let $b(a)$ be the local position, that is, opinion (agree/disagree/neutral) in Remark "b" on the topic in Remark "a". For example, if $b(a)$ and $c(b)$ are *disagree*, one can determine that the authors of the corresponding remarks are in the opposition. That is, the author of Remark "c" agrees with Author A (the author of Remark "a"), that is, the main topic, while Author B is against the others. On the contrary, if $b(a)$ is *disagree* and $c(b)$ is *agree*, then Author C agrees with Author B and therefore it implies that Author C is against Author A. In this case, only Author A supports the main topic while Author B and Author C oppose to the main topic.

To infer supporting or opposing positions with regards to the main topic, two steps are used. First, the degree of disagreement between any two users is computed from the link structure and the text of

each pair of their adjacent replies. This is used as the link weight between nodes (which correspond to users in a debate) in the network. Second, the bipartition of the users in the weighted network is computed by finding a bipartition that induces the *maximum cut* of the network, a partition of nodes into two disjoint sets that maximizes the sum of the weights of the links connecting nodes in different sets. Since the weight of the links is higher (more positive) when the degree of disagreement is higher, the bipartition is expected to express two groups of opposing positions.

In order to evaluate the performance of our method, we conducted some experiments to identify the supporting and opposing positions of participants in online debates. The experimental results indicate that our method leads to higher precision than the baseline method, which is described in (Agrawal et al., 2003).

The rest of this paper is organized as follows. First we describe related work in Section 2, and in Section 3 we propose our method for identifying participants' positions from their reply activities and text contents. In Section 4 we explain the data sets used for the evaluations and show the experimental results of an opinion classifier for adjacent remarks and a support/oppose classifier for the participants in online debates. We conclude this paper and describe future work in Section 5.

2 Related Work

There are some research papers published on analysis of online discussions. Some researches reported on how to analyze and navigate IBM Jam sessions. Millen et al. pointed out the importance of supporting the participants in discussions and demonstrated the effectiveness of their methods in one of these jams (Millen and Fontaine, 2003). Dave et al. described ways for jam participants to navigate using visualization techniques (Dave et al., 2004). One of the authors previously also proposed a method to mine discussion records using XML annotations (Murakami et al., 2001) and a method to find important remarks in a discussion thread based on the reply-to structure and participants' opinions (Murakami et al., 2007).

Classifying agree/disagree opinions in conversational debates using Bayesian networks was presented in (Galley et al., 2004). Agrawal et al. described an observation that reply activities show disagreement with previous authors, and showed a method to classify the supporting/opposing position of users based on this observation in (Agrawal et al., 2003). Thomas et al. (Thomas et al., 2006) introduced some constraints that a single speaker retains the same position for the classification of participants' positions from floor-debate transcripts.

3 Proposed Method

3.1 Calculating the *Reaction Coefficient* between participants

We call the degree of divergence in the opinions between participants a *reaction coefficient*. This reaction coefficient is defined as a function of the participants i, j, represented as $r(i, j)$. To calculate reaction coefficients, we extracted pairs of a remark and its reply remark, and assigned "local position flags" to the pairs. There are three local position flags, "agree", "disagree", and "neutral". The reaction coefficient $r(i, j)$ between participants i and j is defined as:

$$r(i,j) = \alpha N_{\mathrm{disagree}}(i,j) + \beta N_{\mathrm{neutral}}(i,j) + \gamma N_{\mathrm{agree}}(i,j), \quad (1)$$

where $N_{\mathrm{opinion}}(i, j)$ is the number of remark pairs with $\mathrm{opinion}$ as the corresponding local position flag between participants i and j.

Typically we assign a positive value to α, a slightly positive value to β, and a negative value to γ. This means that $r(i, j)$ is positive when there are only neutral remarks between user i and j. This is based on the hypothesis in (Agrawal et al., 2003) that replies usually indicate disagreement with previous remarks. There is no directionality in reaction coefficients so that $r(i, j) = r(j, i)$.

3.2 Classification of Participants' Positions based on the Max Cut Problem

Let the graph corresponding to the activity network of the participants in an online debate be $G(V, E)$, where V is the set of nodes that corresponds to participants and E is the set of edges each of which links participants that exchanged remarks. For any $i, j \in V$, let $r(i, j)$ be the weight of the link between i and j. A partition of the

Table 1: Ideas and Number of Comments and Participants for the Ideas

Idea ID	Title	# of Comments	# of Participant	# of Remarks per Participant
1	Making "IT" Education as a Compulsory Subject in Schools	75	45	1.7
2	Making Personal-Computer Makers to Supplying Service Parts	130	21	6.2
3	Adoption of "Basic Income"	118	57	2.1
4	Votes in elections using Closed Networks	108	40	2.7
5	Computerized Books in Libraries	50	12	4.2

participants into supporting and opposing parties, S_{sup} and S_{opp} respectively, is computed by solving the *max cut* problem on $G(V, E)$ defined as follows.

[Max cut problem] Given $G(V, E)$ as above, find a bipartition of V into S_{sup} and $S_{\text{opp}} = V \setminus S_{\text{sup}}$ so that $\sum_{i \in S_{\text{sup}}, j \in S_{\text{opp}}} r(i, j)$ is maximized.

The max cut problem is known to be NP-hard, and thus in general is difficult to solve. However, good approximation algorithms based on Linear Programming and Semidefinite Programming have been developed recently, and combined with branch-and-bound techniques a good exact max-cut solver called *BiqMac* exists (Rendl et al., 2010). We used BiqMac for solving the max cut problem *exactly* on the activity network. Although a faster approximate max cut solver is used in (Agrawal et al., 2003), it is based on the limiting assumption that the size of S_{opp} is approximately the same as S_{opp}. This cannot be assumed for the networks in this paper.

4 Experiments

4.1 Corpus

The Ministry of Economy, Trade and Industry in Japan (METI) was accepting public opinions on e-government programs via the "e-METI Idea Box[4]" from February 23 to March 15 2010. Participants could show their positions for the ideas since the site accepted comments on the main idea and other comments, so this discussion can be regarded as a kind of debate. We used this data to evaluate our proposed method. The ideas and comments were written in Japanese and the data is available at the METI website.

For the 936 ideas that were posted to the Idea Box, we examined 17 ideas with more than 40 comments. Finally we selected five ideas for the evaluation. The numbers of remarks (a main idea and comments), participants, and remarks per participants are shown in Table 1.

We extracted the reply-to structure information in textual contents. The Idea Box system had a capability to adding a comment to a main topic or the other comment, and the system inserted an identifier in comment's text. Each identifier started with "#" and the IDs of the previous comments followed the identifier, such as "`#003`" (with `#001` referring to the main topic in the thread). An idea or comments may have several comments as replies, so this reply-to structure in a debate is a tree structure whose root node is the main topic. A typical reply-to tree structure is shown in Fig 2.

4.2 Agree/Disagree Classification

To calculate the reaction coefficients, we need to extract the reply-to pairs and classify these pairs into the agree/disagree/neutral classes. To classify these remark pairs we use opinionative and sentiment expressions. If a reply remark contains an expression of "I agree with you" then it should be classified into the agree class. Another example of expressions of the agree class would be "That's a good idea!".

To extract expressions of opinion, we created a simple pattern dictionaries that contains

[4]http://www.meti.go.jp/policy/it_policy/open-meti/

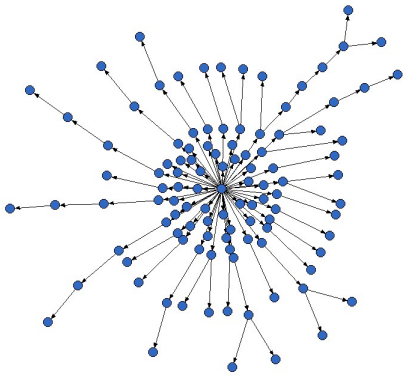

Figure 2: Reply-to Structure of a Debate

agree/disagree expressions. For instance, "I disagree with your idea" and "I don't agree with you" are in the disagree pattern dictionary. At the same time we use a sentiment analysis tool to extract sentiment expressions. The tool we used for sentiment expression extractions is the same as described in (Kanayama et al., 2004), which use machine translation techniques to identify sentiment expressions in text. The tool returns sentiment expressions with a sentiment label, favorable or unfavorable.

After identifying opinionative and sentiment expressions in the remarks, scores for the opinion classification are calculated. The score of each reply-to pair is the number of agreeing and favorable expressions minus the number of disagreeing and unfavorable expressions in the reply remark. When the score is positive, the opinion of the pair is identified as agree, and if the score is negative then the opinion of the pair identified as disagree. If the score equals zero, then the opinion is identified as neutral.

To evaluate this opinion classifier, we did an experiment with the METI data, which was manually assigned agree/disagree/neutral flags. The answers for these evaluation were created by us for three of the idea threads (Idea IDs #1,#2 and #3). Since most remarks do not have agree or disagree expressions, most reply-to pairs are classified into the neutral class. This means that calculating precision and recall for the neutral class are not important. For the evaluation of the classifier we calculated precisions and recalls only for agree and disagree classes. The results are shown in Table 2.

Table 2: Accuracy of opinion classification for reply-to pairs

Idea ID	Precision	Recall
1	0.63	0.25
2	0.62	0.14
3	0.44	0.38
Ave.	0.56	0.26

4.3 Support/Oppose Classification

Using the numbers of agree/disagree/neutral reply-to pairs, we can calculate the reaction coefficients for each pair of participants. After calculating the reaction coefficients for all of the participants' pairs, we can classify each participant into support or oppose sets using the max cut technique. In this subsection, we explain how to evaluate our proposed method and show experimental results.

4.3.1 Answer Sets for Global Position Classification

To evaluate our method we created answer sets for a global position classifier, consisting of participant sets with the position labels *Support* or *Oppose*. We identified the positions of the participants' remarks with contexts, but we assigned the "Unclear" label for some participants since their remarks did not contain enough information to classify their global positions. For showing the validity of the answer sets, two annotators annotated three ideas and calculated a κ value. The κ value is 0.69 so that this answer set is appropriate as an evaluation set. The use of the answer set annotated by a single annotator for the evaluation of support/oppose classification is justified since the agreement rate (the κ value) is enough for the evaluation.

4.3.2 Evaluation Index for Position Classification

For evaluation we defined the estimation index $accuracy$ since the number of participants in the Support position is not always the same as the

number of participants in the Oppose position. If the answers are grossly one-sided, the general accuracy does not work well, since the system can lead to a high score when it classifies all of the participants into the larger side. To minimize this potential bias, we defined an estimation index $accuracy$ using the average of the accuracies for the Support/Oppose sets. The estimation index $accuracy$ is defined as:

$$\text{accuracy} = \frac{1}{2}\left(\frac{|A_{\text{sup}} \cap S_{\text{sup}}|}{|A_{\text{sup}}|} + \frac{|A_{\text{opp}} \cap S_{\text{opp}}|}{|A_{\text{opp}}|}\right), \quad (2)$$

where A_{sup} and A_{opp} are the Support and Oppose participant sets in the answer set and S_{sup} and S_{opp} are the Support and Oppose participant sets generated by the system, respectively. For $accuracy$, we ignore "Unclear" users since the system is a two-class classifier.

4.3.3 Experimental Results

In the experiments we use the reaction coefficients $r(i, j)$ calculated based on the results of the agree/disagree/neutral Classifier, and classify participants into Support/Oppose position sets using BiqMac. Since we assumed that the main topic of the debate is the first remark of the debate thread, we assume that the set which includes the author of the first remark as the "Support" set and the other set as the "Oppose" set[5].

We conducted experiments for $(\alpha, \beta, \gamma) = (1, 0, 0), (1, 0.5, 0), (1, 0.5, -1)$ in Eq. (1) to examine the dependency of the accuracy on the coefficients $r(i, j)$. We also conducted an experiment for $(1, 1, 1)$, which is regarded as a baseline method described in (Agrawal et al., 2003), since all of the reply actions represent "disagree" opinions for the previous remarks with these parameter. The experimental results are shown in Table 3.

The ideas other than ID 1 show better accuracy than the baseline and their accuracies tend to increase in the order of $(1, 0, 0)$, $(1, 0.5, 0)$, $(1, 0.5, -1)$. This result shows that the effectiveness of distinguishing between "disagree" and "agree" replies. This distinction makes it possible to introduce the constraint in which the user pairs with "disagree" and "neutral" should be classified into opposing positions and user pairs with "agree" should be classified into same position in the Support/Oppose user sets.

[5]For this reason, the values of the accuracies can be lower than 0.5.

Table 3: Accuracy of Support/Oppose position classification

ID	Baseline	(1,0,0)	(1,0.5,0)	(1,0.5,-1)
1	47.86	**66.67**	54.52	54.05
2	66.43	76.43	76.43	**89.29**
3	46.47	48.88	42.63	**55.45**
4	53.19	51.52	55.36	**77.60**
5	66.67	58.33	66.67	**75.00**

At the same time, ID 1 shows lower accuracy for $(1, 0.5, 0), (1, 0.5, -1)$ even though the accuracy of agree/disagree classifier is good. In idea ID 1, the number of remarks per participant is the lowest in data sets, so the errors of the Agreement/Disagreement classifier strongly affect the results of the Support/Oppose classifier.

5 Conclusion and Future Work

We have shown how to classify users in an online debate based on their general positions with regards to the main topic by the textual contents of their remarks and the link structure of their replies. The previous work used the assumption that the replies are usually disagreements and based on this assumption used a link-based method to classify the participants. However, in an online debate the replies are also used for clarifying previous remarks and quite often for supporting the previous ones. Our proposed method uses not only the link structure of the replies, but also the textual contents of the local agreement/disagreement positions between the remarks to boost the accuracy of the task of classifying users into the supporting and opposing parties.

The proposed method is based on the observation that it is easier to use the textual contents for classifying the local positions of a user's replies with regards to the previous remarks, than to use them (e.g., by aggregating them) for classifying his/her global position with regards to the main topic of the debate. In our experiments, we used a rule-based classifier to classify the replies into

agree, disagree, and neutral (with regards to the previous replies) and used these classifier's result to determine the weight of the corresponding links in the link structure of the reply network. The max cut algorithm is then applied to the network, which results in a classification of the users into supporting or opposing parties (with regards to the main topic of the debate). The experiments indicate that the accuracies of the link-based method of (Agrawal et al., 2003) can be significantly increased by considering the textual contents of the replies.

There are several directions to extend our method. When an expression of opinion appears in a reply, we have to locate the target of the opinion. In the current method the target is determined by the ID of the remark pointed by the reply. When the ID is not available, we assume that the reply is with regards to the main topic. However, we also observed that even though a reply was directed to a particular remark, it often also contained opinions about the main topic. Identifying such replies can be used to yield higher accuracy in the classification task.

Much work remains for ultimate understanding of the participants' opinions in debate corpus. Understanding the reasons for the position for the main topic is one of the ways to understand their opinions and it may help to decide the next steps for companies or governments which held the debate sessions. An integrated system that includes a discussion system and an analysis system showing the ratio of positions and the reasons would support such purposes.

Abstract

In this paper, we present a two-stage approach to acquire Japanese unknown morphemes from text with full POS tags assigned to them. We first acquire unknown morphemes only making a morphology-level distinction, and then apply semantic classification to acquired nouns. One advantage of this approach is that, at the second stage, we can exploit syntactic clues in addition to morphological ones because as a result of the first stage acquisition, we can rely on automatic parsing. Japanese semantic classification poses an interesting challenge: proper nouns need to be distinguished from common nouns. It is because Japanese has no orthographic distinction between common and proper nouns and no apparent morphosyntactic distinction between them. We explore lexico-syntactic clues that are extracted from automatically parsed text and investigate their effects.

1 Introduction

A dictionary plays an important role in Japanese morphological analysis, or the joint task of segmentation and part-of-speech (POS) tagging (Kurohashi et al., 1994; Asahara and Matsumoto, 2000; Kudo et al., 2004). Like Chinese and Thai, Japanese does not delimit words by white-space. This makes the first step of natural language processing more ambiguous than simple POS tagging. Accordingly, morphemes in a pre-defined dictionary compactly represent our knowledge about both segmentation and POS.

One obvious problem with the dictionary-based approach is caused by unknown morphemes, or morphemes not defined in the dictionary. Even though, historically, extensive human resources were used to build high-coverage dictionaries (Yokoi, 1995), texts other than newspaper articles, in particular web pages, contain a large number of unknown morphemes. These unknown morphemes often cause segmentation errors. For example, morphological analyzer JUMAN 6.0[1] wrongly segments the phrase "さっぽろ駅" (*saQporo eki*, "Sapporo Station"), where "さっぽろ" (*saQporo*) is an unknown morpheme, as follows:

"さ" (*sa*, noun-common, "difference"),
"っ" (*Q*, UNK), "ぽ" (*po*, UNK),
"ろ" (*ro*, noun-common, "sumac") and
"駅" (*eki*, noun-common, "station"),

where UNK refers to unknown morphemes automatically identified by the analyzer. Such an erroneous sequence has disastrous effects on applications of morphological analysis. For example, it can hardly be identified as a LOCATION in named entity recognition.

One solution to the unknown morpheme problem is unknown morpheme acquisition (Mori and Nagao, 1996; Murawaki and Kurohashi, 2008). It is the task of automatically augmenting the dictionary by acquiring unknown morphemes from text. In the above example, the goal is to acquire the morpheme "さっぽろ" (*saQporo*) with the POS tag "noun-location name." However, unknown morpheme acquisition usually adopts a coarser POS tagset that only represents the morphology level distinction among noun, verb and adjective. This means that "さっぽろ" (*saQporo*) is acquired as just a noun and that the semantic label "location name" remains to be assigned. The reason only the morphology level distinction is made is

[1] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/juman-e.html

Coling 2008: Poster Volume, pages 876–884,
Beijing, August 2010

that the semantic level distinction cannot easily be captured with morphological clues that are exploited in unknown morpheme acquisition.

In this paper, we investigate the remaining problem and introduce the new task of semantic classification that is to be applied to automatically acquired nouns. In this task, we can exploit syntactic clues in addition to morphological ones because, as a result of acquisition, we can now rely on automatic parsing. For example, since text containing "さっぽろ" (*saQporo*, noun-*unclassified*) is correctly segmented, we can extract not only the phrase "*saQporo* station," but the tree fragment "ϕ go to *saQporo*," and we can determine its semantic label.

Japanese semantic classification poses an interesting challenge: proper nouns need to be distinguished from common nouns. Like Chinese and Thai, Japanese has no orthographic distinction between common and proper nouns as there is no such thing as capitalization. In addition, there seems no morphosyntactic (i.e. grammatical) distinction between them.

In this paper, we explore lexico-syntactic clues that can be extracted from automatically parsed text. We train a classification model on manually registered nouns and apply it to automatically acquired nouns. We then investigate the effects of lexico-syntactic clues.

2 Semantic Classification Task

2.1 Two-Stage Approach to Unknown Morpheme Acquisition

Our goal is to identify unknown morphemes in unsegmented text and assign POS tags to them. In this section, we omit the details of boundary identification (segmentation) and review the Japanese POS tagset to see why we propose a two-stage approach to assign full POS tags.

The Japanese POS tagset derives from traditional grammar. It is a mixture of several linguistic levels: morphology, syntax and semantics. In other words, information encoded in a POS tag is more than how the morpheme behaves in a sequence of morphemes. In fact, POS tags given to pre-defined morphemes are useful for applications of morphological analysis, such as dependency parsing (Kudo and Matsumoto, 2002), named entity recognition (Asahara and Matsumoto, 2003; Sasano and Kurohashi, 2008) and anaphora resolution (Iida et al., 2009; Sasano and Kurohashi, 2009). In these applications, POS tags are incorporated as features for models.

On the other hand, the mixed nature of the POS tagset poses a challenge to unknown morpheme acquisition. Previous approaches (Mori and Nagao, 1996; Murawaki and Kurohashi, 2008) directly or indirectly reply on morphology, or our knowledge on how a morpheme behaves in a sequence of morphemes. This means that semantic level distinction is difficult to make in these approaches, and in fact, is left unresolved. To be specific, nouns are only distinguished from verbs and adjectives but they have subcategories in the original tagset. These are what we try to classify acquired nouns into in this paper.

2.2 Semantic Labels

The Japanese noun subcategories may require an explanation since they are different from the English ones (Marcus et al., 1993) in many respects. Singular and mass nouns are not distinguished from plural nouns because Japanese has no grammatical distinction between them. More importantly for this paper, proper nouns have subcategories such as person name, location name and organization name in addition to the distinction from common nouns. These subcategories provide important information to named entity recognition among other applications. For proper nouns, we adopt these subcategories as semantic labels in our task.

In contrast to proper nouns, common nouns have only one subcategory "common." However, we consider that subcategories of common nouns similar to those of proper nouns are useful for, for example, anaphora resolution (Sasano and Kurohashi, 2009). We adopt the "categories" of morphological analyzer JUMAN, with which common nouns in its dictionary are annotated. There are 22 "categories" including `PERSON`, `ORGANIZATION` and `CONCEPT`. We collapse these "categories" into coarser semantic labels that roughly correspond to those for proper nouns. To sum up, we define 9 semantic labels as shown

Table 1: List of semantic labels.

labels	P/C	sources[1]	manually registered nouns	automatically acquired nouns
PSN-P	proper	subPOS:person name	松井 (*matsui*, a surname) ジョージ (*jôji*, "George")	佐祐理 (*sayuri*, a given name) キョン (*kyoN*, a nickname)
LOC-P		subPOS:place name	京都 (*kyouto*, "Kyoto") ドイツ (*doitsu*, "Germany")	アキバ (*akiba*, "Akihabara") ワイキキ (*waikiki*, "Waikiki")
ORG-P		subPOS:organization name	日銀 (*nichigin*, a bank) NHK (a broadcaster)	マツダ (*matsuda*, "Mazda") ヤフー (*yahû*, "Yahoo")
OTH-P		subPOS:proper noun	平成 (*heisei*, an era name) スラブ (*surabu*, "Slav")	ジプシー (*jipushî*, "Gypsy")
PSN-C	common	category:PERSON	先生 (*seNsei*, "teacher") スタッフ (*sutaQfu*, "staff")	メル友 (*merutomo*, "keypal") ニート (*nîto*, "NEET")
LOC-C		category:PLACE-*[2]	職場 (*shokuba*, "office") カフェ (*kafe*, "cafe")	囲炉裏 (*irori*, "hearth") 圃場 (*hojou*, "farm field")
ORG-C		category:ORGANIZATION	政府 (*seifu*, "government") チーム (*chîmu*, "team")	メーカ (*mêka*, "manufacturer") 弊所 (*heisho*, "our office")
ANI-C		category:ANIMAL and category:ANIMAL-PART	犬 (*inu*, "dog") 顔 (*kao*, "face")	チワワ (*chiwawa*, "Chihuahua") マンタ (*maNta*, "manta")
OTH-C		other categories	主張 (*shuchou*, "argument") 枕 (*makura*, "pillow")	甚平 (*jiNbei*, a kind of clothing) 着メロ (*chakumero*, "ringtone")

[1] A subPOS refers to a subcategory of noun. For example, PSN-P corresponds to the POS tag "noun-person name".
[2] category:PLACE-INSTITUTION, category:PLACE-INSTITUION PART and others.

in Table 1.

2.3 Related Tasks

A line of research is dedicated to identify unknown morphemes with varying degrees of identification. Asahara and Matsumoto (2004) only focus on boundary identification (segmentation) of unknown morphemes. Mori and Nagao (1996), Nagata (1999) and Murawaki and Kurohashi (2008) assign POS tags at the morphology level. Uchimoto et al. (2001) assign full POS tags but unsurprisingly the accuracy is low. Nakagawa and Matsumoto (2006) also assign full POS tags. They address the fact that local information used in previous studies is inherently insufficient and present a method that uses global information, in other words, takes into consideration all occurrences of each unknown word in a document. They report an improvement in tagging proper nouns in Japanese.

A related task is named entity recognition (NER). It can handle a named entity longer than a single morpheme and is usually formalized as a chunking problem. Since Japanese does not delimit words by white-space, the unit of chunking can be a character (Asahara and Matsumoto, 2003; Kazama and Torisawa, 2008) or a morpheme (Sasano and Kurohashi, 2008). In either case, NER models encode the output of morphological analysis and therefore are affected by its errors. In fact, Saito et al. (2007) report that a majority of unknown named entities (those never appear in a training corpus) contain unknown morphemes as their constituents and that NER models perform poorly on them. A straightforward solution to this problem would be to acquire unknown morphemes and to assign semantic labels to them.

Another related task is supersense tagging (Ciaramita and Johnson, 2003; Curran, 2005; Ciaramita and Altun, 2006). A supersense corresponds to one of the 26 broad categories defined by WordNet (Fellbaum, 1998). Each noun synset is associated with a supersense. For example, "chair" has supersenses PERSON, ARTIFACT and ACT because it belongs to several synsets.

Since supersense tagging is studied in English, it differs from our task in several respects. In English, the distinction between common and proper nouns is clear. In fact, the tagging models can use POS features even for unknown nouns. In addition, the syntactic behavior of English nouns is different from that of Japanese nouns (Gil, 1987). Definiteness is not marked in Japanese as it lacks determiners (e.g. "the" and "a"), and Japanese has no obligatory plural marking. On the other hand, Japanese obligatorily uses numeral classifiers to indicate the count of nouns, as in

(1) *saN satsu no hoN*
three CL GEN book
three volumes of books, or three books,

where "*satsu*" is a numeral classifier for books. A number together with its numeral classifier forms a numeral quantifier. Numeral quantifiers would be informative about the semantic categories of nouns. Note that Japanese shares the above features with Chinese and Thai. Our findings in this paper may hold for these languages.

3 Proposed Method

3.1 Lexico-Syntactic Clues

In the task of semantic classification, we can exploit syntactic clues in addition to morphological ones. As a result of unknown morpheme acquisition, text containing acquired morphemes, or former unknown morphemes, is correctly segmented. Now we can treat automatic parsing as (at least partly) reliable with regard to acquired morphemes.

For noun X, we use the following sets of features for classification.

call: noun phrase Y that appears in a pattern like "Y called X" and "Y such as X," e.g. "`call`:*kuni*" from

X to iu kuni
X QT call country
a country called X.

cf: predicate with a case marker with which it takes X as an argument, e.g. "`cf`:*tooru*:*wo*" from

X wo tooru
X ACC pass
ϕ pass through X.

demo: demonstrative that modifies X, e.g. "`demo`:*kono*" from "*kono X*" (this X) and "`demo`:*doNna*" from "*doNna X*" (what kind of X).

ncf1: noun phrase which X modifies with the genitive case marker "*no*," e.g. "`ncf1`:*heya*" from

X no heya
X GEN room
X's room.

ncf2: noun phrase that modifies X with the genitive case marker "*no*," e.g. "`ncf2`:*subete*" from

subete no X
all GEN X
all X.

suf: suffix or suffix-like noun that follows X, e.g. "`suf`:*saN*" from "X *saN*" (Mr./Ms. X) and "`suf`:*eki*" from "X *eki*" (X station).

Using automatically parsed text to extract syntactic features has an advantage. Since no manual annotation is necessary, we can utilize a huge raw corpus. On the other hand, parsing errors are inevitable. However, we can circumvent this problem by using the constraints of Japanese dependency structures: head-final and projective. The simplest example is the second last element of a sentence, which always depends on the last element. With these constraints, we can focus on syntactically unambiguous dependency pairs and extract syntactic features accurately. We follow Kawahara and Kurohashi (2001) to extract a pair of an argument noun and a predicate (**cf**), and Sasano et al. (2004) to extract a pair of nouns connected with the genitive case marker "*no*" (**ncf1** and **ncf2**).

Noun X can be part of a compound noun. We leave it for named entity recognition. Except for **suf**, we extract features only when X alone forms a word. Similarly, we extract **suf** features only when X and a suffix alone form a noun phrase.

For **call**, **ncf1**, and **ncf2**, we generalize numerals within noun phrases. For "*hoN*" (book) in example 1, we extract the feature "`ncf2`:<NUM>*satsu*."

3.2 Instances for Classification

Now that features are extracted for each noun, the question is how to combine them together to make an instance for classification. One factor we need to consider is polysemy: a noun can be a person name in one context and a location name in another. If we combine features extracted from the whole corpus, they may represent several semantic labels.

Modeling a mixture of semantic labels might be a solution, but we do not take this approach on the grounds that each occurrence of a noun corresponds to a single semantic label.

In our strategy, we perform classification multiple times for each noun and aggregate the results at the end. The features for each classification are extracted from a relatively small subset of a corpus where the noun is supposedly consistent in

terms of semantic labels. In the field of named entity recognition, it is known that label consistency holds strongly at the level of a document and less strongly across different documents (Krishnan and Manning, 2006). Thus we start with a document and gradually cluster related documents until a sufficient number of features are obtained. For the specific procedures we took in the experiments, see Section 4.1.

3.3 Training Data

Following unknown morpheme acquisition (Murawaki and Kurohashi, 2008), we create training data using manually registered nouns, for which we can obtain correct semantic labels. We perform the same procedure as above to make instances of registered nouns.

Some registered nouns are tagged with more than one semantic label, which we call "explicit polysemy." We drop them from the training data. The remaining problem is "implicit polysemy." Nouns are sometimes used with an uncovered sense. In preliminary experiments, we found that a typical case of implicit polysemy was that a proper noun derived from a basic noun. To alleviate this problem, we use an NE tagger for filtering. We run an NE tagger over a small portion of the corpus and extract common nouns that are frequently tagged as named entities. Then we remove these nouns from the training data.

We also drop nouns that appear extremely frequently such as "人" (*hito*, "person"), "事" (*koto*, "thing") and "私" (*watashi*, "I"[2]). Since acquired nouns to be classified are typically low frequency morphemes, they would not behave similarly to these basic nouns.

3.4 Classifier

To assign a semantic label to each instance, we use a multiclass discriminative classifier. The input it takes is an instance that is represented by a feature vector $x \in \mathbb{R}^d$. The output is one semantic label $y \in Y$, where Y is the set of semantic labels.

We use a linear classifier. It has a weight vector $w_y \in \mathbb{R}^d$ for each y and outputs y that maximizes the inner product of w_y and x.

$$y = \operatorname*{argmax}_y \langle w_y, x \rangle.$$

Several methods have been proposed to estimate weight vector w_y from training data. We use online algorithms because they are easy to implement and scale to huge instances. We try the Perceptron family of algorithms.

4 Experiments

4.1 Settings

We used JUMAN for morphological analysis and KNP[3] for dependency parsing. The dictionary of JUMAN was augmented with automatically acquired morphemes (Murawaki and Kurohashi, 2008). The number of manually registered morphemes was 120 thousands while there were 13,071 acquired morphemes, of which 12,615 morphemes were nouns.

We used a web corpus that was compiled through the procedures proposed by Kawahara and Kurohashi (2006). It consisted of 100 million pages.

We first extracted features from the web corpus. To keep the model size manageable, we used 447,082 features that appeared more than 100 times in the corpus.

We constructed training data from manually registered nouns and test data from automatically acquired nouns. For each noun, we combined text together until the number of features grew to more than 100. We started with a single web page, then merge pages that share a domain name and finally clustered texts across different domains. We split the web corpus into 40 subcorpora and applied this procedure in parallel. We used Bayon[4] for clustering domain texts. We sequentially read texts and applied the repeated bisections clustering every time some 5,000 pages were appended. The vectors for clustering were nouns, both registered and acquired, with their tf-idf scores. We obtained 4,843,085 instances for 10,613 registered nouns and 196,098 instances for 2,556 acquired nouns.

[2] Japanese personal pronouns are treated as common nouns because they show no special morphosyntactic behavior.

[4] http://code.google.com/p/bayon/

Table 2: Results of semantic classification.

learning algorithms	acquired nouns	registered nouns
Averaged Perceptron	86.40% (432 / 500)	88.59% (123,113 / 138,971)
Passive-Aggressive	**87.00**% (435 / 500)	**91.68**% (127,407 / 138,971)
Confidence-Weighted	85.20% (426 / 500)	89.66% (124,604 / 138,971)
baseline[1]	69.60% (348 / 500)	79.14% (109,980 / 138,971)

[1] assign OTH−C to all instances.

Table 3: Examples of aggregated instances.

acquired nouns	instances	labels
ヒカル (*hikaru*, a person name)	84	PSN−P:58.33%, PSN−C:41.67%
チワワ (*chiwawa*, "Chihuahua")	128	ANI−C:54.69%, OTH−C:45.31%
かみさん (*kamisaN*, colloq. "wife")	131	PSN−C:100%
ラスベガス (*rasubegasu*, "Las Vegas")	136	LOC−P:97.06%, LOC−C:2.94%
アップル (*aQpuru*, "Apple/apple")	187	ORG−P:63.10%, PSN−C:34.76%, OTH−C:2.14%
メルマガ (*merumaga*, abbr. of "mail magazine")	1,622	OTH−C:99.32%, LOC−C:0.55%, PSN−C:0.06%

In order to handle polysemy, we evaluated semantic classification on an instance-by-instance basis. We randomly selected 500 instances from the test data and manually assigned the correct labels to them. For comparison purposes, we also classified registered nouns. We split the training data: 829 nouns or 138,971 instances for testing and the rest for training.

We trained the model with three online learning algorithms, (1) the averaged version (Collins, 2002) of Perceptron (Crammer and Singer, 2003), (2) the Passive-Aggressive algorithm (Crammer et al., 2006), and (3) the Confidence-Weighted algorithm (Crammer et al., 2009). For Passive-Aggressive algorithm, we used *PA-I* and set parameter C to 1. For Confidence-Weighted, we used the single-constraint updates. All algorithms iterated five times through the training data.

4.2 Results

Table 2 shows the results of semantic classification. All algorithms significantly improved over the baseline. As suggested by the gap in accuracy between acquired and registered nouns in the baseline method, the label distribution of the training data differed from that of the test data, but the decrease in accuracy was smaller than expected.

The Passive-Aggressive algorithm performed best on both acquired and registered nouns. For the rest of this paper, we report the results of the Passive-Aggressive algorithm.

Table 3 shows aggregated instances of some acquired nouns. Although classification sometimes failed, correct labels took the majority. However, it is noticeable that PSN−P was frequently misidentified as PSN−C while PSN−C was correctly identified. This phenomenon is clearly seen in the confusion matrix (Table 4). Half of PSN−P instances were misidentified as PSN−C but the percentage of errors in the opposite direction was just above 9%. We will investigate this in the next section.

4.3 Discussion

Our interest is in determining what kinds of features are effective in semantic classification. We first performed standard ablation experiments. We trained a series of models on the training data after removing each feature set. The training and test data were the same with those in Section 4.1.

Table 5 shows the results of ablation experiments. Significant decreases in accuracy are observed in the **cf** dataset. This is easily explained by the fact that more than half of features belonged to **cf**. The ratio of **ncf1** was much the same with that of **ncf2**, but the removal of **ncf1** resulted in a worse performance in classifying registered nouns than that of **ncf2**. This means that a modifiee of a noun explains more about the noun than its modifier.

The ablation experiments cannot capture interesting properties of features because each feature set has a great diversity within it. Next, we directly examine features instead. Since we use a simple linear classifier, a feature has $|Y|$ corresponding weights, each of which represents how likely a noun belongs to label y. For example, features whose weights for PSN−C are the largest

Table 4: Confusion matrix of acquired nouns.

		Actual								
		PSN-P	LOC-P	ORG-P	OTH-P	PSN-C	LOC-C	ORG-C	ANI-C	OTH-C
Predicted	PSN-P	16		1		4				1
	LOC-P									1
	ORG-P			4

-ncf2	18.40%	85.60% (428 / 500)	91.54% (127,220 / 138,971)
-suf	5.10%	87.40% (437 / 500)	91.30% (126,889 / 138,971)
all		87.00% (435 / 500)	**91.68**% (127,407 / 138,971)

[1] The proportion of each feature set that appears in the instances of the test data.

include:

- cf:*nakusu*:*wo* ("ϕ lose X to the disease"),
- cf:*oshieru*:*ni* ("ϕ_1 teach X ϕ_2"),
- ncf2:*ooku* ("many/much X"), and
- ncf2:<NUM>*niN* (X is modified by <NUM> plus a numeral classifier for persons).

As briefly mentioned in Section 2.3, Japanese numeral quantifiers received scholarly attention in the fields of linguistic philosophy and linguistics in relation to the count/mass distinction (Quine, 1969; Gil, 1987). In our feature sets, numeral quantifiers typically appear as **ncf2**, e.g. "ncf2:<NUM>*niN*." The weights given to them demonstrate their effectiveness in semantic classification. They discriminate common nouns from proper nouns as the weights given to common nouns are larger with wide margins. It is not surprising because, say, the phrase "two Johns" is semantically acceptable but extremely rare in reality. They are also informative about the distinction among PSN, LOC and others. For example, the classifier "*niN*" for persons suggest the noun in question is a person while "*keN*" for houses would modify a location-like noun. However, we found quite a few "noises" about these features in data. The modifiee of a numeral expression is not always the noun to be counted, as demonstrated by the following example:

(2) *saN niN no moNdai*
three CL GEN problem
matters among the three persons.

From the above, the feature "ncf2:<NUM>*niN*" is extracted although "*moNdai*" is OTH-C. Theis "noise" is attributed to the genitive case marker "*no*" because it can denote a wide range of relations between two nouns. We might be able to avoid this problem if we focus on "floating" numeral quantifiers. A floating numeral quantifier has no direct dependency relation to the noun to be counted, as in

(3) *seito ga saN niN keQseki shita*
student NOM three CL absence do
three students were absent,

where the numeral quantifier modifies the verb phrase instead of the noun. Further work is needed to anchor floating numeral quantifiers since they bring a different kind of ambiguity themselves (Bond et al., 1998).

Closely related to numeral quantifiers are quantificational nouns that appear as "ncf2:*ooku*" ("many/much"), "ncf2:*subete*" ("all") and others. They distinguish common nouns from proper

nouns but does not make a further classification. The same is true of other numeral expressions such as "cf:*hueru*:*ga*" ("X increase in number") and "cf:*nai*:*ga*" ("there is no X" or "X do not exist"). We found that, other than numeral expressions, some features distinguished common nouns from proper nouns because they indicated the noun denoted an attribute. Such features include "cf:*naru*:*ni*" ("ϕ become X") and "cf:*kaneru*:*wo*" ("ϕ double as X").

We expected that demonstratives (**demo**) served similar functions to quantificational expressions, but it turned out to be more complex. The distal demonstrative "*ano*" ("that") often modifies proper nouns to give emphasis. In fact, the model gave larger weights to proper nouns. On the other hand, interrogative demonstratives such as "*dono*" ("which") and "*doNna*" ("what kind of") are rarely used with proper nouns although semantically acceptable.

As seen above, there is an abundant variety of features that distinguish common nouns from proper nouns. Also, it is not difficult to make a distinction among PSN, LOC and others although the far largest cluster OTH−C sometimes absorbs other instances. The remaining question is how to distinguish proper nouns from common nouns, or specifically PSN−P from PSN−C. We examined features that gave larger weights to PSN−P than to PSN−C. They generally had smaller margins in weights than those which distinguish PSN−C from PSN−P. Among them, features such as "cf:*utau*:*ga*" ("X sing") and "cf:*hanasu*:*ni*" ("ϕ talk to X") have no problem with being used for common nouns in terms of both semantics and pragmatics. They seem to have resulted from over-training. There were seemingly appropriate features such as "suf:*saNchi*" ("X's house") and "suf:*seNshu*" (honorific suffix for players), but they were not ubiquitous in the corpus. PSN−P instances suffered from lack of distinctive features.

One solution to this problem is to combine additional knowledge about person names. For example, a Japanese family name is followed by a given name, and most Chinese names consist of three Chinese characters. However, quite a few person names in the web corpus do not follow the usual patterns of person names because they are handles (or nicknames) and names for fictional characters. Thus it would be desirable to be able to classify person names without additional knowledge.

5 Conclusion

In this paper, we presented the new task of semantic classification of Japanese nouns and applied it to nouns automatically acquired from text. Unlike in unknown morpheme identification in previous studies, we can exploit automatically parsed text. We explored lexico-syntactic clues and investigated their effects. We found plenty of features that distinguished common nouns from proper nouns, but few features worked in the opposite direction. Further work is needed to overcome this bias.

A Learnable Constraint-based Grammar Formalism

Smaranda Muresan
School of Communication and Information
Rutgers University
smuresan@rci.rutgers.edu

Abstract

Lexicalized Well-Founded Grammar (LWFG) is a recently developed syntactic-semantic grammar formalism for deep language understanding, which balances expressiveness with provable learnability results. The learnability result for LWFGs assumes that the semantic composition constraints are learnable. In this paper, we show what are the properties and principles the semantic representation and grammar formalism require, in order to be able to learn these constraints from examples, and give a learning algorithm. We also introduce a LWFG parser as a deductive system, used as an inference engine during LWFG induction. An example for learning a grammar for noun compounds is given.

1 Introduction

Recently, several machine learning approaches have been proposed for mapping sentences to their formal meaning representations (Ge and Mooney, 2005; Zettlemoyer and Collins, 2005; Muresan, 2008; Wong and Mooney, 2007; Zettlemoyer and Collins, 2009). However, only few of them integrate the semantic representation with a grammar formalism: λ-expressions and Combinatory Categorial Grammars (CCGs) (Steedman, 1996) are used by Zettlemoyer and Collins (2005;2009), and ontology-based representations and Lexicalized Well-Founded Grammars (LWFGs) (Muresan and Rambow, 2007) are used by Muresan (2008).

An advantage of the LWFG formalism, compared to most constraint-based grammar formalisms developed for deep language understanding, is that it is accompanied by a learnability guarantee, the search space for LWFG induction being a complete grammar lattice (Muresan and Rambow, 2007). Like other constraint-based grammar formalisms, the semantic structures in LWFG are composed by constraint solving, semantic composition being realized through constraints at the grammar rule level. Moreover, semantic interpretation is also realized through constraints at the grammar rule level, providing access to meaning during parsing.

However, the learnability result given by Muresan and Rambow (2007) assumed that the grammar constraints were learnable. In this paper we present the properties and principles of the semantic representation and grammar formalism that allow us to learn the semantic composition constraints. These constraints are a simplified version of "path equations" (Shieber et al., 1983), and we present an algorithm for learning these constraints from examples (Section 5). We also present a LWFG parser as a deductive system (Shieber et al., 1995) (Section 3). The LWFG parser is used as an innate inference engine during LWFG learning, and we present an algorithm for learning LWFGs from examples (Section 4). A discussion and an example of learning a grammar for noun compounds are given is Section 6.

2 Lexicalized Well-Founded Grammars

Lexicalized Well-Founded Grammar (LWFG) is a recently developed formalism that balances expressiveness with provable learnability results (Muresan and Rambow, 2007). LWFGs are a type of Definite Clause Grammars (Pereira and Warren, 1980) in which (1) the context-free backbone is extended by introducing a partial ordering relation among nonterminals, 2) grammar nonterminals are augmented with strings and their syntactic-semantic representations, called *semantic molecules*, and (3) grammar rules can have

Coling 2008: Poster Volume, pages 885–893,
Beijing, August 2010

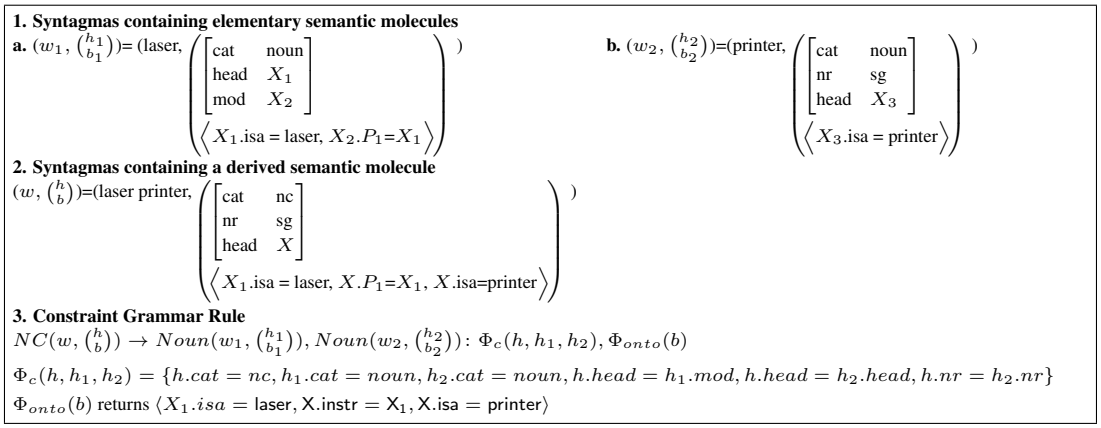

Figure 1: Syntagmas containing elementary semantic molecules (1) and a derived semantic molecule (2); A constraint grammar rule together with the semantic composition and ontology-based interpretation constraints, Φ_c and Φ_{onto} (3)

two types of constraints, one for semantic composition and one for semantic interpretation. The first property allows LWFG learning from a small set of examples. The last two properties make LWFGs a type of syntactic-semantic grammars.

Definition 1. *A semantic molecule associated with a natural language string w, is a syntactic-semantic representation, $w' = \binom{h}{b}$, where h (head) encodes compositional information, while b (body) is the actual semantic representation of the string w.*

Grammar nonterminals are augmented with pairs of strings and their semantic molecules. These pairs are called *syntagmas*, and are denoted by $\sigma = (w, w') = (w, \binom{h}{b})$.

Examples of semantic molecules for the nouns *laser* and *printer* and the noun-noun compound *laser printer* are given in Figure 1. When associated with lexical items, semantic molecules are called *elementary semantic molecules*. When semantic molecules are built by the combination of others, they are called *derived semantic molecules*. Formally, the semantic molecule head, h, is a one-level feature structure (i.e., values are atomic), while the semantic molecule body, b, is a logical form built as a conjunction of atomic predicates $\langle concept\rangle.\langle attr\rangle = \langle concept\rangle$, where variables are either concept or slot identifiers in an ontology.[1]

Muresan and Rambow (2007) formally defined LWFGs, and we present here a slight modification of their definition.

Definition 2. *A Lexicalized Well-Founded Grammar (LWFG) is a 7-tuple, $G = \langle \Sigma, \Sigma', N_G, \succeq, P_G, P_\Sigma, S\rangle$, where:*

1. *Σ is a finite set of terminal symbols.*
2. *Σ' is a finite set of elementary semantic molecules corresponding to the terminal symbols.*
3. *N_G is a finite set of nonterminal symbols. $N_G \cap \Sigma = \emptyset$. We denote $pre(N_G) \subseteq N_G$, the set of pre-terminals (a.k.a, parts of speech)*
4. *$\succeq$ is a partial ordering relation among nonterminals.*
5. *P_G is the set of constraint grammar rules. A constraint grammar rule is written $A(\sigma) \rightarrow B_1(\sigma_1), \ldots, B_n(\sigma_n)$: $\Phi(\bar{\sigma})$, where $A, B_i \in N_G$, $\bar{\sigma} = (\sigma, \sigma_1, ..., \sigma_n)$ such that $\sigma = (w, w'), \sigma_i = (w_i, w_i'), 1 \leq i \leq n, w = w_1 \cdots w_n, w' = w_1' \circ \cdots \circ w_n'$, and $\circ$ is the composition operator for semantic molecules (more details about the composition operator are given in Section 5). For brevity, we denote a rule by $A \rightarrow \beta$: Φ, where $A \in N_G, \beta \in N_G^+$. P_Σ is the set of constraint grammar rules whose left-hand side are pre-terminals, $A(\sigma) \rightarrow$, $A \in pre(N_G)$.*

[1]The body of a semantic molecule is called OntoSeR and is a flat ontology-based semantic representation.

We use the notation $A \rightarrow \sigma$ for this grammar rules. In LWFG due to partial ordering among nonterminals we can have ordered constraint grammar rules and non-ordered constraint grammar rules (both types can be recursive or non-recursive). A grammar rule $A(\sigma) \rightarrow B_1(\sigma_1), \ldots, B_n(\sigma_n)\colon \Phi(\bar{\sigma})$, is an ordered rule, if for all B_i, we have $A \succeq B_i$. In LWFGs, each nonterminal symbol is a left-hand side in at least one ordered non-recursive rule and the empty string cannot be derived from any nonterminal symbol.

6. *$S \in N_G$ is the start nonterminal symbol, and $\forall A \in N_G, S \succeq A$ (we use the same notation for the reflexive, transitive closure of $\succeq$).*

The partial ordering relation $\succeq$ makes the set of nonterminals well-founded[2] , which allows the ordering of the grammar rules, as well as the ordering of the syntagmas generated by LWFGs. This ordering allow LWFG learning from a small set of representative examples (Muresan and Rambow, 2007) (P_Σ is not learned).

An example of a LWFG rule is given in Figure 1(3). Nonterminals are augmented with syntagmas. Moreover, in LWFG the semantic composition and interpretation are realized via constraints at the grammar rule level ($\Phi(\bar{\sigma})$ in Definition 2). More precisely, syntagma composition means string concatenation ($w = w_1 w_2$) and semantic molecule composition ($\binom{h}{b} = \binom{h_1}{b_1} \circ \binom{h_2}{b_2}$) —- where the bodies of semantic molecules are concatenated through logical conjunction ($b = (b_1, b_2)\nu$, where ν is a variable substitution $\nu = \{X_2/X, X_3/X\}$), while the semantic molecules heads are composed through compositional constraints $\Phi_c(h, h_1, h_2)$, which are a simplified version of "path equations" (Shieber et al., 1983) (see Figure 1(3)). During LWFG learning, *compositional constraints Φ_c are learned* together with the grammar rules. Semantic interpretation, which is ontology-based in LWFG, is also encoded as constraints at the grammar rule level — Φ_{onto} — providing access to meaning during parsing. $\Phi_{onto}(b)$ constraints are applied to the body of the semantic molecule corresponding to the syntagma associated with the left-hand side nonterminal. *The ontology-based constraints are not learned*; rather, Φ_{onto} is a general predicate that succeed or fail as a result of querying an ontology — when it succeeds, it instantiates the variables of the semantic representation with concepts/slots in the ontology (see the example in Figure 1(3)).

[2] $\succeq$ should not be confused with information ordering derived from flat feature structures

2.1 Derivation in LWFG

The derivation in LWFG is called ground syntagma derivation, and it can be seen as the bottom up counterpart of the usual derivation. Given a LWFG, G, the *ground syntagma derivation* relation, $\stackrel{*G}{\Rightarrow}$, is defined as: $\frac{A \rightarrow \sigma}{A \stackrel{*G}{\Rightarrow} \sigma}$ (if $\sigma = (w, w'), w \in \Sigma, w' \in \Sigma'$, i.e., $A \in pre(N_G,)$, and $\frac{B_i \stackrel{*G}{\Rightarrow} \sigma_i,\ i=1,\ldots,n, \quad A(\sigma) \rightarrow B_1(\sigma_1),\ldots,B_n(\sigma_n)\colon \Phi(\bar{\sigma})}{A \stackrel{*G}{\Rightarrow} \sigma}$.

The *set of all syntagmas* generated by *a grammar G* is $L_\sigma(G) = \{\sigma | \sigma = (w, w'), w \in \Sigma^+, \exists A \in N_G, A \stackrel{*G}{\Rightarrow} \sigma\}$. Given a LWFG G, $E_\sigma \subseteq L_\sigma(G)$ is called a sublanguage of G. Extending the notation, given a LWFG G, the set of syntagmas generated by a *rule* $(A \rightarrow \beta\colon \Phi) \in P_G$ is $L_\sigma(A \rightarrow \beta\colon \Phi) = \{\sigma | \sigma = (w, w'), w \in \Sigma^+, (A \rightarrow \beta\colon \Phi) \stackrel{*G}{\Rightarrow} \sigma\}$, where $(A \rightarrow \beta\colon \Phi) \stackrel{*G}{\Rightarrow} \sigma$ denotes the ground derivation $A \stackrel{*G}{\Rightarrow} \sigma$ obtained using the rule $A \rightarrow \beta\colon \Phi$ in the last derivation step.

3 LWFG Parsing as Deduction

Following Shieber (1995), we present the Lexicalized Well-Founded Grammar parser as a deductive proof system in Table 1. The *items* of the logic are of the form $[i, j, \sigma_{ij}, A \rightarrow \alpha \bullet \beta \Phi^A]$, where $A \rightarrow \alpha\beta\colon \Phi^A$ is a grammar rule, Φ^A — the constraints corresponding to the grammar rule whose left-hand side nonterminal is A— can be true, $\bullet$ shows how much of the right-hand side of the rule has been recognized so far, i points to the parent node where the rule was invoked, and j points to the position in the input that the recognition has reached. We use the following notations: $\sigma^R_{ij} = (w^R_{ij}, \binom{h^R_{ij}}{b^R_{ij}})$ are syntagmas corresponding to the partially parsed right-hand side of a rule; $\sigma^L_{ij} = (w^L_{ij}, \binom{h^L_{ij}}{b^L_{ij}})$ are ground-derived syntagmas (i.e., they are augmenting the left-hand side non-

Item form	$[i, j, \sigma_{ij}, A \rightarrow \alpha \bullet \beta \Phi^A]$	$1 \leq i, j \leq n+1, A \in N_G, \alpha\beta \in N_G^*$ the Φ^A constraint can be true
Axioms	$[i, i+1, \sigma^L_{ii+1}, B_i \rightarrow \bullet]$	$1 \leq i \leq n, B_i \in pre(N_G), B_i \rightarrow \sigma^L_{ii+1} \in P_\Sigma$
Goals	$[i, j, \sigma^L_{ij}, A \rightarrow \alpha\Phi^A \bullet]$	$1 \leq i, j \leq n+1, A \in N_G, \alpha \in N_G^+$
Inference Rules		
Prediction	$\frac{[i,j,\sigma^L_{ij}, B \rightarrow \beta \Phi^B \bullet]}{[i,i,\sigma^R_{ii}, A \rightarrow \bullet B\gamma\Phi^A]}$ $\langle A \rightarrow B\gamma \colon \Phi^A \rangle$	$(A \rightarrow B\gamma \colon \Phi^A) \in P_G$ $\sigma^R_{ii} = \sigma_\emptyset$ (i.e., $w^R_{ii} = \epsilon$, $b^R_{ii} = true$ and $h^R_{ii} = \emptyset$)
Completion	$\frac{[i,j,\sigma^R_{ij}, A \rightarrow \alpha \bullet B\ \gamma\ \Phi^A] \quad [j,k,\sigma^L_{jk}, B \rightarrow \beta\ \Phi^B\ \bullet]}{[i,k,\sigma^R_{ik}, A \rightarrow \alpha\ B \bullet \gamma\ \Phi^A]}$	$\sigma^R_{ik} = \sigma^R_{ij} \circ \sigma^L_{jk}$, where $w^R_{ik} = w^R_{ij} w^L_{jk}$, $b^R_{ik} = b^R_{ij} b^L_{jk}$, $h^R_{ik} = h^R_{ij} \cup h^L_{jk}$
Constraint	$\frac{[i,j,\sigma^R_{ij}, A \rightarrow \alpha \bullet \Phi^A]}{[i,j,\sigma^L_{ij}, A \rightarrow \alpha\Phi^A \bullet]}$ $\langle \Phi^A$ is satisfiable $\rangle$	$\sigma^L_{ij} = \phi(\sigma^R_{ij})$

Table 1: LWFG parsing as deductive system

terminal of a LWFG rule). The goal items are of the form $[i, j, \sigma^L_{ij}, A \rightarrow \alpha\Phi^A \bullet]$, where σ^L_{ij} is ground-derived from the rule $A \rightarrow \alpha \colon \Phi^A$.

Compared to the deductive system in (Shieber et al., 1995), the LWFG parser has the following characteristics: each item is augmented with a syntagma; the *Constraint rule* is a *new inference rule*, and the goal items are associated to *every nonterminal in the grammar*, not only to the start symbol (i.e., LWFG parser is a robust parser). The **Constraint** inference rule is the only one that obtains an inactive edge[3], from an active edge by executing the grammar constraint Φ^A (the $\bullet$ is shifted across the constraint). By applying the Constraint rule as the last inference rule we obtain the ground-derived syntagmas σ^L_{ij}. Thus, the goal items are obtained only after the Constraint rule is applied. During this inference rule we have that $\sigma^L_{ij} = \phi(\sigma^R_{ij})$, where ϕ is defined by: $w^L_{ij} = w^R_{ij}$, $b^L_{ij} = b^R_{ij}\nu_{ij}$, and $h^L_{ij} = \varphi(h^R_{ij})$. The substitution ν_{ij} and the function φ are implicitly contained in the grammar constraint $\Phi^A_c(h^L_{ij}, h^R_{ij})$ (see Section 5 for details)

Definition 3 (Robust parsing provability)**.** *Robust parsing provability corresponds to reaching the goal item:* $\vdash_{rp} A(\sigma^L_{ij})$ *iff* $[i, j, \sigma^L_{ij}, A \rightarrow \alpha\Phi^A \bullet]$.

Thus, we can notice that the ground syntagma derivation is equivalent to robust parsing provability, i.e., $A \stackrel{*G}{\Rightarrow} \sigma$ iff $G \vdash_{rp} A(\sigma)$.

[3]We use Kay's terminology: items are edges, where the axioms and goals are inactive edges having $\bullet$ at the end, while the rest are active edges (Kay, 1986).

4 Learning LWFGs

The theoretical learning model for LWFG induction, Grammar Approximation by Representative Sublanguage (GARS), together with a learnability theorem was introduced in (Muresan and Rambow, 2007). LWFG's learning framework characterizes the "importance" of substructures in the model not simply by frequency, but rather linguistically, by defining a notion of "representative examples" that drives the acquisition process. Informally, representative examples are "building blocks" from which larger structures can be inferred via reference to a larger generalization corpus referred to as representative sublanguage in (Muresan and Rambow, 2007). The GARS model uses a polynomial algorithm for LWFG learning that take advantage of the building blocks nature of representative examples.

The LWFG induction algorithm belongs to the class of Inductive Logic Programming methods (ILP), based on entailment (Muggleton, 1995; Dzeroski, 2007). At each step a new constraint grammar rule is learned from the current representative example, σ. Then this rule is added to the grammar rule set. The process continues until all the representative examples are covered. We describe below the process of learning a grammar rule from the current representative example:

1. **Most Specific Grammar Rule Generation**. In the first step, the most specific grammar rule is generated from the current representative example σ. The category annotated

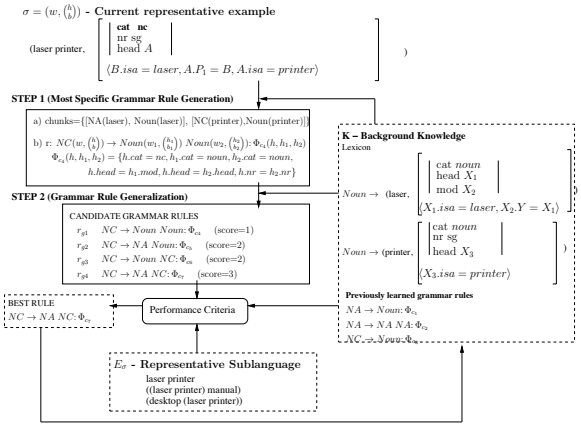

Figure 2: Example of Grammar Rule Learning

in the representative example gives the left-hand-side nonterminal, while a robust parser returns the minimum number of chunks covering the representative example. The categories of the chunks give the nonterminals of the right-hand side of the most specific rule. For example, in Figure 2, given the representative example *laser printer* annotated with its semantic molecule, and the background knowledge containing the already learned rules $NA \rightarrow Noun\colon \Phi_{c_1}$, $NA \rightarrow NA\ NA\colon \Phi_{c_2}$, $NC \rightarrow Noun\colon \Phi_{c_3}$ the robust parser generates the chunks corresponding to the noun *laser* and the noun *printer*: [NA(laser),Noun(laser)] and [NC(printer),Noun(printer)], respectively. The most specific rule is $NC \rightarrow Noun\ \ Noun\colon \Phi_{c_4}$, where the left-hand side nonterminal is given by the category of the representative example, in this case nc. Compositional constraints Φ_{c_4} are learned as well. In section 5 we give the algorithm for learning these constraints, and several properties and principles that are needed in order for these constraints to be learnable.

2. **Grammar Rule Generalization**. In the second step, this most specific rule is generalized, obtaining a set of candidate grammar rules (the generalization step is the inverse of the derivation step used to define the complete grammar lattice search space in (Muresan and Rambow, 2007)). The performance criterion in choosing the best grammar rule among these candidate hypotheses is the number of examples in the representative sublanguage E_σ (generalization corpus) that can be parsed using the candidate grammar rule, r_{gi} in the last ground derivation step, together with the previous learned rules, i.e., $|E_\sigma \cap L_\sigma(r_{gi})|$. In Figure 2 given the representative sublanguage E_σ={ *laser printer, laser printer manual, desktop laser printer*} the learner will generalize to the recursive rule $NC \rightarrow NA\ NC\colon \Phi_7$, since only this rule can parse all the examples in E_σ.

5 Learnable Composition Constraints

In LWFG, the semantic structures are composed by constraint solving, rather than functional application (with lambda expressions and lambda reduction). This section presents the properties and principles that guarantee the learnability of the compositional constraints,Φ_c, and presents an algorithm to generate these constraints from examples, which is a key result for LWFG learnability.

The information for semantic composition is encoded in the head of semantic molecules. There are three types of attributes that belong to the semantic molecule head h: category attributes $\mathcal{A}_h^c$, variable attributes $\mathcal{A}_h^v$, and feature attributes $\mathcal{A}_h^f$. Thus, $\mathcal{A}_h = \mathcal{A}_h^c \cup \mathcal{A}_h^v \cup \mathcal{A}_h^f$ and $\mathcal{A}_h^c, \mathcal{A}_h^v, \mathcal{A}_h^f$ are pairwise disjoint. For example, in Figure 1 for the noun-noun compound *laser printer*, we have that $\mathcal{A}_h^c = \{cat\}$, $\mathcal{A}_h^f = \{nr\}$, and $\mathcal{A}_h^v = \{head\}$, while for the noun *laser* we have that $\mathcal{A}_{h_1}^c = \{cat\}$, $\mathcal{A}_{h_1}^f = \emptyset$, and $\mathcal{A}_{h_1}^v = \{head, mod\}$ (nouns can be modifiers of other nouns, so their representation is similar to that of an adjective).

We describe in turn each of these types of attributes and their corresponding principles. All principles, except the first and the last mirror principles in other constraint-based linguistic formalisms, such as HPSG (Pollard and Sag, 1994).

The category attributes $\mathcal{A}_h^c$ are state attributes, and their value set gives the category of the semantic molecule. There is one attribute, cat $\in \mathcal{A}_h^c$, which is mandatory and whose value is the name of the category (e.g., $h.cat = nc$ in Figure

1). The category of a semantic molecule can be given by: 1) the cat attribute alone, or 2) the cat attribute together with other state attributes in $\mathcal{A}_h^c$ which are syntactic-semantic markers.

Principle 1 (Category Name Principle)**.** *The category name $h.cat$ of a syntagma $\sigma = (w, \binom{h}{b})$ is the same as the grammar nonterminal augmented with syntagma σ.*

When learning a LWFG rule from an example σ, the above principle allows us to determine the nonterminal in the left-hand side of the grammar rule. For example, when learning the LWFG rule from the syntagma corresponding to *laser printer* in Figure 2, the nonterminal in the left-hand side of the LWFG rule is NC since $h.cat = nc$.

The variable attributes $\mathcal{A}_h^v$ are attributes whose values are logical variables and represent the semantic valence of the molecule, which allows the binding of the semantic representations. These logical variables appear in the semantic molecule body as well. For example, in Figure 1(2) for the noun-noun compound *laser printer*, the value of the variable attribute $head \in \mathcal{A}_h^v$ is a variable X, which appears also in the body of the semantic molecule $\langle X_1.isa = laser, X.P_1 = X_1, X.isa = printer\rangle$. It can be noticed that the semantic molecule body contains other variables as well (X_1, P_1). However, only the variables present in the semantic molecule head as well (X) will participate in further composition.

Principle 2 (Semantic Representation Binding Principle)**.** *All the logical variables that the body b of a semantic molecule corresponding to a syntagma $\sigma = (w, \binom{h}{b})$, share with other syntagmas, are at the same time values of the variable attributes ($\mathcal{A}_h^v$) of the semantic molecule head.*

There is one variable attribute, $head \in \mathcal{A}_h^v$ that represents the head of a syntagma, giving the following principle:

Principle 3 (Semantic Head Principle)**.** *Given a syntagma $\sigma = (w, \binom{h}{b})$ ground derived from a grammar rule, r, there exists one and only one syntagma $\sigma_i = (w_i, \binom{h_i}{b_i})$ corresponding to a nonterminal B_i in rule r's right-hand side, which has the same value of the attribute $head$, i.e., $h.head = h_i.head$.*

The feature attributes $\mathcal{A}_h^f$ are the attributes whose values express the specific properties of the semantic molecules (e.g., number, person).

Principle 4 (Feature Inheritance Principle)**.** *If $\sigma_i = (w_i, \binom{h_i}{b_i})$ is the semantic head of a ground-derived syntagma $\sigma = (w, \binom{h}{b})$, then all feature attributes of σ inherit the values of the corresponding attributes that belong to the semantic head σ_i. That is, if $h.head = h_i.head$, then $h.f = h_i.f$, $\forall f \in \mathcal{A}_h^f \cap A_{h_i}^f$.*

Besides this principle, the feature attributes are used for category agreement. The categories that enter in agreement are maximum projection categories. This linguistic knowledge about agreement is used in the form of the following principle:

Principle 5 (Feature Agreement Principle)**.** *The agreeing categories and the agreement features are a-priori given based on linguistic knowledge, and are applied only at the semantic head level.*

Given all the above principles, we can now formulate the general Composition Principle:

Principle 6 (Composition Principle)**.** *A syntagma $\sigma = (w, w')$ corresponding to the left-hand side nonterminal of a grammar rule is obtained by string concatenation ($w = w_1 \dots w_n$) and the composition of semantic molecules corresponding to the nonterminals from the rule right-hand side:*

$$w' = \binom{h}{b} = (w_1 \cdots w_n)' = w_1' \circ \cdots \circ w_n'$$
$$= \binom{h_1}{b_1} \circ \cdots \circ \binom{h_n}{b_n} = \binom{h_1 \circ \cdots \circ h_n}{\langle b_1, \dots, b_n\rangle\nu}$$

The composition of the semantic molecule bodies is realized through conjunction after the application of a variable substitution ν. The body variable specialization substitution ν is the most general unifier (mgu) of b and $b_1, \dots, b_n$, s.t $b = (b_1, \dots, b_n)\nu$. It is a particular form of the commonly used substitution (Lloyd, 2003), i.e., a finite set of the form $\{X_1/Y_1, \dots, X_m/Y_m\}$, where $X_1, \dots, X_m, Y_1, \dots, Y_m$ are variables, and $X_1, \dots, X_m$ are distinct.

The composition of the semantic molecule heads is realized by a set of constraints $\Phi_c(h, h_1 ..., h_n)$, which is a system of equations

similar to "path equations" (Shieber et al., 1983; van Noord, 1993), but applied to flat feature structures:

$$\left\{\begin{array}{l} h_i.c = ct \\ h_i.v_i = h_j.v_j \\ h_i.f = ct\ or \\ h_i.f = h_j.f \end{array}\right\} \text{ where } \begin{array}{l} 0 \le i,j \le n, i \ne j \\ c \in \mathcal{A}^c_{h_i} \\ v_i \in \mathcal{A}^v_{h_i}, v_j \in \mathcal{A}^v_{h_j} \\ f \in \mathcal{A}^f_{h_i}, f \in \mathcal{A}^f_{h_j} \end{array}$$

When learning a LWFG rule from a representative example σ as in Figure 2, the robust parser returns the minimum number of chunks, n, covering σ. The body variable substitution ν is fully determined by the representative example as mgu of b and $b_1, \ldots, b_n$, and the compositional constraints $\Phi_c(h, h_1, \ldots, h_n)$ are learned using Alg 1. For example, in Figure 2, when learning from the representative example corresponding to the string *laser printer*, we have that $\nu = \{X_1/B, X_2/A, X_3/A, Y/P_1\}$.

In Alg 1 we use the notation $\sigma_0 = (w_0, \binom{h_0}{b_0})$ to denote the representative example σ.

Alg 1: Learn_Constraints($\sigma_0, \sigma_1, \ldots, \sigma_n$)

$\sigma_i = (w_i, \binom{h_i}{b_i}), 0 \le i \le n$
$\Phi_c \leftarrow \emptyset$
$\nu \leftarrow mgu(b_0, (b_1, \ldots, b_n))$
1 **foreach** $0 \le i \le n \wedge c \in \mathcal{A}^c_{h_i}$ **do**
  if $h_i.c = c1$ **then**
    $\Phi_c \leftarrow \Phi_c \cup \{h_i.c = c1\}$
2 **foreach** $0 \le i,j \le n \wedge i \ne j \wedge X/Y \in \nu \wedge$ $v_i \in \mathcal{A}^v_{h_i} \wedge v_j \in \mathcal{A}^v_{h_j}$ **do**
  if $h_i.v_i = X \wedge h_j.v_j = Y$ **then**
    $\Phi_c \leftarrow \Phi_c \cup \{h_i.v_i = h_j.v_j\}$
3 **if** $h_s.head = h_0.head, 1 \le s \le n$ **then**
  foreach $f \in \mathcal{A}^f_{h_0} \cap \mathcal{A}^f_{h_s}$ **do**
    if $h_0.f = c1 \wedge h_s.f = c1$ **then**
      $\Phi_c \leftarrow \Phi_c \cup \{h_0.f = h_s.f\}$
  if $h_s.cat = c_s \wedge h_i.cat = c_i \wedge agr(c_s, c_i)$, $1 \le i \le n$ **then**
    foreach $f \in agrFeatures(c_s, c_i)$ **do**
      if $h_s.f = c1 \wedge h_i.f = c1$ **then**
        $\Phi_c \leftarrow \Phi_c \cup \{h_s.f = h_i.f\}$
4 **for** *all other* $f \in \mathcal{A}^f_{h_i}, 0 \le i \le n$ **do**
  /*i.e., if we are not in case 3 */
  if $h_i.f = c1$ **then**
    $\Phi_c \leftarrow \Phi_c \cup \{h_i.f = c1\}$
return Φ_c /*i.e., $\Phi_c(h_0, h_1, \ldots, h_n)$ */

In the first step, the constraints corresponding to category attributes are fully determined by the values of these attributes that appear in the semantic molecule heads of $\sigma_0, \ldots \sigma_n$. In Figure 2, when learning the most specific rule r from the representative example *laser printer*, the set of constraints $\{h.cat = nc, h_1.cat = noun, h_2 = noun\} \subset \Phi_{c_4}$ are the constraints corresponding to category attributes. In the second step, the constraints corresponding to variable attributes are fully determined by the variables in the substitution ν that also appear as values of variable attributes $h_i.v_i, h_j.v_j$, where $0 \le i,j \le n$ and $i \ne j$. In Figure 2, only $\{X_2/A, X_3/A\} \subset \nu$ will be used, generating the set of constraints $\{h.head = h_1.mod, h.head = h_2.head\} \subset \Phi_{c_4}$. In the third step, the values of the feature attributes which obey Principles 4 and 5 are generalized — agr(c_s, c_i) is the predicate which gives us the agreement between the categories c_s and c_i (e.g., the subject agrees with the verb), and agrFeatures(c_s, c_i) gives us the set of feature attributes that participate in agreement (e.g., nr, pers, case). In Figure 2, the set of constraints $\{h.nr = h_2.nr\} \subset \Phi_{c_4}$ represents the generalization of the feature attribute values for nr, using Principle 4 . For all features attributes besides the ones that obey the above two principles, the generated constraints keep the particular values of these attributes (step 4 of Alg 1).

6 Examples

The LWFG formalism allows us to learn grammars for deep language understanding from examples. Instead of writing syntactic-semantic grammar by hand (both rules and constraints), we need to provide only a small set of representative examples — strings and their semantic molecules. Qualitative experiments on learning LWFGs showed that complex linguistic constructions can be learned and covered, such as complex noun phrases, relative clauses and reduced relative clauses, finite and non-finite verbal constructions (including, tense, aspect, negation, and subject-verb agreement), and raising and control constructions (Muresan and Rambow, 2007). In Figure 3 we show an example of learning a LWFG grammar for noun-noun compounds. The first four examples (1-4) are representative examples, while the last four examples are used for gener-

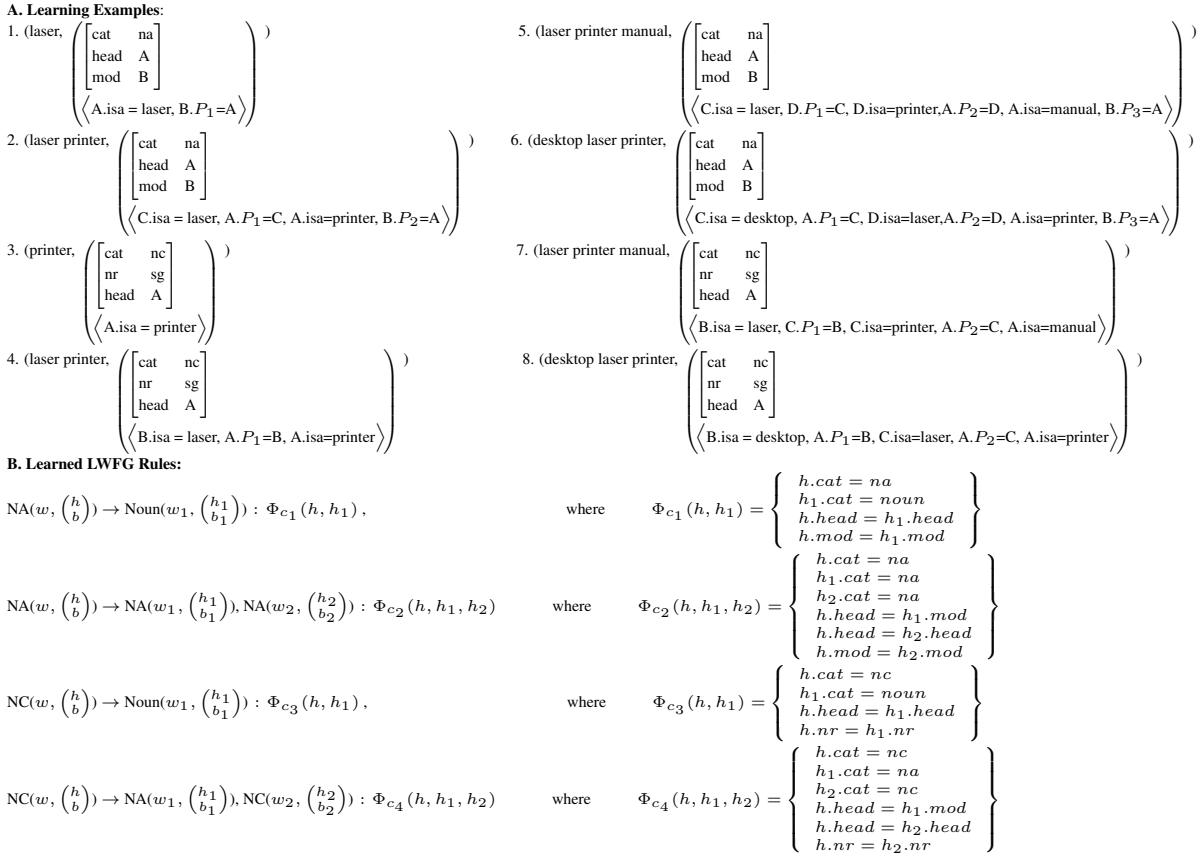

Figure 3: Learning LWFG Rules for Noun-Noun Compounds

alization (5-8). The learned grammar rules, including the learned composition constraints are also shown. The first two LWFG rules ground derive syntagmas for noun adjuncts, while the last two rules ground derive syntagmas for noun compounds. For example, "desktop laser printer" can be either a fully-formed noun compound (category nc), or it can be further combined with the noun "invoice" to obtain "desktop laser printer invoice", case in which it is a noun adjunct (category na). The learned rule for noun adjuncts is both left and right recursive, accounting for both left and right-branching noun compounds. Even though we can obtain overgeneralization in syntax, the ontology-based interpretation constraint at the rule level will prune some erroneous parses. Preliminary results in the medical domain show that Φ_{onto} can help remove erroneous parses even when using just a weak ontological model (semantic roles of verbs, prepositions, attributes of adjectives and adverbs, but no synonymy, or hierarchy of concepts or roles). However, more experiments need to be run for reporting quantitative results.

7 Conclusions

We have presented the properties and principles that the semantic representation integrated in LWFG requires so that the semantic compositional constraints are learnable from examples. These properties together with Alg 1 give a theoretical result that in conjunction with the learnability result of Muresan and Rambow (2007) show that LWFG is a learnable constraint-based grammar formalism that can be used for deep language understanding. Instead of writing grammar rules and constraints by hand, one needs to provide only a small set of annotated examples.[4]

Evaluating performance of grammatical error detection to maximize learning effect

Ryo Nagata

Kazuhide Nakatani
Konan University

Abstract

This paper proposes a method for evaluating grammatical error detection methods to maximize the learning effect obtained by grammatical error detection. To achieve this, this paper sets out the following two hypotheses — imperfect, rather than perfect, error detection maximizes learning effect; and precision-oriented error detection is better than a recall-oriented one in terms of learning effect. Experiments reveal that (i) precision-oriented error detection has a learning effect comparable to that of feedback by a human tutor, although the first hypothesis is not supported; (ii) precision-oriented error detection is better than recall-oriented in terms of learning effect; (iii) F-measure is not always the best way of evaluating error detection methods.

1 Introduction

To reduce the efforts taken to correct grammatical errors in English writing, there has been a great deal of work on grammatical error detection (Brockett et al., 2006; Chodorow and Leacock, 2000; Chodorow and Leacock, 2002; Han et al., 2004; Han et al., 2006; Izumi et al., 2003; Nagata et al., 2004; Nagata et al., 2005; Nagata et al., 2006). One of its promising applications is writing learning assistance by detecting errors and showing the results to the learner as feedback that he or she can use to rewrite his or her essay. Grammatical error detection has greatly improved in detection performance as well as in the types of the errors it is able to detect, including errors in articles, number, prepositions, and agreement.

In view of writing learning assistance, however, one important factor has been missing in the previous work. In the application to writing learning assistance, error detection methods should be evaluated by learning effect obtained by error detection. Nevertheless, they have been evaluated only by detection performance such as F-measure.

This brings up a further research question — are any of the previous methods effective as writing learning assistance? It is very important to answer this question because it is almost impossible to develop a perfect method. In other words, one has to use an imperfect method to assist learners no matter how much improvement is achieved. In practice, it is crucial to reveal the lower bound of detection performance that has a learning effect.

Related to this, one should discuss the following question. Most error detection methods are adjustable to be recall-oriented/precision-oriented by tuning their parameters. Despite this fact, no one has examined which is better in terms of learning effect — recall-oriented or precision-oriented? (hereafter, this problem will be referred to as the *recall-precision problem*). Chodorow and Leacock (2000) and Chodorow et al. (2007) argue that precision-oriented is better, but they do not give any concrete reason. This means that the recall-precision problem has not yet been solved.

Accordingly, this paper explores the relation between detection performance and learning effect. To do this, this paper sets out two hypotheses:

Hypothesis I : imperfect, rather than perfect, error detection maximizes learning effect

Hypothesis II : precision-oriented is better than recall-oriented in terms of learning effect

Hypothesis I contradicts the intuition that the better the detection performance is, the higher the learning effect is. To see the motivation for this,

Coling 2008: Poster Volume, pages 894–900,
Beijing, August 2010

suppose that we had a perfect method. It would detect all errors in a given essay with no false-positives. In that case, the learner would not have to find any errors by himself or herself. Neither would he or she have to examine the causes of the errors. In the worst case, they just copy the detection results. By contrast, with an imperfect method, he or she has to do these activities, which is expected to result in better learning effect. Besides, researchers, including Robb et al. (1986), Bitchener et al. (2005), and Ferris and Roberts (2001), report that the amount of feedback that learners receive does not necessarily correspond to the amount of learning effect. For instance, Robb et al. (1986) compared four types of feedback ((1) error detection and correction, (2) error detection and error type, (3) error detection, and (4) number of errors per line) and reported that (1), the most-detailed feedback, did not necessarily have the highest learning effect.

Hypothesis II concerns the recall-precision problem. If a limited number of errors are detected with high precision (i.e., precision-oriented), learners have to carefully read their own essay to find the rest of the errors by examining whether their writing is correct or not, using several sources of information including (i) the information that can be obtained from the detected errors, which is useful for finding undetected errors similar to the detected ones; (ii) their knowledge on English grammar and writing, and (iii) dictionaries and textbooks. We believe that learning activities, especially learning from similar instances, have a favorable learning effect. By contrast, in a recall-oriented setting, these activities relatively decrease. Instead, learners focus on judging whether given detection results are correct or not. Besides, learning from similar instances is likely not to work well because a recall-oriented setting frequently makes false-positives.

This paper proposes a method for testing the two hypotheses in Sect. 2. It conducts experiments based on the method in Sect. 3. It discusses the experimental results in Sect. 4.

2 Method

We conducted a pre-experiment where ten subjects participated and wrote 5.6 essays on average. We used the obtained data to design the method.

2.1 Target Errors

To obtain general conclusions, one has to test **Hypothesis I** and **Hypothesis II** against a variety of errors and also a variety of error detection methods. However, it would not be reasonable or feasible to do this from the beginning.

Considering this, this paper targets errors in articles and number. The reasons for selecting these are that (a) articles and number are difficult for learners of English (Izumi et al., 2003; Nagata et al., 2005), and (b) there has been a great deal of work on the detection of these errors.

2.2 Error detection method

Among the previous methods for detecting errors in articles and number, this paper selects Nagata et al. (2006)'s method that detects errors in articles and number based on countability prediction. It has been shown to be effective in the detection of errors in articles and number (Nagata et al., 2005; Nagata et al., 2006). It also has the favorable property that it can be adjusted to be recall-oriented or precision-oriented by setting a threshold for the probability used in countability prediction. This subsection briefly describes Nagata et al. (2006)'s method (See Nagata et al. (2006) for the details).

The method, first, automatically generates training instances for countability prediction. Instances of each noun that head their noun phrase (NP) are collected from a corpus with their surrounding words. Then, the collected instances are tagged with their countability by a set of hand-coded rules. The resulting tagged instances are used as training data for countability prediction.

Decision lists (Yarowsky, 1995) are used to predict countability. Tree types of contextual cue are used as features: (i) words in the NP that the target noun heads; (ii) three words to the left of the NP; (iii) three words to its right. The log-likelihood ratio (Yarowsky, 1995) decides in which order rules in a decision list are applied to the target noun in countability prediction. It is the log ratio of the probabilities of the target noun being count and non-count when one of the features appears in its context. To predict countability in error detection, each rule in the decision list is tested on the target

noun in the sorted order until the first applicable one is found. The prediction is made by the first applicable one.

After countability prediction, errors in articles and number are detected by using a set of rules. For example, if the noun in question is plural and predicted to be non-count, then it is an error. Similarly, the noun in question has no article and is singular and is predicted to be count, then it is an error.

The balance of recall and precision in error detection can be adjusted by setting a certain threshold to the probabilities used to calculate the log-likelihood ratio[1]. If the probability of the applied rule in countability prediction is lower than a certain threshed, error detection is blocked. Namely, the higher the threshed is, the more precision-oriented the detection is.

2.3 Learning Activity

The proposed method is based on a learning activity consisting of essay writing, error detection, and rewriting. Table 1 shows the flow of the learning activity. In Step 1, an essay topic is assigned to learners. In Step 2, they have time to think about what to write with a piece of white paper for preparation (e.g., to summarize his or her ideas). In Step 3, they write an essay on a blog system in which the error detection method (Nagata et al., 2005) is implemented. This system allows them to write, submit, and rewrite their essays (though it does not allow them to access the others' essays or their own previous essays). They are not allowed to use any dictionary or textbook in this step. They are required to write ten sentences or more. In Step 4, the system detects errors in each essay. It displays each essay of which errors are indicated in red to the corresponding learner. Although the detection itself takes only a few seconds, five minutes are assigned to this step for two purposes: to take a short break for learners and to remove time differences between learners. Finally, in Step 5, learners rewrite their essay using the given feedback. Here, they are allowed to use a dictionary (Konishi and Minamide, 2007) and an A4 paper that briefly explains article and number usage, which was made based on grammar books (Hirota, 1992; Iizuka and Hagino, 1997). They are informed that the feedback may contain false-positives and false-negatives.

Table 1: Flow of learning activity

Procedure	Min
1. Learner is assigned an essay topic	–
2. Learner prepares for writing	5
3. Learner writes an essay	35
4. System detects errors in the essay	5
5. Learner rewrites the essay	15

2.4 How to Measure Learning Effect

Before discussing how to measure learning effect, one has to define the ability to write English. Considering that this paper aims at the evaluation of error detection, it is reasonable to define the ability as the degree of error occurrence (that is, the fewer errors, the better). To measure this, this paper uses error rate, which is defined by

$$e = \frac{\text{Number of target errors in Step 3} + 1}{\text{Number of NPs in Step 3} + 1}. \quad (1)$$

Ones ("+1") are added to the numerator and denominator for a mathematical reason that will be clear shortly. The addition also has the advantage that it can evaluate a longer essay to be better when no errors occur.

Having defined ability, it is natural to measure learning effect by a decrease in the error rate. Simply, it is estimated by applying the linear regression to the number of instances of learning and the corresponding error rates.

Having said this, this paper applies an exponential regression instead of the linear regression. There are two reasons for this. The first is that it becomes more difficult to decrease the error rate as it decreases (in other words, it becomes more difficulty to improve one's ability as one improves). The other is that the error rate is expected to asymptotically decrease to zero as learning proceeds. The exponential regression is defined by

$$e = \exp\{a(t + b)\} \quad (2)$$

[1] Setting a threshold to the probability is equivalent to setting a threshold to the log-likelihood and both has the same effect on the balance of recall and precision. However, we use the former because it is intuitive and easy to set a threshold

where t, a, and b denote the number of instances of learning, decrease in the error rate (learning effect), and the ability before the learning starts, respectively. The parameters a and b can be estimated from experimental data by least squares.

To examine **Hypothesis I** and **Hypothesis II**, the learning effect parameter a must be estimated for several error detection conditions. To do this, detection performance (recall, precision, and F-measure) is first defined. Recall and precision is defined by

$$r = \frac{\text{Number of errors correctly detected}}{\text{Number of errors}} \quad (3)$$

and

$$p = \frac{\text{Number of errors correctly detected}}{\text{Number of errors detected}}, \quad (4)$$

respectively. Using recall and precision, F-measure is defined by

$$f = \frac{2rp}{r+p}. \quad (5)$$

With these, this paper compares four conditions. In the first condition, the system detects no error at all. Thus, it plays a role as a baseline. The second and third conditions are recall-oriented and precision-oriented, respectively. The threshold that maximized F-measure, which was 0.60, was computed by applying the error detection method to the essays obtained in the pre-experiment (increasing the threshold from 0 to 1, 0.05 at a time). This was selected as the recall-oriented condition. Then, the threshold for the precision-oriented condition was determined to be 0.90 so that its precision became higher. The final condition corresponds to the perfect error detection. Because it was impossible to implement such error detection, a native speaker of English took this part. Hereafter, the four conditions will be referred to as **No-feedback**, **Recall-oriented**, **Precision-oriented**, and **Human**.

3 Experiments

As subjects, 26 Japanese college students (first to fourth grade) participated in the experiments. These 26 subjects were assigned to each condition as follows: **Human**: 6; **Recall-oriented**: 7; **Precision-oriented**: 7; **No-feedback** 6:.

Table 2: Essay topics used in the experiments

No.	Topic
1	University life
2	Summer vacation
3	Gardening
4	My hobby
5	My frightening experience
6	Reading
7	My home town
8	Traveling
9	My favorite thing
10	Cooking

The number of learning activities was ten. Essay Topics for each learning activity is shown in Table 2 They were selected based on a writing textbook (Okihara, 1985). The experiments were conducted from Oct. 2008 to Dec. 2008. The subjects basically did the learning activity twice a week on average. Some of them could not finish the ten-essays assignment during this term. Subjects who did not do the learning activity eight or more times were excluded from the experiments. As a result, 22 subjects were valid in the end (**Human**: 4; **Recall-oriented**: 7; **Precision-oriented**: 6; **No-feedback**: 5).

Figure 1 shows the experimental results. It shows the plots of Eq. (2) where a is calculated by averaging the estimated values of a over each condition (**No-feedback**: $a = -0.024$; **Recall-oriented**: $a = -0.015$; **Precision-oriented**: $a = -0.038$; **Human**: $a = -0.046$). The value of b is set to 0 for the purpose of comparison.

4 Discussion

Although **Hypothesis I** is not supported, the experimental results reveal that **Precision-oriented** has a learning effect comparable to **Human**. A concrete example makes this clearer. **Precision-oriented** takes 18 instances of learning to decrease the error rate 32%, which is the average of the subjects at the beginning, by half. This is very near the 16 instances of **Human**. By contrast, **No-feedback** takes nearly double that (29 times), and **Recall-oriented** far more (47 times).

From these results, it follows that one should

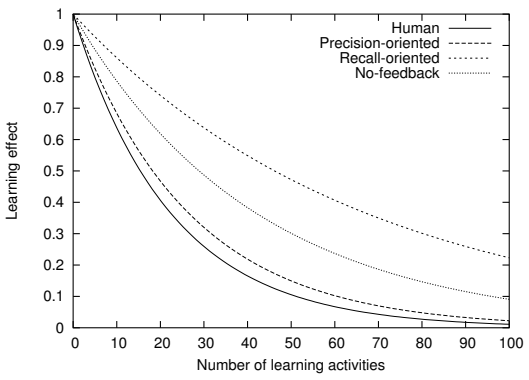

Figure 1: Experimental results

use precision-oriented error detection for writing learning assistance in a circumstance where feedback by a human tutor is not fully available (e.g., writing classroom consisting of a number of students). According to Burstein et al. (1998), the best way to improve one's writing skills is (i) to write, (ii) to receive feedback from a human tutor, (iii) to revise based on the feedback, and then repeat the whole process as often as possible. However, it is almost impossible to practice this in a writing classroom consisting of a number of students. In such circumstances, this can be done by using precision-oriented error detection. At the end, learners may have their essays corrected by a human tutor, which guarantees the quality of feedback, still reducing the efforts of human tutors.

At the same time, it should be emphasized that this is not a general but a limited conclusion because the experiments involve limited target errors and a limited number of subjects. In different conditions (e.g., setting a higher threshold), **Precision-oriented** may outperform **Human**, meaning that **Hypothesis I** is not conclusively rejected.

The experimental results support **Hypothesis II** as we expected. The learning effect of **Recall-oriented** is even less than **No-feedback**. A possible reason for this is that false-positives, which **Recall-oriented** frequently makes, confused the subjects. By contrast, **Precision-oriented** achieved better learning effect because it detected a few errors with a high precision. To be precise, **Recall-oriented** achieved a precision of 0.60 with a recall 0.31 whereas a precision of 0.72 with a recall of 0.25 in **Precision-oriented**. Besides, the fact that **Recall-oriented** detects errors more frequently with less precision (that is, the number of false-positives is higher) might make learners feel as if the precision is lower than is actually. This might have discouraged the subjects in **Recall-oriented** from learning.

These results suggest interesting findings from another point of view. In the past, overall performance of error detection has often been evaluated by F-measure, which considers both recall and precision. Following this convention, one comes to the conclusion that **Recall-oriented** ($F = 0.41$) is superior to **Precision-oriented** ($F = 0.37$). Contrary to this, the experimental results favor **Precision-oriented** over **Recall-oriented** in terms of learning effect. This suggest that F-measure is not always the best method of evaluation.

To conclude this section, let us discuss some problems with the proposed method that the experiments have revealed. To obtain more general conclusions, the amount of experimental data should be increased. However, it appeared to be difficult for the subjects to do the learning activity more than ten times; some subjects might have got bored with repeating the same learning activities. This is the problem that has to be solved in its actual use in learning assistance. Another problem is that detection performance tends to decrease relative to the original as learning proceeds because subjects improve (for instance, $F = 0.44$ for the first half and $F = 0.38$ for the last half in **Recall-oriented**). In order to investigate the relation between detection performance and learning effect more deeply, one should take this fact into consideration.

5 Conclusions

This paper tested the two hypotheses — imperfect, rather than perfect, error detection maximizes learning effect; and precision-oriented error detection is better than a recall-oriented one in terms of learning effect. The experiments revealed the interesting findings that precision-oriented error detection has learning effect similar to that of

feedback by a human tutor, although the first hypothesis was not supported. Considering the findings, this paper has come to the conclusion that one should use precision-oriented error detection to assist writing learning in a circumstance where feedback by human tutors is not fully available. By contrast, the experiments supported the second hypothesis. They also showed that F-measure was not always the best way of evaluation.

In future work, we will expand the experiments in terms of both the number of subjects and target errors, such as errors in preposition, to obtain more general conclusions. The essays which are collected and error-annotated[2] in the experiments are available as a learner corpus for research and education purposes. Those who are interested in the learner corpus should contact the author.

Kernel-based Reranking for Named-Entity Extraction

Truc-Vien T. Nguyen and **Alessandro Moschitti** and **Giuseppe Riccardi**
Department of Information Engineering and Computer Science
University of Trento
nguyenthi,moschitti,riccardi@disi.unitn.it

Abstract

We present novel kernels based on structured and unstructured features for reranking the *N*-best hypotheses of conditional random fields (CRFs) applied to entity extraction. The former features are generated by a polynomial kernel encoding entity features whereas tree kernels are used to model dependencies amongst tagged candidate examples. The experiments on two standard corpora in two languages, i.e. the Italian EVALITA 2009 and the English CoNLL 2003 datasets, show a large improvement on CRFs in F-measure, i.e. from 80.34% to 84.33% and from 84.86% to 88.16%, respectively. Our analysis reveals that both kernels provide a comparable improvement over the CRFs baseline. Additionally, their combination improves CRFs much more than the sum of the individual contributions, suggesting an interesting kernel synergy.

1 Introduction

Reranking is a promising computational framework, which has drawn special attention in the Natural Language Processing (NLP) community. Basically, this method first employs a probabilistic model to generate a list of top-*n* candidates and then reranks this *n*-best list with additional features. One appeal of this approach is its flexibility of incorporating arbitrary features into a model. These features help in discriminating good from bad hypotheses and consequently their automatic learning. Various algorithms have been applied for reranking in NLP applications (Huang, 2008; Shen et al., 2004; Collins, 2002b; Collins and Koo, 2000), including parsing, name tagging and machine translation. This work has exploited the disciminative property as one of the key criterion of the reranking algorithm.

Reranking appears extremely interesting if coupled with kernel methods (Dinarelli et al., 2009; Moschitti, 2004; Collins and Duffy, 2001), as the latter allow for extracting from the ranking hypotheses a huge amount of features along with their dependencies. Indeed, while feature-based learning algorithms involve only the dot-product between feature vectors, kernel methods allow for a higher generalization by replacing the dot-product with a function between pairs of linguistic objects. Such functions are a kind of similarity measure satisfying certain properties. An example is the tree kernel (Collins and Duffy, 2001), where the objects are syntactic trees that encode grammatical derivations and the kernel function computes the number of common *subtrees*. Similarly, sequence kernels (Lodhi et al., 2002) count the number of common *subsequences* shared by two input strings.

Named-entities (NEs) are essential for defining the semantics of a document. NEs are objects that can be referred by names (Chinchor and Robinson, 1998), such as people, organizations, and locations. The research on NER has been promoted by the Message Understanding Conferences (MUCs, 1987-1998), the shared task of the Conference on Natural Language Learning (CoNLL, 2002-2003), and the Automatic Content Extraction program (ACE, 2002-2005). In the literature, there exist various learning approaches to extract named-entities from text. A NER sys-

Coling 2008: Poster Volume, pages 901–909,
Beijing, August 2010

tem often builds some generative/discriminative model, then, either uses only one classifier (Carreras et al., 2002) or combines many classifiers using some heuristics (Florian et al., 2003).

To the best of our knowledge, reranking has not been applied to NER except for the reranking algorithms defined in (Collins, 2002b; Collins, 2002a), which only targeted the entity detection (and not entity classification) task. Besides, since kernel methods offer a natural way to exploit linguistic properties, applying kernels for NE reranking is worthwhile.

In this paper, we describe how kernel methods can be applied for reranking, i.e. detection and classification of named-entities, in standard corpora for Italian and English. The key aspect of our reranking approach is how structured and flat features can be employed in discriminating candidate tagged sequences. For this purpose, we apply tree kernels to a tree structure encoding NE tags of a sentence and combined them with a polynomial kernel, which efficiently exploits global features.

Our main contribution is to show that (a) tree kernels can be used to define general features (not merely syntactic) and (b) using appropriate algorithms and features, reranking can be very effective for named-entity recognition. Our study demonstrates that the composite kernel is very effective for reranking named-entity sequences. Without the need of producing and heuristically combining learning models like previous work on NER, the composite kernel not only captures most of the flat features but also efficiently exploits structured features. More interestingly, this kernel yields significant improvement when applied to two corpora of two different languages. The evaluation in the Italian corpus shows that our method outperforms the best reported methods whereas on the English data it reaches the state-of-the-art.

2 Background

2.1 The data

Different languages exhibit different linguistic phenomena and challenges. A robust NER system is expected to be well-adapted to multiple domains and languages. Therefore, we experimented with two datasets: the EVALITA 2009 Italian corpus and the well-known CoNLL 2003 English shared task corpus.

The EVALITA 2009 Italian dataset is based on I-CAB, the Italian Content Annotation Bank (Magnini et al., 2006), annotated with four entity types: Person (PER), Organization (ORG), Geo-Political Entity (GPE) and Location (LOC). The training data, taken from the local newspaper "L'Adige", consists of 525 news stories which belong to five categories: News Stories, Cultural News, Economic News, Sports News and Local News. Test data, on the other hand, consist of completely new data, taken from the same newspaper and consists of 180 news stories.

The CoNLL 2003 English dataset is created within the shared task of CoNLL-2003 (Sang and Meulder, 2003). It is a collection of news wire articles from the Reuters Corpus, annotated with four entity types: Person (PER), Location (LOC), Organization (ORG) and Miscellaneous name (MISC). The training and the development datasets are news feeds from August 1996, while the test set contains news feeds from December 1996. Accordingly, the named entities in the test dataset are considerably different from those that appear in the training or the development set.

Italian	GPE	LOC	ORG	PER

Table 1: Statistics on the Italian EVALITA 2009 and English CoNLL 2003 corpora.

2.2 The baseline algorithm

We selected Conditional Random Fields (Lafferty et al., 2001) as the baseline model. Conditional

random fields (CRFs) are a probabilistic framework for labeling and segmenting sequence data. They present several advantages over other purely generative models such as Hidden Markov models (HMMs) by relaxing the independence assumptions required by HMMs. Besides, HMMs and other discriminative Markov models are prone to the label bias problem, which is effectively solved by CRFs.

The named-entity recognition (NER) task is framed as assigning label sequences to a set of observation sequences. We follow the IOB notation where the NE tags have the format B-TYPE, I-TYPE or O, which mean that the word is a beginning, a continuation of an entity, or not part of an entity at all. For example, consider the sentence with their corresponding NE tags, each word is labeled with a tag indicating its appropriate named-entity, resulting in annotated text, such as:

Il/O **presidente**/O **della**/O **Fifa**/B-ORG **Sepp**/B-PER **Blatter**/I-PER **affermando**/O **che**/O **il**/O **torneo**/O **era**/O **stato**/O **ottimo**/O (FIFA president Sepp Blatter says that the tournament was excellent)

For our experiments, we used CRF++ [1] to build our recognizer, which is a model trained discriminatively with the unigram and bigram features. These are extracted from a window at k words centered in the target word *w* (i.e. the one we want to classify with the B, O, I tags). More in detail such features are:

- The **word itself**, its **prefixes**, **suffixes**, and **part-of-speech**
- **Orthographic/Word features**. These are binary and mutually exclusive features that test whether a word contains *all upper-cased, initial letter upper-cased, all lower-cased, roman-number, dots, hyphens, acronym, lonely initial, punctuation mark, single-char, and functional-word*.
- **Gazetteer features**. Class (geographical, first name, surname, organization prefix, location prefix) of words in the window.
- **Left Predictions**. The predicted tags on the left of the word in the current classification.

[1] http://crfpp.sourceforge.net

The gazetteer lists are built with names imported from different sources. For English, the geographic features are imported from NIMA's GEOnet Names Server (GNS)[2], The Alexandria Digital Library (ADL) gazetteer[3]. The company data is included with all the publicly traded companies listed in Google directory[4], the European business directory[5]. For Italian, the generic proper nouns are extracted from Wikipedia and various Italian sites.

2.3 Support Vector Machines (SVMs)

Support Vector Machines refer to a supervised machine learning technique based on the latest results of the statistical learning theory. Given a vector space and a set of training points, i.e. positive and negative examples, SVMs find a separating hyperplane $H(\vec{x}) = \vec{\omega} \times \vec{x} + b = 0$ where $\omega \in R^n$ and $b \in R$ are learned by applying the Structural Risk Minimization principle (Vapnik, 1998). SVMs are a binary classifier, but they can be easily extended to multi-class classifier, e.g. by means of the *one-vs-all* method (Rifkin and Poggio, 2002).

One strong point of SVMs is the possibility to apply kernel methods to implicitly map data in a new space where the examples are *more easily* separable as described in the next section.

2.4 Kernel methods

Kernel methods (Schölkopf and Smola, 2001) are an attractive alternative to feature-based methods since the applied learning algorithm only needs to compute a product between a pair of objects (by means of kernel functions), avoiding the explicit feature representation. A kernel function is a scalar product in a possibly unknown feature space. More precisely, The object *o* is mapped in $\vec{x}$ with a feature function $\phi : \mathcal{O} \rightarrow \Re^n$, where $\mathcal{O}$ is the set of the objects.

The kernel trick allows us to rewrite the decision hyperplane as:

$$H(\vec{x}) = \Big(\sum_{i=1..l} y_i \alpha_i \vec{x}_i \Big) \cdot \vec{x} + b =$$

[2] http://www.nima.mil/gns/html
[3] http://www.alexandria.ucsb.edu
[4] http://directory.google.com/Top/Business
[5] http://www.europages.net

$$\sum_{i=1..l} y_i \alpha_i \vec{x}_i \cdot \vec{x} + b = \sum_{i=1..l} y_i \alpha_i \phi(o_i) \cdot \phi(o) + b,$$

where y_i is equal to 1 for positive and -1 for negative examples, $\alpha_i \in \Re$ with $\alpha_i \geq 0$, o_i $\forall i \in \{1, .., l\}$ are the training instances and the product $K(o_i, o) = \langle \phi(o_i) \cdot \phi(o) \rangle$ is the kernel function associated with the mapping ϕ.

Kernel engineering can be carried out by combining basic kernels with additive or multiplicative operators or by designing specific data objects (vectors, sequences and tree structures) for the target tasks.

Regarding NLP applications, kernel methods have attracted much interest due to the ability of implicitly exploring huge amounts of structural features. The parse tree kernel (Collins and Duffy, 2001) and string kernel (Lodhi et al., 2002) are examples of the well-known convolution kernels used in various NLP tasks.

2.5 Tree Kernels

Tree kernels represent trees in terms of their substructures (called tree fragments). Such fragments form a feature space which, in turn, is mapped into a vector space. Tree kernels measure the similarity between pair of trees by counting the number of fragments in common. There are three important characterizations of fragment type: the SubTrees (ST), the SubSet Trees (SST) and the Partial Trees (PT). For sake of space, we do not report the mathematical description of them, which is available in (Vishwanathan and Smola, 2002), (Collins and Duffy, 2001) and (Moschitti, 2006), respectively. In contrast, we report some descriptions in terms of feature space that may be useful to understand the new engineered kernels.

In principle, a SubTree (ST) is defined by taking any node along with its descendants. A SubSet Tree (SST) is a more general structure which does not necessarily include all the descendants. The distinction is that an SST must be generated by applying the same grammatical rule set which generated the original tree, as pointed out in (Collins and Duffy, 2001). A Partial Tree (PT) is a more general form of sub-structures obtained by relaxing constraints over the SSTs. Figure 1 shows the overall fragment set of the ST, SST and PT kernels for the syntactic parse tree of the sentence fragment: *gives a talk* .

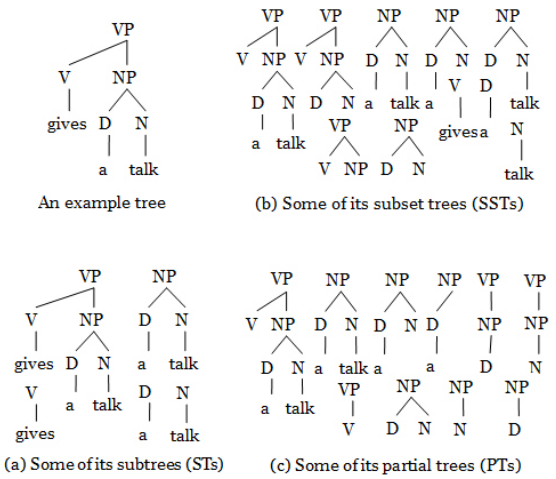

Figure 1: Three kinds of tree kernels.

In the next section, we will define new structures for tagged sequences of NEs which along with the application of the PT kernel produce innovative tagging kernels for reranking.

3 Reranking Method

3.1 Reranking Strategy

As a baseline we trained the CRFs model to generate *10*-best candidates per sentence, along with their probabilities. Each candidate was then represented by a semantic tree together with a feature vector. We consider our reranking task as a binary classification problem where examples are pairs of hypotheses $< H_i, H_j >$.

Given a sentence "**South African Breweries Ltd bought stakes in the Lech and Tychy brewers**" and three of its candidate tagged sequences:

H_1 *B-ORG I-ORG I-ORG I-ORG O O O O B-ORG O B-ORG O* (the correct sequence)

H_2 *B-MISC I-MISC B-ORG I-ORG O O O O B-ORG I-ORG I-ORG O*

H_3 *B-ORG I-ORG I-ORG I-ORG O O O O B-ORG O B-LOC O*

where B-ORG, I-ORG, B-LOC, O are the generated NE tags according to IOB notation as described in Section 3.2.

With the above data (an original sentence together with a list of candidate tagged sequences), the following pairs of hypotheses will be gener-

ated $< H_1, H_2 >$, $< H_1, H_3 >$,$< H_2, H_1 >$ and $< H_3, H_1 >$, where the first two pairs are positive and the latter pairs are negative instances. Then a binary classifier based on SVMs and kernel methods can be trained to discriminate between the best hypothesis, i.e. $< H_1 >$ and the others. At testing time the hypothesis receiving the highest score is selected (Collins and Duffy, 2001).

3.2 Representation of Tagged Sequences in Semantic Trees

We now consider the representation that exploits the most discriminative aspects of candidate structures. As in the case of NER, an input candidate is a sequence of word/tag pairs $x = \{w_1/t_1...w_n/t_n\}$ where w_i is the i'th word and t_i is the i'th NE tag for that word. The first representation we consider is the tree structure. See figure 2 as an example of candidate tagged sequence and its semantic tree.

With the sentence "**South African Breweries Ltd bought stakes in the Lech and Tychy brewers**" and three of its candidate tagged sequences in the previous section, the training algorithm considers to construct a tree for each sequence, with the named-entity tags as pre-terminals and the words as leaves. See figure 2 for an example of the semantic tree for the first tagged sequence.

With this tree representation, for a word w_i, the target NE tag would be set at parent and the features for this word are at child nodes. This allows us to best exploit the inner product between competing candidates. Indeed, in the kernel space, the inner product counts the number of common subtrees thus sequences with similar NE tags are likely to have higher score. For example, the similarity between H_1 and H_3 will be higher than the similarity of the previous hypotheses with H_2; this is reasonable since these two also have higher F_1.

It is worth noting that another useful modification is the flexibility of incorporate diverse, arbitrary features into this tree structure by adding children to the parent node that contains entity tag. These characteristics can be exploited efficiently with the PT kernel, which relaxes constraints of production rules. The inner product can implicitly include these features and deal better with sparse data.

3.3 Global features

Mixed *n-grams* features

In previous works, some global features have been used (Collins, 2002b; Collins, 2002a) but the employed algorithm just exploited arbitrary information regarding word types and linguistic patterns. In contrast, we define and study diverse features by also considering *n-grams* patterns preceding, and following the target entity.

Complementary *context*

In supervised learning, NER systems often suffer from low recall, which is caused by lack of both resource and context. For example, a word like "Arkansas" may not appear in the training set and in the test set, there may not be enough context to infer its NE tag. In such cases, neither global features (Chieu and Ng, 2002) nor aggregated contexts (Chieu and Ng, 2003) can help.

To overcome this deficiency, we employed the following unsupervised procedure: first, the baseline NER is applied to the target un-annotated corpus. Second, we associate each word of the corpus with the most frequent NE category assigned in the previous step. Finally, the above tags are used as features during the training of the improved NER and also for building the feature representation for a new classification instance.

This way, for any unknown word w of the test set, we can rely on the most probable NE category as feature. The advantage is that we derived it by using the average over many possible contexts of w, which are in the different instances of the unnanotated corpus.

The unlabeled corpus for Italian was collected from La Repubblica [6] and it contains over 20 millions words. Whereas the unlabeled corpus for English was collected mainly from The New York Times [7] and BBC news stories [8] with more than 35 millions words.

Head word

As the head word of an entity plays an important role in information extraction (Bunescu and Mooney, 2005a; Surdeanu et al., 2003), it is in-

[6] http://www.repubblica.it/
[7] http://www.nytimes.com/
[8] http://news.bbc.co.uk/

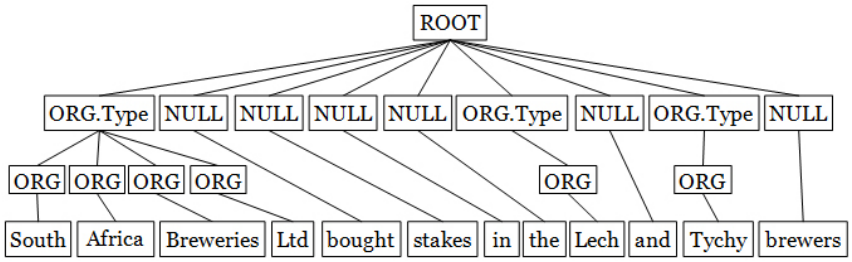

Figure 2: Semantic structure of the first sequence

cluded in the global set together with its orthographic feature. We now describe some primitives for our global feature framework.

1. w_i for $i = 1 \ldots n$ is the i'th word
2. t_i is the NE tag of w_i
3. g_i is the gazetteer feature of the word w_i
4. f_i is the most frequent NE tag seen in a large corpus of w_i
5. h_i is the head word of the entity. We normally set the head word of an entity as its last word. However, when a preposition exists in the entity string, its head word is set as the last word before the preposition. For example, the head word of the entity "University of Pennsylvania" is "University".
6. Mixed *n-grams* features of the words and their gazetteers/frequent-tag before/after the start/end of an entity. In addition to the normal *n-grams* solely based on words, we mixed words with gazetteers/frequent-tag seen from a large corpus and create mixed *n-grams* features.

Table 2 shows the full set of global features in our reranking framework. Features are anchored to each entity instance and adapted to entity types. This helps to discriminate different entities with the same surface forms. Moreover, they can be combined with *n-grams* patterns to learn and explicitly push the score of the correct sequence above the score of competing sequences.

3.4 Reranking with Composite Kernel

In this section we describe our novel tagging kernels based on diverse global features as well as semantic trees for reranking candidate tagged sequences. As mentioned in the previous section, we can engineer kernels by combining tree and entity kernels. Thus we focus on the problem to define structure embedding the desired relational information among tagged sequences.

The Partial Tree Kernel

Let $F = f_1, f_2, \ldots, f_{|F|}$ be a tree fragment space of type PTs and let the indicator function $I_i(n)$ be equal to 1 if the target f_1 is rooted at node n and 0 otherwise, we define the PT kernel as:

$$K(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2)$$

where N_{T_1} and N_{T_2} are the set of nodes in T_1 and T_2 respectively and $\Delta(n_1, n_2) = \sum_{i=1}^{|F|} I_i(n_1) I_i(n_2)$, i.e. the number of common fragments rooted at the n_1 and n_2 nodes of the type shown in Figure 1.c.

The Polynomial Kernel

The polynomial kernel between two candidate tagged sequences is defined as:

$$K(x, y) = (1 + \vec{x}_1 \cdot \vec{x}_2)^2,$$

where $\vec{x}_1$ and $\vec{x}_2$ are two feature vectors extracted from the two sequences with the global feature template.

The Tagging Kernels

In our reranking framework, we incorporate the probability from the original model with the tree structure as well as the feature vectors. Let us consider the following notations:

Feature	Description
$w_s\_w_{s+1}\_\ldots\_w_e$	Entity string
$g_s\_g_{s+1}\_\ldots\_g_e$	The gazetteer feature within the entity
$f_s\_f_{s+1}\_\ldots\_f_e$	The most frequent NE tag feature (seen from a large corpus) within the entity
hw	The head word of the entity
lhw	Indicates whether the head word is lower-cased
$w_{s-1}\_w_s$; $w_{s-1}\_g_s$; $g_{s-1}\_w_s$; $g_{s-1}\_g_s$	Mixed bigrams of the words/gazetteer features before/after the start of the entity
$w_e\_w_{e+1}$; $w_e\_g_{e+1}$; $g_e\_w_{e+1}$; $g_e\_g_{e+1}$	Mixed bigrams of the words/gazetteer features before/after the end of the entity
$w_{s-1}\_w_s$; $w_{s-1}\_f_s$; $f_{s-1}\_w_s$; $f_{s-1}\_f_s$	Mixed bigrams of the words/frequent-tag features before/after the start of the entity
$w_e\_w_{e+1}$; $w_e\_f_{e+1}$; $f_e\_w_{e+1}$; $f_e\_f_{e+1}$	Mixed bigrams of the words/frequent-tag features before/after the end of the entity
$w_{s-2}\_w_{s-1}\_w_s$; $w_{s-1}\_w_s\_w_{s+1}$; $w_{e-1}\_w_e\_w_{e+1}$; $w_{e-2}\_w_{e-1}\_w_e$	Trigram features of the words before/after the start/end of the entity
$w_{s-2}\_w_{s-1}\_g_s$; $w_{s-2}\_g_{s-1}\_w_s$; $w_{s-2}\_g_{s-1}\_g_s$; $g_{s-2}\_w_{s-1}\_w_s$; $g_{s-2}\_w_{s-1}\_g_s$; $g_{s-2}\_g_{s-1}\_w_s$; $g_{s-2}\_g_{s-1}\_g_s$; $w_{s-1}\_w_s\_g_{s+1}$; $w_{s-1}\_g_s\_w_{s+1}$; $w_{s-1}\_g_s\_g_{s+1}$; $g_{s-1}\_w_s\_w_{s+1}$; $g_{s-1}\_w_s\_g_{s+1}$; $g_{s-1}\_g_s\_w_{s+1}$; $g_{s-1}\_g_s\_g_{s+1}$	Mixed trigrams of the words/gazetteer features before/after the start of the entity
$w_{e-1}\_w_e\_g_{e+1}$; $w_{e-1}\_g_e\_w_{e+1}$; $w_{e-1}\_g_e\_g_{e+1}$; $g_{e-1}\_w_e\_w_{e+1}$; $g_{e-1}\_w_e\_g_{e+1}$; $g_{e-1}\_g_e\_w_{e+1}$; $g_{e-1}\_g_e\_g_{e+1}$; $w_{e-2}\_w_{e-1}\_g_e$; $w_{e-2}\_g_{e-1}\_w_e$; $w_{e-2}\_g_{e-1}\_g_e$; $g_{e-2}\_w_{e-1}\_w_e$; $g_{e-2}\_w_{e-1}\_g_e$; $g_{e-2}\_g_{e-1}\_w_e$; $g_{e-2}\_g_{e-1}\_g_e$	Mixed trigrams of the words/gazetteer features before/after the end of the entity
$w_{s-2}\_w_{s-1}\_f_s$; $w_{s-2}\_f_{s-1}\_w_s$; $w_{s-2}\_f_{s-1}\_f_s$; $f_{s-2}\_w_{s-1}\_w_s$; $f_{s-2}\_w_{s-1}\_f_s$; $f_{s-2}\_f_{s-1}\_w_s$; $f_{s-2}\_f_{s-1}\_f_s$; $w_{s-1}\_w_s\_f_{s+1}$; $w_{s-1}\_f_s\_w_{s+1}$; $w_{s-1}\_f_s\_f_{s+1}$; $f_{s-1}\_w_s\_w_{s+1}$; $f_{s-1}\_w_s\_f_{s+1}$; $f_{s-1}\_f_s\_w_{s+1}$; $f_{s-1}\_f_s\_f_{s+1}$	Mixed trigrams of the words/frequent-tag features before/after the start of the entity
$w_{e-1}\_w_e\_f_{e+1}$; $w_{e-1}\_f_e\_w_{e+1}$; $w_{e-1}\_f_e\_f_{e+1}$; $f_{e-1}\_w_e\_w_{e+1}$; $f_{e-1}\_w_e\_f_{e+1}$; $f_{e-1}\_f_e\_w_{e+1}$; $f_{e-1}\_f_e\_f_{e+1}$; $w_{e-2}\_w_{e-1}\_f_e$; $w_{e-2}\_f_{e-1}\_w_e$; $w_{e-2}\_f_{e-1}\_f_e$; $f_{e-2}\_w_{e-1}\_w_e$; $f_{e-2}\_w_{e-1}\_f_e$; $f_{e-2}\_f_{e-1}\_w_e$; $f_{e-2}\_f_{e-1}\_f_e$	Mixed trigrams of the words/frequent-tag features before/after the end of the entity

Table 2: Global features in the entity kernel for reranking. These features are anchored for each entity instance and adapted to entity categories. For example, the entity string (first feature) of the entity "United Nations" with entity type "ORG" is "ORG United Nations".

- $K(x, y) = L(x) \cdot L(y)$ is the basic kernel where $L(x)$ is the log probability of a candidate tagged sequence x under the original probability model.
- $TK(x, y) = t(x) \cdot t(y)$ is the partial tree kernel under the structure representation
- $FK(x, y) = f(x) \cdot f(y)$ is the polynomial kernel under the global features

The tagging kernels between two tagged sequences are defined in the following combinations:

1. $CTK = \alpha \cdot K + (1 - \alpha) \cdot TK$
2. $CFK = \beta \cdot K + (1 - \beta) \cdot FK$
3. $CTFK = \gamma \cdot K + (1 - \gamma) \cdot (TK + FK)$

where α, β, γ are parameters weighting the two participating terms. Experiments on the validation set showed that these combinations yield the best performance with $\alpha = 0.2$ for both languages, $\beta = 0.4$ for English and $\beta = 0.3$ for and Italian, $\gamma = 0.24$ for English and $\gamma = 0.2$ for Italian.

4 Experimens and Results

4.1 Experimental Setup

As a baseline we trained the CRFs classifier on the full training portion (11,227 sentences in the Italian and 14,987 sentences in the English corpus). In developing a reranking strategy for both English and Italian, the training data was split into 5 sections, and in each case the baseline classifier was trained on 4/5 of the data, then used to decode the remaining 1/5.

The top 10 hypotheses together with their log probabilities were recovered for each training sentence. Similarly, a model trained on the whole training data was used to produce 10 hypotheses for each sentence in the development set. For the reranking experiments, we applied different kernel setups to the two corpora described in Section 2.1. The three kernels were trained on the training portion.

Italian Test	P	R	F
$CRFs$	83.43	77.48	80.34
CTK	84.97	78.03	81.35
CFK	84.93	79.13	81.93
CTFK	**85.99**	**82.73**	**84.33**
(Zanoli et al., 2009)	*84.07*	*80.02*	*82.00*

English Test	P	R	F
$CRFs$	85.37	84.35	84.86
CTK	87.19	84.79	85.97
CFK	86.53	86.75	86.64
CTFK	**88.07**	**88.25**	**88.16**
(Ratinov and Roth,)	*N/A*	*N/A*	*90.57*

Table 3: Reranking results of the three tagging kernels on the Italian and English testset.

4.2 Discussion

Table 3 presents the reranking results on the test data of both corpora. The results show a 20.29% relative improvement in F-measure for Italian and 21.79% for English.

CFK based on unstructured features achieves higher accuracy than CTK based on structured features. However, the huge amount of subtrees generated by the PT kernel may limit the expressivity of some structural features, e.g. many fragments may only generate noise. This problem is less important with the polynomial kernel where global features are tailored for individual entities.

In any case, the experiments demonstrate that both tagging kernels CTK and CFK give improvement over the CRFs baseline in both languages. This suggests that structured and unstructured features are effective in discriminating between competing NE annotations.

Furthermore, the combination of the two tagging kernels on both standard corpora shows a large improvement in F-measure from 80.34% to 84.33% for Italian and from 84.86% to 88.16% for English data. This suggests that these two kernels, corresponding to two kinds of feature, complement each other.

To better collocate our results with previous work, we report the best NER outcome on the Italian (Zanoli et al., 2009) and the English (Ratinov and Roth,) datasets, in the last row (in italic) of each table. This shows that our model outperforms the best Italian NER system and it is close to the state-of-art model for English, which exploits many complex features[9]. Also note that we are very close to the F1 achieved by the best system of CoNLL 2003, i.e. 88.8.

5 Conclusion

We analyzed the impact of kernel-based approaches for modeling dependencies between tagged sequences for NER. Our study illustrates that each individual kernel, either with structured or with flat features clearly gives improvement to the base model. Most interestingly, as we showed, these contributions are independent and, the approaches can be used together to yield better results. The composite kernel, which combines both kinds of features, can outperform the state-of-the-art.

In the future, it will be very interesting to use syntactic/semantic kernels, as for example in (Basili et al., 2005; Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b). Another promising direction is the use of syntactic trees, feature sequences and pairs of instances, e.g. (Nguyen et al., 2009; Moschitti, 2008).

Acknowledgments

We would like to thank Roberto Zanoli and Marco Dinarelli for helpful explanation about their work. This work has been partially funded by the LiveMemories project (http://www.livememories.org/) and Expert System (http://www.expertsystem.net/) research grant.

[9] In the future we will be able to integrate them with the authors collaboration.

Abstract

In this paper we propose a novel algorithm for opinion summarization that takes account of content and coherence, simultaneously. We consider a summary as a sequence of sentences and directly acquire the optimum sequence from multiple review documents by extracting and ordering the sentences. We achieve this with a novel Integer Linear Programming (ILP) formulation. Our proposed formulation is a powerful mixture of the Maximum Coverage Problem and the Traveling Salesman Problem, and is widely applicable to text generation and summarization tasks. We score each candidate sequence according to its content and coherence. Since our research goal is to summarize reviews, the content score is defined by opinions and the coherence score is developed in training against the review document corpus. We evaluate our method using the reviews of commodities and restaurants. Our method outperforms existing opinion summarizers as indicated by its ROUGE score. We also report the results of human readability experiments.

1 Introduction

The Web now holds a massive number of reviews describing the opinions of customers about products and services. These reviews can help the customer to reach purchasing decisions and guide the business activities of companies such as product improvement. It is, however, almost impossible to read all reviews given their sheer number.

Automatic text summarization, particularly opinion summarization, is expected to allow all possible reviews to be efficiently utilized. Given multiple review documents, our summarizer outputs text consisting of ordered sentences. A typical summary is shown in Table 1. This task is considered as multidocument summarization.

This restaurant offers customers a delicious menu and a relaxing atmosphere. The staff are very friendly but the price is a little high.

Table 1: A typical summary.

Existing summarizers focus on organizing sentences so as to include important information in the given document into a summary under some size limitation. A serious problem is that most of these summarizers completely ignore coherence of the summary, which improves reader's comprehension as reported by Barzilay et al. (2002).

To make summaries coherent, the extracted sentences must be appropriately ordered. However, most summarization systems delink sentence extraction from sentence ordering, so a sentence can be extracted that can never be ordered naturally with the other extracted sentences. Moreover, due to recent advances in decoding techniques for text summarization, the summarizers tend to select shorter sentences to optimize summary content. It aggravates this problem.

Although a preceding work tackles this problem by performing sentence extraction and ordering simultaneously (Nishikawa et al., 2010), they adopt beam search and dynamic programming to search for the optimal solution, so their proposed method may fail to locate it.

To overcome this weakness, this paper proposes a novel Integer Linear Programming (ILP) formulation for searching for the optimal solution efficiently. We formulate the multidocument summarization task as an ILP problem that tries to optimize the content and coherence of the summary by extracting and ordering sentences simultaneously. We apply our method to opinion summarization and show that it outperforms state-of-the-art opinion summarizers in terms of ROUGE evaluations. Although in this paper we challenge

Coling 2008: Poster Volume, pages 910–918,
Beijing, August 2010

our method with opinion summarization, it can be widely applied to other text generation and summarization tasks.

This paper is organized as follows: Section 2 describes related work. Section 3 describes our proposal. Section 4 reports our evaluation experiments. We conclude this paper in Section 5.

2 Related Work

2.1 Sentence Extraction

Although a lot of summarization algorithms have been proposed, most of them solely extract sentences from a set of sentences in the source document set. These methods perform *extractive summarization* and can be formalized as follows:

$$\hat{S} = \underset{S \subseteq T}{\operatorname{argmax}} \mathcal{L}(S) \quad (1)$$
$$\text{s.t. } \operatorname{length}(S) \leq K$$

T stands for all sentences in the source document set and S is an arbitrary subset of T. $\mathcal{L}(\mathcal{S})$ is a function indicating the score of S as determined by one or more criteria. $\operatorname{length}(S)$ indicates the length of S, K is the maximum size of the summary. That is, most summarization algorithms search for, or decode, the set of sentences $\hat{S}$ that maximizes function $\mathcal{L}$ under the given maximum size of the summary K. Thus most studies focus on the design of function $\mathcal{L}$ and efficient search algorithms (i.e. argmax operation in Eq.1).

Objective Function

Many useful $\mathcal{L}$ functions have been proposed including the cosine similarity of given sentences (Carbonell and Goldstein, 1998) and centroid (Radev et al., 2004); some approaches directly learn function $\mathcal{L}$ from references (Kupiec et al., 1995; Hirao et al., 2002).

There are two approaches to defining the score of the summary. One defines the weight on each sentence forming the summary. The other defines a weight for a sub-sentence, *concept*, that the summary contains.

McDonald (2007) and Martins and Smith (2009) directly weight sentences and use MMR to avoid redundancy (Carbonell and Goldstein, 1998). In contrast to their approaches, we set weights on concepts, not sentences. Gillick and Favre (2009) reported that the concept-based model achieves better performance and scalability than the sentence-based model when it is formulated as ILP.

There is a wide range of choice with regard to the unit of the concept. Concepts include words and the relationship between named entities (Filatova and Hatzivassiloglou, 2004), bigrams (Gillick and Favre, 2009), and word stems (Takamura and Okumura, 2009).

Some summarization systems that target reviews, opinion summarizers, extract particular information, *opinion*, from the input sentences and leverage them to select important sentences (Carenini et al., 2006; Lerman et al., 2009). In this paper, since we aim to summarize reviews, the objective function is defined through opinion as the concept that the reviews contain. We explain our detailed objective function in Section 3. We describe features of above existing summarizers in Section 4 and compare our method to them as baselines.

Decoding Method

The algorithms proposed for argmax operation include the greedy method (Filatova and Hatzivassiloglou, 2004), stack decoding (Yih et al., 2007; Takamura and Okumura, 2009) and Integer Linear Programming (Clarke and Lapata, 2007; McDonald, 2007; Gillick and Favre, 2009; Martins and Smith, 2009). Gillick and Favre (2009) and Takamura and Okumura (2009) formulate summarization as a Maximum Coverage Problem. We also use this formulation. While these methods focus on extracting a set of sentences from the source document set, our method performs extraction and ordering simultaneously.

Some studies attempt to generate a single sentence (i.e. headline) from the source document (Banko et al., 2000; Deshpande et al., 2007). While they extract and order *words* from the source document as a unit, our model uses the unit of *sentences*. This problem can be formulated as the Traveling Salesman Problem and its variants. Banko et al. (2000) uses beam search to identify approximate solutions. Deshpande et al. (2007) uses ILP and a randomized algorithm to find the optimal solution.

2.2 Sentence Ordering

It is known that the readability of a collection of sentences, a summary, can be greatly improved by appropriately ordering them (Barzilay et al., 2002). Features proposed to create the appropriate order include publication date of document (Barzilay et al., 2002), content words (Lapata, 2003; Althaus et al., 2004), and syntactic role of

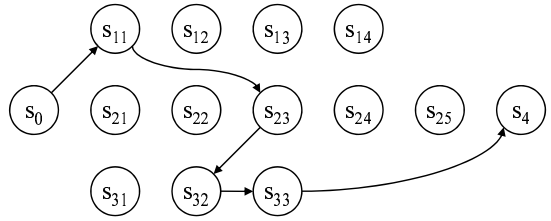

Figure 1: Graph representation of summarization.

words (Barzilay and Lapata, 2005). Some approaches use machine learning to integrate these features (Soricut and Marcu, 2006; Elsner et al., 2007). Generally speaking, these methods score the discourse coherence of a fixed set of sentences. These methods are separated from the extraction step so they may fail if the set includes sentences that are impossible to order naturally.

As mentioned above, there is a preceding work that attempted to perform sentence extraction and ordering simultaneously (Nishikawa et al., 2010). Differences between this paper and that work are as follows:

- This work adopts ILP solver as a decoder. ILP solver allows the summarizer to search for the optimal solution much more rapidly than beam search (Deshpande et al., 2007), which was adopted by the prior work. To permit ILP solver incorporation, we propose in this paper a totally new ILP formulation. The formulation can be widely used for text summarization and generation.
- Moreover, to learn better discourse coherence, we adopt the Passive-Aggressive algorithm (Crammer et al., 2006) and use Kendall's tau (Lapata, 2006) as the loss function. In contrast, the above work adopts Averaged Perceptron (Collins, 2002) and has no explicit loss function.

These advances make this work very different from that work.

3 Our Method

3.1 The Model

We consider a summary as a sequence of sentences. As an example, document set $D = \{d_1, d_2, d_3\}$ is given to a summarizer. We define d as a single document. Document d_1, which consists of four sentences, is describe by $d_1 = \{s_{11}, s_{12}, s_{13}, s_{14}\}$. Documents d_2 and d_3 consist of five sentences and three sentences (i.e. $d_2 = \{s_{21}, s_{22}, s_{23}, s_{24}, s_{25}\}$, $d_3 = \{s_{31}, s_{32}, s_{33}\}$). If the summary consists of four sentences $s_{11}, s_{23}, s_{32}, s_{33}$ and they are ordered as $s_{11} \rightarrow s_{23} \rightarrow s_{32} \rightarrow s_{33}$, we add symbols indicating the beginning of the summary s_0 and the end of the summary s_4, and describe the summary as $S = \langle s_0, s_{11}, s_{23}, s_{32}, s_{33}, s_4 \rangle$. Summary S can be represented as a directed path that starts at s_0 and ends at s_4 as shown in Fig. 1.

	e_1	e_2	e_3	$\ldots$	e_6	e_7	e_8
s_{11}	1	0	0		1	0	0
s_{12}	0	1	0		0	0	0
s_{13}	0	0	0		0	0	1
$\vdots$				$\ddots$			
s_{31}	0	0	0		0	0	0
s_{32}	0	0	1		0	1	0
s_{33}	0	0	0		0	0	1

Table 2: Sentence-Concept Matrix.

We describe a directed arc between s_i and s_j as $a_{i,j} \in A$. The directed path shown in Fig. 1 is decomposed into nodes, $s_0, s_{11}, s_{23}, s_{32}, s_{33}, s_4$, and arcs, $a_{0,11}, a_{11,23}, a_{23,32}, a_{32,33}, a_{33,4}$.

To represent the discourse coherence of two adjacent sentences, we define weight $c_{i,j} \in C$ as the coherence score on the directed arc $a_{i,j}$. We assume that better summaries have higher coherence scores, i.e. if the sum of the scores of the arcs $\sum_{a_{i,j} \in S} c_{i,j} a_{i,j}$ is high, the summary is coherent.

We also assume that the source document set D includes set of concepts $e \in E$. Each concept e is covered by one or more of the sentences in the document set. We show this schema in Table 2. According to Table 2, document set D has eight concepts $e_1, e_2, \ldots, e_7, e_8$ and sentence s_{11} includes concepts e_1 and e_6 while sentence s_{12} includes e_2.

We consider each concept e_i has a weight w_i. We assume that concept e_i will have high weight w_i if it is important. This paper improves summary quality by maximizing the sum of these weights.

We define, based on the above assumption, the following objective function:

$$\mathcal{L}(S) = \sum_{e_i \in S} w_i e_i + \sum_{a_{i,j} \in S} c_{i,j} a_{i,j} \quad (2)$$
$$\text{s.t. } \text{length}(S) \leq K$$

Summarization is, in this paper, realized by maximizing the sum of weights of concepts included in the summary and the coherence score of all adjacent sentences in the summary under the

limit of maximum summary size. Note that while S and T represents the *set* of sentences in Eq.1, they represent the *sequence* of sentences in Eq.2.

Maximizing Eq.2 is NP-hard. If each sentence in the source document set has one concept (i.e. Table 2 is a diagonal matrix), Eq.2 becomes the Prize Collecting Traveling Salesman Problem (Balas, 1989). Therefore, a highly efficient decoding method is essential.

3.2 Parameter Estimation

Our method requires two parameters: weights $w \in W$ of concepts and coherence $c \in C$ of two adjacent sentences. We describe them here.

Content Score

In this paper, as mentioned above, since we attempt to summarize reviews, we adopt *opinion* as a concept. We define opinion $e = \langle t, a, p \rangle$ as the tuple of *target* t, *aspect* a and its *polarity* $p \in \{-1, 0, 1\}$. We define target t as the target of an opinion. For example, the target t of the sentence "This digital camera has good image quality." is *digital camera*. We define aspect a as a word that represents a standpoint appropriate for evaluating products and services. With regard to digital cameras, aspects include *image quality*, *design* and *battery life*. In the above example sentence, the aspect is *image quality*. Polarity p represents whether the opinion is positive or negative. In this paper, we define $p = -1$ as negative, $p = 0$ as neutral and $p = 1$ as positive. Thus the example sentence contains opinion $e = \langle digital\ camera, image\ quality, 1 \rangle$.

Opinions are extracted using a sentiment expression dictionary and pattern matching from dependency trees of sentences. This opinion extractor is the same as that used in Nishikawa et al. (2010).

As the weight w_i of concept e_i, we use only the frequency of each opinion in the input document set, i.e. we assume that an opinion that appears frequently in the input is important. While this weighting is relatively naive compared to Lerman et al. (2009)'s method, our ROUGE evaluation shows that this approach is effective.

Coherence Score

In this section, we define coherence score c. Since it is not easy to model the global coherence of a set of sentences, we approximate the global coherence by the sum of local coherence i.e. the sum of coherence scores of sentence pairs. We define local coherence score $c_{i,j}$ of two sentences $x = \{s_i, s_j\}$ and their order $y = \langle s_i, s_j \rangle$ representing $s_i \rightarrow s_j$ as follows:

$$c_{i,j} = \mathbf{w} \cdot \phi(x, y) \tag{3}$$

$\mathbf{w} \cdot \phi(x, y)$ is the inner product of $\mathbf{w}$ and $\phi(x, y)$, $\mathbf{w}$ is a parameter vector and $\phi(x, y)$ is a feature vector of the two sentences s_i and s_j.

Since coherence consists of many different elements and it is difficult to model all of them, we approximate the features of coherence as the Cartesian product of the following features: content words, POS tags of content words, named entity tags (e.g. `LOC`, `ORG`) and conjunctions. Lapata (2003) proposed most of these features.

We also define feature vector $\Phi(\mathbf{x}, \mathbf{y})$ of the bag of sentences $\mathbf{x} = \{s_0, s_1, \ldots, s_n, s_{n+1}\}$ and its entire order $\mathbf{y} = \langle s_0, s_1, \ldots, s_n, s_{n+1} \rangle$ as follows:

$$\Phi(\mathbf{x}, \mathbf{y}) = \sum_{x,y} \phi(x, y) \tag{4}$$

Therefore, the score of order $\mathbf{y}$ is $\mathbf{w} \cdot \Phi(\mathbf{x}, \mathbf{y})$. Given a training set, if trained parameter vector $\mathbf{w}$ assigns score $\mathbf{w} \cdot \Phi(\mathbf{x}, \mathbf{y}_t)$ to correct order $\mathbf{y}_t$ that is higher than score $\mathbf{w} \cdot \Phi(\mathbf{x}, \hat{\mathbf{y}})$ assigned to incorrect order $\hat{\mathbf{y}}$, it is expected that the trained parameter vector will give a higher score to coherently ordered sentences than to incoherently ordered sentences.

We use the Passive-Aggressive algorithm (Crammer et al., 2006) to find $\mathbf{w}$. The Passive-Aggressive algorithm is an online learning algorithm that updates the parameter vector by taking up one example from the training examples and outputting the solution that has the highest score under the current parameter vector. If the output differs from the training example, the parameter vector is updated as follows;

$$\begin{gathered} \min ||\mathbf{w}^{i+1} - \mathbf{w}^{i}|| \\ \text{s.t. } \mathrm{s}(\mathbf{x}, \mathbf{y}_t; \mathbf{w}^{i+1}) - \mathrm{s}(\mathbf{x}, \hat{\mathbf{y}}; \mathbf{w}^{i+1}) \geq \ell(\hat{\mathbf{y}}; \mathbf{y}_t) \\ \mathrm{s}(\mathbf{x}, \mathbf{y}; \mathbf{w}) = \mathbf{w} \cdot \Phi(\mathbf{x}, \mathbf{y}) \end{gathered} \tag{5}$$

$\mathbf{w}^i$ is the current parameter vector and $\mathbf{w}^{i+1}$ is the updated parameter vector. That is, Eq.5 means that the score of the correct order must exceed the score of an incorrect order by more than loss function $\ell(\hat{\mathbf{y}}; \mathbf{y}_t)$ while minimizing the change in parameters.

When updating the parameter vector, this algorithm requires the solution that has the highest score under the current parameter vector, so we have to run an argmax operation. Since we are

attempting to order a set of sentences, the operation is regarded as solving the Traveling Salesman Problem (Althaus et al., 2004); that is, we locate the path that offers the maximum score through all n sentences where s_0 and s_{n+1} are starting and ending points, respectively. This operation is NP-hard and it is difficult to find the global optimal solution. To overcome this, we find an approximate solution by beam search.[1]

We define loss function $\ell(\hat{\mathbf{y}}; \mathbf{y}_t)$ as follows:

$$\ell(\hat{\mathbf{y}}; \mathbf{y}_t) = 1 - \tau \quad (6)$$

$$\tau = 1 - 4\frac{\mathrm{S}(\hat{\mathbf{y}}, \mathbf{y}_t)}{N(N-1)} \quad (7)$$

τ indicates Kendall's tau. $\mathrm{S}(\hat{\mathbf{y}}, \mathbf{y}_t)$ is the minimum number of operations that swap adjacent elements (i.e. sentences) needed to bring $\hat{\mathbf{y}}$ to $\mathbf{y}_t$ (Lapata, 2006). N indicates the number of elements. Since Lapata (2006) reported that Kendall's tau reliably reproduces human ratings with regard to sentence ordering, using it to minimize the loss function is expected to yield more reliable parameters.

We omit detailed derivations due to space limitations. Parameters are updated as per the following equation.

$$\mathbf{w}^{i+1} = \mathbf{w}^i + \eta^i(\Phi(\mathbf{x}, \mathbf{y}_t) - \Phi(\mathbf{x}, \hat{\mathbf{y}})) \quad (8)$$

$$\eta^i = \frac{\ell(\hat{\mathbf{y}}; \mathbf{y}_t) - \mathrm{s}(\mathbf{x}, \mathbf{y}_t; \mathbf{w}^i) + \mathrm{s}(\mathbf{x}, \hat{\mathbf{y}}; \mathbf{w}^i)}{||\Phi(\mathbf{x}, \mathbf{y}_t) - \Phi(\mathbf{x}, \hat{\mathbf{y}})||^2 + \frac{1}{2C}} \quad (9)$$

C in Eq.9 is the *aggressiveness parameter* that controls the degree of parameter change.

Note that our method learns $\mathbf{w}$ from documents automatically annotated by a POS tagger and a named entity tagger. That is, manual annotation isn't required.

3.3 Decoding with Integer Linear Programming Formulation

This section describes an ILP formulation of the above model. We use the same notation convention as introduced in Section 3.1. We use $s \in S, a \in A, e \in E$ as the decision variable. Variable $s_i \in S$ indicates the inclusion of the i th sentence. If the i th sentence is part of the summary, then s_i is 1. If it is not part of the summary, then s_i is 0. Variable $a_{i,j} \in A$ indicates the adjacency of the i th and j th sentences. If these two sentences are ordered as $s_i \rightarrow s_j$, then $a_{i,j}$ is 1. Variable $e_i \in E$ indicates the inclusion of the i th concept e_i. Taking Fig.1 as an example, variables $s_0, s_{11}, s_{23}, s_{32}, s_{33}, s_4$ and $a_{0,11}, a_{11,23}, a_{23,32}, a_{32,33}, a_{33,4}$ are 1. e_i, which correspond to the concepts in the above extracted sentences, are also 1.

We represent the above objective function (Eq.2) as follows:

$$\max\left\{\lambda \sum_{e_i \in E} w_i e_i + (1-\lambda) \sum_{a_{i,j} \in A} c_{i,j} a_{i,j}\right\} \quad (10)$$

Eq.10 attempts to cover as much of the concepts included in input document set as possible according to their weights $w \in W$ and orders sentences according to discourse coherence $c \in C$. λ is a scaling factor to balance w and c.

We then impose some constraints on Eq.10 to acquire the optimum solution.

First, we range the above three variables $s \in S, a \in A, e \in E$.

$$s_i, a_{i,j}, e_i \in \{0, 1\} \ \ \forall i, j$$

In our model, a summary can't include the same sentence, arc, or concept twice. Taking Table 2 for example, if s_{13} and s_{33} are included in a summary, the summary has two e_8, but e_8 is 1. This constraint avoids summary redundancy.

The summary must meet the condition of maximum summary size. The following inequality represents the size constraint:

$$\sum_{s_i \in S} l_i s_i \leq K$$

$l_i \in L$ indicates the length of sentence s_i. K is the maximum size of the summary.

The following inequality represents the relationship between sentences and concepts in the sentences.

$$\sum_i m_{ij} s_i \geq e_j \ \ \forall j$$

The above constraint represents Table 2. $m_{i,j}$ is an element of Table 2. If s_i is not included in the summary, the concepts in s_i are not included.

Symbols indicating the beginning and end of the summary must be part of the summary.

[1] Obviously, ILP can be used to search for the path that maximizes the score. While beam search tends to fail to find out the optimal solution, it is tractable and the learning algorithm can estimate the parameter from approximate solutions. For these reasons we use beam search.

$$
\begin{aligned}
s_0 &= 1 \\
s_{n+1} &= 1
\end{aligned}
$$

n is the number of sentences in the input document set.

Next, we describe the constraints placed on arcs.

The beginning symbol must be followed by a sentence or a symbol and must not have any preceding sentences/symbols. The end symbol must be preceded by a sentence or a symbol and must not have any following sentences/symbols. The following equations represent these constraints:

$$
\begin{aligned}
\sum_i a_{0,i} &= 1 \\
\sum_i a_{i,0} &= 0 \\
\sum_i a_{n+1,i} &= 0 \\
\sum_i a_{i,n+1} &= 1
\end{aligned}
$$

Each sentence in the summary must be preceded and followed by a sentence/symbol.

$$
\begin{aligned}
\sum_i a_{i,j} + \sum_i a_{j,i} &= 2s_j \ \ \forall j \\
\sum_i a_{i,j} &= \sum_i a_{j,i} \ \ \forall j
\end{aligned}
$$

The above constraints fail to prevent cycles. To rectify this, we set the following constraints.

$$
\begin{aligned}
\sum_i f_{0,i} &= n \\
\sum_i f_{i,0} &\geq 1 \\
\sum_i f_{i,j} - \sum_i f_{j,i} &= s_j \ \ \forall j \\
f_{i,j} &\leq n a_{i,j} \ \ \forall i,j
\end{aligned}
$$

The above constraints indicate that *flows* f are sent from s_0 as a source to s_{n+1} as a sink. n unit flows are sent from the source and each node expends one unit of flows. More than one flow has to arrive at the sink. By setting these constraints, the nodes consisting of a cycle have no flow. Thus solutions that contain a cycle are prevented. These constraints have also been used to avoid cycles in headline generation (Deshpande et al., 2007).

4 Experiments

This section evaluates our method in terms of ROUGE score and readability. We tested our method and two baselines in two domains: reviews of commodities and restaurants. We collected 4,475 reviews of 100 commodities and 2,940 reviews of 100 restaurants from websites. The commodities included items such as digital cameras, printers, video games, and wines. The average document size was 10,173 bytes in the commodity domain and 5,343 bytes in the restaurant domain. We attempted to generate 300 byte summaries, so the summarization rates were about 3% and 6%, respectively.

We prepared 4 references for each review, thus there were 400 references in each domain. The authors were not those who made up the references. These references were used for ROUGE and readability evaluation.

Since our method requires the parameter vector $\mathbf{w}$ for determining the coherence scores. We trained the parameter vector for each domain. Each parameter vector was trained using 10-fold cross validation. We used 8 samples to train, 1 to develop, and 1 to test. In the restaurant domain, we added 4,390 reviews to each training set to alleviate data sparseness. In the commodity domain, we add 47,570 reviews.[2]

As the solver, we used glpk.[3] According to the development set, λ in Eq.10 was set as 0.1.

4.1 Baselines

We compare our method to the references (which also provide the upper bound) and the opinion summarizers proposed by Carenini et al. (2006) and Lerman et al. (2009) as the baselines.

In the ROUGE evaluations, Human indicates ROUGE scores between references. To compare our summarizer to human summarization, we calculated ROUGE scores between each reference and the other three references, and averaged them.

In the readability evaluations, we randomly selected one reference for each commodity and each restaurant and compared them to the results of the three summarizers.

Carenini et al. (2006)

Carenini et al. (2006) proposed two opinion

[2]The commodities domain suffers from stronger review variation than the restaurant domain so more training data was needed.

[3]`http://www.gnu.org/software/glpk/`

summarizers. One uses a natural language generation module, and other is based on MEAD (Radev et al., 2004). Since it is difficult to mimic the natural language generation module, we implemented the latter one. The objective function Carenini et al. (2006) proposed is as follows:

$$\mathcal{L}_1(S) = \sum_{a \in S} \sum_{s \in D} |\mathrm{polarity}_s(a)| \quad (11)$$

$\mathrm{polarity}_s(a)$ indicates the polarity of aspect a in sentence s present in source document set D. That is, this function gives a high score to a summary that covers aspects frequently mentioned in the input, and whose polarities tend to be either positive or negative.

The solution is identified using the greedy method. If there is more than one sentence that has the same score, the sentence that has the higher centroid score (Radev et al., 2004) is extracted.

Lerman et al. (2009)

Lerman et al. (2009) proposed three objective functions for opinion summarization, and we implemented one of them. The function is as follows:

$$\mathcal{L}_2(S) = -(\mathrm{KL}(p_S(a), p_D(a)) \quad (12)$$
$$+ \sum_{a \in A} \mathrm{KL}(\mathcal{N}(x|\mu_{a_S}, \sigma^2_{a_S}), \mathcal{N}(x|\mu_{a_D}, \sigma^2_{a_D})))$$

$\mathrm{KL}(p, q)$ means the Kullback-Leibler divergence between probability distribution p and q. $p_S(a)$ and $p_D(a)$ are probability distributions indicating how often aspect $a \in A$ occurs in summary S and source document set D respectively. $\mathcal{N}(x|\mu, \sigma^2)$ is a Gaussian distribution indicating distribution of polarity of an aspect whose mean is μ and variance is σ^2. μ_{a_S}, μ_{a_D} and $\sigma^2_{a_S}, \sigma^2_{a_D}$ are the means and the variances of aspect a in summary S and source document set D, respectively. These parameters are determined using maximum-likelihood estimation.

That is, the above objective function gives high score to a summary whose distributions of aspects and polarities mirror those of the source document set.

To identify the optimal solution, Lerman et al. (2009) use a randomized algorithm. First, the summarizer randomly extracts sentences from the source document set, then iteratively performs insert/delete/swap operations on the summary to increase Eq.12 until summary improvement saturates. While this method is prone to lock onto local solutions, the summarizer can reach the optimal solution by changing the starting sentences and repeating the process. In this experiment, we used 100 randomly selected starting points.

Commodity	R-2	R-SU4	R-SU9
(Carenini et al., 2006)	0.158	0.202	0.186
(Lerman et al., 2009)	0.205	0.247	0.227

Human	5.83

Table 4: Average number of sentences in the summary.

4.2 ROUGE

We used ROUGE (Lin, 2004) for evaluating the content of summaries. We chose ROUGE-2, ROUGE-SU4 and ROUGE-SU9. We prepared four reference summaries for each document set.

The results of these experiments are shown in Table 3. ROUGE scores increase in the order of (Carenini et al., 2006), (Lerman et al., 2009) and our method, but no method could match the performance of Human. Our method significantly outperformed Lerman et al. (2009)'s method over ROUGE-2 according to the Wilcoxon signed-rank test, while it shows no advantage over ROUGE-SU4 and ROUGE-SU9.

Although our weighting of the set of sentences is relatively naive compared to the weighting proposed by Lerman et al. (2009), our method outperforms their method. There are two reasons for this; one is that we adopt ILP for decoding, so we can acquire preferable solutions efficiently. While the score of Lerman et al. (2009)'s method may be improved by adopting ILP, it is difficult to do so because their objective function is extremely complex. The other reason is the coherence score. Since our coherence score is based on

Commodity	(Carenini et al., 2006)	(Lerman et al., 2009)	Our Method	Human
(Carenini et al., 2006)	-	27/45	18/29	8/46
(Lerman et al., 2009)	18/45	-	29/48	11/47
Our Method	11/29	19/48	-	5/46
Human	38/46	36/47	41/46	-

Restaurant	(Carenini et al., 2006)	(Lerman et al., 2009)	Our Method	Human
(Carenini et al., 2006)	-	31/45	17/31	8/48
(Lerman et al., 2009)	14/45	-	25/47	7/46

Human	40/48	39/46	42/50	-

Table 5: Readability evaluation.

content words, it may impact the content of the summary.

4.3 Readability

Readability was evaluated by human judges. Since it is difficult to perform absolute evaluation to judge the readability of summaries, we performed a paired comparison test. The judges were shown two summaries of the same input and decided which was more readable. The judges weren't informed which method generated which summary. We randomly chose 50 sets of reviews from each domain, so there were 600 paired summaries.[4] However, as shown in Table 4, the average numbers of sentences in the summary differed widely from the methods and this might affect the readability evaluation. It was not fair to include the pairs that were too different in terms of the number of sentences. Therefore, we removed the pairs that differed by more than five sentences. In the experiment, 523 pairs were used, and 21 judges evaluated about 25 summaries each. We drew on DUC 2007 quality questions[5] for readability assessment.

Table 5 shows the results of the experiment. Each element in the table indicates the number of times the corresponding method won against other method. For example, in the commodity domain, the summaries that Lerman et al. (2009)'s method generated were compared with the summaries that Carenini et al. (2006)'s method generated 45 times, and Lerman et al. (2009)'s method won 18 times. The judges significantly preferred the references in both domains. There were no significant differences between our method and the other two methods. In the restaurant domain, there was a significant difference between (Carenini et al., 2006) and (Lerman et al., 2009).

Since we adopt ILP, our method tends to pack shorter sentences into the summary. However, our coherence score prevents this from degrading summary readability.

[4] ${}_4\mathrm{C}_2 \times 100 = 600$

[5] http://www-nlpir.nist.gov/projects/duc/duc2007/quality-questions.txt

5 Conclusion

This paper proposed a novel algorithm for opinion summarization that takes account of content and coherence, simultaneously. Our method directly searches for the optimum sentence sequence by extracting and ordering sentences present in the input document set. We proposed a novel ILP formulation against selection-and-ordering problems; it is a powerful mixture of the Maximum Coverage Problem and the Traveling Salesman Problem. Experiments revealed that the algorithm creates summaries that have higher ROUGE scores than existing opinion summarizers. We also performed readability experiments. While our summarizer tends to extract shorter sentences to optimize summary content, our proposed coherence score prevented this from degrading the readability of the summary.

One future work includes enriching the features used to determine the coherence score. We expect that features such as entity grid (Barzilay and Lapata, 2005) will improve overall algorithm performance. We also plan to apply our model to tasks other than opinion summarization.

A Study on Position Information in Document Summarization

You Ouyang Wenjie Li Qin Lu Renxian Zhang
Department of Computing, the Hong Kong Polytechnic University
{csyouyang,cswjli,csluqin,csrzhang}@comp.polyu.edu.hk

Abstract

Position information has been proved to be very effective in document summarization, especially in generic summarization. Existing approaches mostly consider the information of sentence positions in a document, based on a sentence position hypothesis that the importance of a sentence decreases with its distance from the beginning of the document. In this paper, we consider another kind of position information, i.e., the word position information, which is based on the ordinal positions of word appearances instead of sentence positions. An extractive summarization model is proposed to provide an evaluation framework for the position information. The resulting systems are evaluated on various data sets to demonstrate the effectiveness of the position information in different summarization tasks. Experimental results show that word position information is more effective and adaptive than sentence position information.

1 Introduction

Position information has been frequently used in document summarization. It springs from human's tendency of writing sentences of greater topic centrality at particular positions in a document. For example, in newswire documents, topic sentences are usually written earlier. A *sentence position hypothesis* is then given as: the first sentence in a document is the most important and the importance decreases as the sentence gets further away from the beginning. Based on this sentence position hypothesis, sentence position features are defined by the ordinal position of sentences. These position features have been proved to be very effective in generic document summarization. In more recent summarization tasks, such as query-focused and update summarization tasks, position features are also widely used.

Although in these tasks position features may be used in different ways, they are all based on the sentence position hypothesis. So we regard them as providing the sentence position information. In this paper, we study a new kind of position information, i.e., the word position information. The motivation of word position information comes from the idea of assigning different importance to multiple appearances of one word in a document.

As to many language models such as the bag-of-words model, it is well acknowledged that a word which appears more frequently is usually more important. If we take a closer look at all the appearances of one word, we can view this as a process that the different appearances of the same word raise the importance of each other. Now let's also take the order of the appearances into account. When reading a document, we can view it as a word token stream from the first token to the last. When a new token is read, we attach more importance to previous tokens that have the same lemma because they are just repeated by the new token. Inspired by this, we postulate a *word position hypothesis* here: for all the appearances of a fixed word, the importance of each appearance depends on all its following appearances. Therefore, the first appearance of a word is the most important and the importance decreases with the ordinal

Coling 2008: Poster Volume, pages 919–927,
Beijing, August 2010

positions of the appearances. Then, a novel kind of position features can be defined for the word appearances based on their ordinal positions. We believe that these word position features have some advantages when compared to traditional sentence position features. According to the sentence position hypothesis, sentence position features generally prefer earlier sentences in a document. As to the word position features that attempt to differentiate word appearances instead of sentences, a sentence which is not the first one in the document may still not be penalized as long as its words do not appear in previous sentences. Therefore, word position features are able to discover topic sentences in deep positions of the document. On the other hand, the assertion that the first sentence is always the most important is not true in actual data. It depends on the writing style indeed. For example, some authors may like to write some background sentences before topic sentences. In conclusion, we can expect word position features to be more adaptive to documents with different structures.

In the study of this paper, we define several word position features based on the ordinal positions of word appearances. We also develop a word-based summarization system to evaluate the effectiveness of the proposed word position features on a series of summarization data sets. The main contributions of our work are:

(1) representation of word position information, which is a new kind of position information in document summarization area.

(2) empirical results on various data sets that demonstrate the impact of position information in different summarization tasks.

2 Related Work

The use of position information in document summarization has a long history. In the seminal work by (Luhn, 1958), position information was already considered as a good indicator of significant sentences. In (Edmundson, 1969), a location method was proposed that assigns positive weights to the sentences to their ordinal positions in the document. Position information has since been adopted by many successful summarization systems, usually in the form of sentence position features. For example, Radev et al. (2004) developed a feature-based system MEAD based on word frequencies and sentence positions. The position feature was defined as a descending function of the sentence position. The MEAD system performed very well in the generic multi-document summarization task of the DUC 2004 competition. Later, position information is also applied to more summarization tasks. For example, in query-focused task, sentence position features are widely used in learning-based summarization systems as a component feature for calculating the composite sentence score (Ouyang et al, 2007; Toutanova et al, 2007). However, the effect of position features alone was not studied in these works.

There were also studies aimed at analyzing and explaining the effectiveness of position information. Lin and Hovy (1997) provided an empirical validation on the sentence position hypothesis. For each position, the *sentence position yield* was defined as the average value of the significance of the sentences with the fixed position. It was observed that the average significance at earlier positions was indeed larger. Nenkova (2005) did a conclusive overview on the DUC 2001-2004 evaluation results. It was reported that position information is very effective in generic summarization. In generic single-document summarization, a lead-based baseline that simply takes the leading sentences as the summary can outperform most submitted summarization system in DUC 2001 and 2002. As in multi-document summarization, the position-based baseline system is competitive in generating short summaries but not in longer summaries. Schilder and Kondadadi (2008) analyzed the effectiveness of the features that are used in their learning-based sentence scoring model for query-focused summarization. By comparing the ROUGE-2 results of each individual feature, it was reported that position-based features are less effective than frequency-based features. In (Gillick et al., 2009), the effect of position information in the update summarization task was studied. By using ROUGE to measure the density of valuable words at each sentence position, it was observed that the first sentence of newswire document was especially important for composing update summaries. They defined a binary sentence position feature based on the

observation and the feature did improve the performance on the update summarization data.

3 Methodology

In the section, we first describe the word-based summarization model. The word position features are then defined and incorporated into the summarization model.

3.1 Basic Summarization Model

To test the effectiveness of position information in document summarization, we first propose a word-based summarization model for applying the position information. The system follows a typical extractive style that constructs the target summary by selecting the most salient sentences.

Under the bag-of-words model, the probability of a word w in a document set D can be scaled by its frequency, i.e., $p(w)=freq(w)/|D|$, where $freq(w)$ indicates the frequency of w in D and $|D|$ indicates the total number of words in D. The probability of a sentence $s=\{w_1, \ldots, w_N\}$ is then calculated as the product of the word probabilities, i.e., $p(s)=\Pi_i\, p(w_i)$. Moreover, the probability of a summary consisting a set of sentences, denoted as $S=\{s_1, \ldots, s_M\}$, can be calculated by the product of the sentence probabilities, i.e., $p(S)=\Pi_j\, p(s_j)$. To obtain the optimum summary, an intuitive idea is to select the sentences to maximize the overall summary probability $p(S)$, equivalent to maximizing $\log(p(S)) = \Sigma_j\Sigma_i \log(p(w_{ji})) = \Sigma_j\Sigma_i (\log freq(w_{ji}) - \log|D|) = \Sigma_j\Sigma_i \log freq(w_{ji}) - |S|\cdot\log|D|$,
where w_{ji} indicates the ith word in s_j and $|S|$ indicates the total number of words in S. As to practical summarization tasks, a maximum summary length is usually postulated. So here we just assume that the length of the summary is fixed. Then, the above optimization target is equivalent to maximizing $\Sigma_j\Sigma_i \log freq(w_{ji})$. From the view of information theory, the sum can also be interpreted as a simple measure on the total information amount of the summary. In this interpretation, the information of a single word w_{ji} is measured by $\log freq(w_{ji})$ and the summary information is the sum of the word information. So the optimization target can also be interpreted as including the most informative words to form the most informative summary given the length limit.

In extractive summarization, summaries are composed by sentence selection. As to the above optimization target, the sentence scoring function for ranking the sentences should be calculated as the average word information, i.e., $score(s) = \Sigma_i \log freq(w_i) / |s|$.

After ranking the sentences by their ranking scores, we can select the sentences into the summary by the descending order of their score until the length limit is reached. By this process, the summary with the largest $p(S)$ can be composed.

3.2 Word Position Features

With the above model, word position features are defined to represent the word position information and are then incorporated into the model. According to the motivation, the features are defined by the ordinal positions of word appearances, based on the position hypothesis that earlier appearances of a word are more informative. Formally, for the ith appearance among the total n appearances of a word w, four position features are defined based on i and n using different formulas as described below.

(1) Direct proportion (DP) With the word position hypothesis, an intuitive idea is to regard the information degree of the first appearance as 1 and the last one as $1/n$, and then let the degree decrease linearly to the position i. So we can obtain the first position feature defined by the direct proportion function, i.e., $f(i)=(n-i+1)/n$.

(2) Inverse proportion (IP). Besides the linear function, other functions can also be used to characterize the relationship between the position and the importance. The second position feature adopts another widely-used function, the inversed proportion function, i.e., $f(i)=1/i$. This measure is similar to the above one, but the information degree decreases by the inverse proportional function. Therefore, the degree decreases more quickly at smaller positions, which implies a stronger preference for leading sentences.

(3) Geometric sequence (GS). For the third feature, we make an assumption that the degree of every appearance is the sum of the degree of all the following appearances, i.e., $f(i) = f(i+1)+ f(i+2)+\ldots+ f(n)$. It can be easily derived that the sequence also satisfies $f(i) = 2\cdot f(i-1)$. That is, the information degree of each new appearance is

halved. Then the feature value of the ith appearance can be calculated as $f(i) = (1/2)^{i-1}$.

(4) Binary function (BF). The final feature is a binary position feature that regards the first appearance as much more informative than the all the other appearances, i.e., $f(i)=1$, if $i=1$; λ else, where λ is a small positive real number.

3.3 Incorporating the Position Features

To incorporate the position features into the word-based summarization model, we use them to adjust the importance of the word appearance. For the ith appearance of a word w, its original importance is multiplied by the position feature value, i.e., $\log freq(w) \cdot pos(w, i)$, where $pos(w, i)$ is calculated by one of the four position features introduced above. By this, the position feature is also incorporated into the sentence scores, i.e.,

$$score'(s) = \Sigma_i [\log freq(w_i) \cdot pos(w_i)] / |s|$$

3.4 Sentence Position Features

In our study, another type of position features, which model sentence position information, is defined for comparison with the word position features. The sentence position features are also defined by the above four formulas. However, for each appearance, the definition of i and n in the formulas are changed to the ordinal position of the sentence that contains this appearance and the total number of sentences in the document respectively. In fact, the effects of the features defined in this way are equivalent to traditional sentence position features. Since i and n are now defined by sentence positions, the feature values of the word tokens in the same sentence s are all equal. Denote it by $pos(s)$, and the sentence score with the position feature can be written as

$$score'(s) = (\Sigma_{w \text{ in } s} \log freq(w) \cdot pos(s))/|s|$$
$$= pos(s) \cdot (\Sigma \log_{w \text{ in } s} freq(w)/|s|),$$

which can just be viewed as the product of the original score and a sentence position feature.

3.5 Discussion

By using the four functions to measure word or sentence position information, we can generate a total of eight position features. Among the four functions, the importance drops fastest under the binary function and the order is **BF** > **GS** > **IP** > **DP**. Therefore, the features based on the binary function are the most biased to the leading sentences in the document and the features based on the direct proportion function are the least. On the other hand, as mentioned in the introduction, sentence-based features have larger preferences for leading sentences than word-based position features.

An example is given below to illustrate the difference between word and sentence position features. This is a document from DUC 2001.

1. GENERAL ACCIDENT, the leading British insurer, said yesterday that insurance claims arising from Hurricane Andrew could 'cost it as much as Dollars 40m.'
2. Lord Airlie, the chairman who was addressing an extraordinary shareholders' meeting, said: 'On the basis of emerging information, General Accident advise that the losses to their US operations arising from Hurricane Andrew, which struck Florida and Louisiana, might in total reach the level at which external catastrophe reinsurance covers would become exposed'.
3. What this means is that GA is able to pass on its losses to external reinsurers once a certain claims **threshold** has been breached.
4. It believes this **threshold** may be breached in respect of Hurricane Andrew claims.
5. However, if this happens, it would suffer a post-tax loss of Dollars 40m (Pounds 20m).
6. Mr Nelson Robertson, GA's chief general manager, explained later that the company has a 1/2 per cent share of the Florida market.
7. It has a branch in Orlando.
8. The company's loss adjusters are in the area trying to **estimate** the losses.
9. Their guess is that losses to be faced by all insurers may total more than Dollars 8bn.
10. Not all damaged property in the area is insured and there have been **estimates** that the storm caused more than Dollars 20bn of damage.
11. However, other insurers have **estimated** that losses could be as low as Dollars 1bn in total.
12 Mr Robertson said: 'No one knows at this time what the exact loss is'.

For the word "threshold" which appears twice in the document, its original importance is log(2), for the appearance of "threshold" in the 4th sentence, the modified score based on word position feature with the direct proportion function is $1/2 \cdot \log(2)$. In contrast, the score based on sentence position feature with the

same function is 9/12·log(2), which is larger. For the appearance of the word "estimate" in the 8th sentence, its original importance is log(3) (the three boldfaced tokens are regarded as one word with stemming). The word-based and sentence-based scores are log(3) and 5/12·log(3) respectively. So its importance is larger under word position feature. Therefore, the system with word position features may prefer the 8th sentence that is in deeper positions but the system with sentence position feature may prefer the 4th sentence. As for this document, the top 5 sentences selected by sentence position feature are {1, 4, 3, 5, 2} and the those selected by the word position features are {1, 8, 3, 6, 9}. This clearly demonstrates the difference between the position features.

4 Experimental Results

4.1 Experiment Settings

We conduct the experiments on the data sets from the Document Understanding Conference (DUC) run by NIST. The DUC competition started at year 2001 and has successfully evaluated various summarization tasks up to now. In the experiments, we evaluate the effectiveness of position information on several DUC data sets that involve various summarization tasks. One of the evaluation criteria used in DUC, the automatic summarization evaluation package ROUGE, is used to evaluate the effectiveness of the proposed word position features in the context of document summarization[1]. The recall scores of ROUGE-1 and ROUGE-2, which are based on unigram and bigram matching between system summaries and reference summaries, are adopted as the evaluation criteria.

In the data sets used in the experiments, the original documents are all pre-processed by sentence segmentation, stop-word removal and word stemming. Based on the word-based summarization model, a total of nine systems are evaluated in the experiments, including the system with the original ranking model (denoted as **None**), four systems with each word position feature (denoted as **WP**) and four systems with each sentence position feature (denoted as **SP**). For reference, the average ROUGE scores of all the human summarizers and all the submitted systems from the official results of NIST are also given (denoted as **Hum** and **NIST** respectively).

4.2 Redundancy Removal

To reduce the redundancy in the generated summaries, we use an approach similar to the maximum marginal relevance (MMR) approach in the sentence selection process (Carbonell and Goldstein, 1998). In each round of the sentence selection, the candidate sentence is compared against the already-selected sentences. The sentence is added to the summary only if it is not significantly similar to any already-selected sentence, which is judged by the condition that the cosine similarity between the two sentences is less than 0.7.

4.3 Generic Summarization

In the first experiment, we use the DUC 2001 data set for generic single-document summarization and the DUC 2004 data set for generic multi-document summarization. The DUC 2001 data set contains 303 document-summary pairs; the DUC 2004 data set contains 45 document sets, with each set consisting of 10 documents. A summary is required for each document set. Here we need to adjust the ranking model for the multi-document task, i.e., the importance of a word is calculated as its total frequency in the whole document set instead of a single document. For both tasks, the summary length limit is 100 words.

Table 1 and 2 below provide the average ROUGE-1 and ROUGE-2 scores (denoted as **R-1** and **R-2**) of all the systems. Moreover, we used paired two sample t-test to calculate the significance of the differences between a pair of word and sentence position features. The bolded score in the tables indicates that that score is significantly better than the corresponding paired one. For example, in Table 1, the bolded **R-1** score of system **WP DP** means that it is significantly better than the **R-1** score of system **SP DP**. Besides the ROUGE scores, two statistics, the number of "first sentences[2]" among the selected sentences (**FS-N**) and the

[1] We run ROUGE-1.5.5 with the parameters "-x -m -n 2 -2 4 -u -c 95 -p 0.5 -t 0"

[2] A "first sentence" is the sentence at the fist position of a document.

average position of the selected sentences (**A-SP**), are also reported in the tables for analysis.

Table 2. Results on the DUC 2004 data set

From Table 1 and Table 2, it is observed that position information is indeed very effective in generic summarization so that all the systems with position features performed better than the system **None** which does not use any position information. Moreover, it is also clear that the proposed word position features consistently outperform the corresponding sentence position features. Though the gaps between the ROUGE scores are not large, the t-tests proved that word position features are significantly better on the DUC 2001 data set. On the other hand, the advantages of word position features over sentence position features are less significant on the DUC 2004 data set. One reason may be that the multiple documents have provided more candidate sentences for composing the summary. Thus it is possible to generate a good summary only from the leading sentences in the documents. According to Table 2, the average-sentence-position of system **SP BF** is 1, which means that all the selected sentences are "first sentences". Even under this extreme condition, the performance is not much worse.

The two statistics also show the different preferences of the features. Compared to word position features, sentence position features are likely to select more "first sentences" and also have smaller average-sentence-positions. The abnormally large average-sentence-position of **SP BF** in DUC 2001 is because it does not differentiate all the other sentences except the first one. The corresponding word-position-based system **WP BF** can differentiate the sentences since it is based on word positions, so its average-sentence-position is not that large.

4.4 Query-focused Summarization

Since year 2005, DUC has adopted query-focused multi-document summarization tasks that require creating a summary from a set of documents to a given query. This task has been specified as the main evaluation task over three years (2005-2007). The data set of each year contains about 50 DUC topics, with each topic including 25-50 documents and a query. In this experiment, we adjust the calculation of the word importance again for the query-focused issue. It is changed to the total number of the appearances that fall into the sentences with at least one word in the query. Formally, given the query which is viewed as a set of words $Q=\{w_1, \ldots, w_T\}$, a sentence set S_Q is defined as the set of sentences that contain at least one w_i in Q. Then the importance of a word w is calculated by its frequency in S_Q. For the query-focused task, the summary length limit is 250 words.

Table 3 below provides the average ROUGE-1 and ROUGE-2 scores of all the systems on the DUC 2005-2007 data sets. The boldfaced terms in the tables indicate the best results in each column. According to the results, on query-focused summarization, position information seems to be not as effective as on generic summarization. The systems with position features can not outperform the system **None**. In fact, this is reasonable due to the requirement specified by the pre-defined query. Given the query, the content of interest may be in any

position of the document and thus the position information becomes less meaningful.

On the other hand, we find that though the systems with word position features cannot outperform the system **None**, it does significantly outperform the systems with sentence position features. This is also due to the role of the query. Since it may refer to the specified content in any position of the documents, sentence position features are more likely to fail in discovering the desired sentences since they always prefer leading sentences. In contrast, word position features are less sensitive to this problem and thus perform better. Similarly, we can see that the direct proportion (**DP**), which has the least bias for leading sentences, has the best performance among the four functions.

Table 4. Results on the TAC 2008 - 2009 data sets

4.5 Update Summarization

Since year 2008, the DUC summarization track has become a part of the Text Analysis Conference (TAC). In the update summarization task, each document set is divided into two ordered sets A and B. The summarization target on set A is the same as the query-focused task in DUC 2005-2007. As to the set B, the target is to write an update summary of the documents in set B, under the assumption that the reader has already read the documents in set A. The data set of each year contains about 50 topics, and each topic includes 10 documents for set A, 10 documents for set B and an additional query. For set A, we follow exactly the same method used in section 4.4; for set B, we make an additional novelty check for the sentences in B with the MMR approach. Each candidate sentence for set B is now compared to both the selected sentences in set B and in set A to

ensure its novelty. In the update task, the summary length limit is 100 words.

Table 4 above provides the average ROUGE-1 and ROUGE-2 scores of all the systems on the TAC 2008-2009 data sets. The results on set A and set B are shown individually. For the task on set A which is almost the same as the DUC 2005-2007 tasks, the results are also very similar. A small difference is that the systems with position features perform slightly better than the system **None** on these two data sets. Also, the difference between word position features and sentence position features becomes smaller. One reason may be that the shorter summary length increases the chance of generating good summaries only from the leading sentences. This is somewhat similar to the results reported in (Nenkova, 2005) that position information is more effective for short summaries.

For the update set B, the results show that position information is indeed very effective. In the results, all the systems with position features significantly outperform the system **None**. We attribute the reason to the fact that we are more concerned with novel information when summarizing update set B. Therefore, the effect of the query is less on set B, which means that the effect of position information may be more pronounced in contrast. On the other hand, when comparing the position features, we can see that though the difference of the position features is quite small, word position features are still better in most cases.

4.6 Discussion

Based on the experiments, we briefly conclude the effectiveness of position information in document summarization. In different tasks, the effectiveness varies indeed. It depends on whether the given task has a preference for the sentences at particular positions. Generally, in generic summarization, the position hypothesis works well and thus the ordinal position information is effective. In this case, those position features that are more distinctive, such as **GS** and **BF**, can achieve better performances. In contrast, in the query-focused task that relates to specified content in the documents, ordinal position information is not so useful. Therefore, the more distinctive a position feature is, the worse performance it leads to. However, in the update summarization task that also involves queries, position information becomes effective again since the role of the query is less dominant on the update document set.

On the other hand, by comparing the sentence position features and word position features on all the data sets, we can draw an overall conclusion that word position features are consistently more appreciated. For both generic tasks in which position information is effective and query-focused tasks in which it is not so effective, word position features show their advantages over sentence position features. This is because of the looser position hypothesis postulated by them. By avoiding arbitrarily regarding the leading sentences as more important, they are more adaptive to different tasks and data sets.

5 Conclusion and Future Work

In this paper, we proposed a novel kind of word position features which consider the positions of word appearances instead of sentence positions. The word position features were compared to sentence position features under the proposed sentence ranking model. From the results on a series of DUC data sets, we drew the conclusion that the word position features are more effective and adaptive than traditional sentence position features. Moreover, we also discussed the effectiveness of position information in different summarization tasks.

In our future work, we'd like to conduct more detailed analysis on position information. Besides the ordinal positions, more kinds of position information can be considered to better model the document structures. Moreover, since position hypothesis is not always correct in all documents, we'd also like to consider a pre-classification method, aiming at identifying the documents for which position information is more suitable.

Evaluating FrameNet-style semantic parsing: the role of coverage gaps in FrameNet

Alexis Palmer and Caroline Sporleder
Computational Linguistics
Saarland University
{apalmer, csporled}@coli.uni-saarland.de

Abstract

Supervised semantic role labeling (SRL) systems are generally claimed to have accuracies in the range of 80% and higher (Erk and Padó, 2006). These numbers, though, are the result of highly-restricted evaluations, i.e., typically evaluating on hand-picked lemmas for which training data is available. In this paper we consider performance of such systems when we evaluate at the document level rather than on the lemma level. While it is well-known that coverage gaps exist in the resources available for training supervised SRL systems, what we have been lacking until now is an understanding of the precise nature of this coverage problem and its impact on the performance of SRL systems. We present a typology of five different types of coverage gaps in FrameNet. We then analyze the impact of the coverage gaps on performance of a supervised semantic role labeling system on full texts, showing an average oracle upper bound of 46.8%.

1 Introduction

A lot of progress has been made in semantic role labeling over the past years, but the performance of state-of-the-art systems is still relatively low, especially for deep, FrameNet-style semantic parsing. Furthermore, many of the reported performance figures are somewhat unrealistic because system performance is evaluated on hand-selected lemmas, usually under the implicit assumptions that (i) all relevant word senses (frames) of each lemma are known, and (ii) there is a suitable amount of training data for each sense. This approach to evaluation arises from the limited coverage of the available hand-coded data against which to evaluate. More realistic evaluations test systems on full text, but these same coverage limitations mean that the assumptions made in more restricted evaluations do not necessarily hold for full text. This paper provides an analysis of the extent and nature of the coverage gaps in FrameNet. A more precise understanding of the limitations of existing resources with respect to robust semantic analysis of texts is an important foundational component both for improving existing systems and for developing future systems, and it is in this spirit that we make our analysis.

Full-text semantic analysis

Automated frame-semantic analysis aims to extract from text the key event-denoting predicates and the semantic argument structure for those predicates. The semantic argument structure of a predicate describing an event encodes relationships between the participants involved in the event, e.g. who did what to whom. Knowledge of semantic argument structure is essential for language understanding and thus important for applications such as information extraction (Moschitti et al., 2003; Surdeanu et al., 2003), question answering (Shen and Lapata, 2007), or recognizing textual entailment (Burchardt et al., 2009). Evaluating an existing system for its ability to aid such tasks is unrealistic if the evaluation is lemma-based rather than text-based. Consequently, there continues to be significant interest in developing semantic role labeling (SRL) systems able to automatically compute the semantic argument structures in an input text.

Performance on the full text task, though, is typically much lower than for the more restricted evaluations. The SemEval 2007 Task on "Frame Semantic Structure Extraction," for example, required systems to identify key predicates in texts,

Coling 2008: Poster Volume, pages 928–936,
Beijing, August 2010

assign a semantic frame to the relevant predicates, identify the semantic arguments for the predicates, and finally label those arguments with their semantic roles. The systems participating in this task only obtained F-Scores between 55% and 78% for frame assignment, despite the fact that the task organizers adopted a lenient evaluation scheme which gave partial credit for near-misses (Baker et al., 2007). For the combined task of frame assigment and role labeling the performance was even lower, ranging from 35% to 54% F-Score.

Note that this distinction between evaluation schemes for SRL systems corresponds to the distinction between "lexical sample" and "all words" evaluations in word sense disambiguation, where results for the latter scheme are also typically lower (McCarthy, 2009).

The low performances are at least partly due to coverage problems. For example, Baker et al. (2007) annotated three new texts for their SemEval 2007 task. Although these new texts overlap in domain with existing FrameNet data, the task organizers had to create 40 new frames in order to complete annotation. The new frames were for word senses found in the test set but missing from FrameNet. The test set contained only 272 frames (types), meaning that nearly 15% of the frames therein were not yet defined in FrameNet. Obviously, coverage issues of this degree make full SRL a difficult task, but this is a realistic scenario that will be encountered in real applications as well.

As mentioned above, for many tasks it is necessary to compute the semantic argument structures for the whole text, or at least for multi-sentence passages. Due to non-local relations between argument structures this is also true for tasks like question answering, where it might be possible to automatically determine a subset of lemmas which are relevant for the task. For example, in (1) it might be possible to determine that the second sentence contains the answer to the question "*Was Thomas Preston acquitted of theft?*" However, to correctly answer this question, it is necessary to resolve the null instantiation of the CHARGES role of the VERDICT frame. This null instantiation links back to the previous sentence, and resolving it might require obtaining an analysis of the word *tried*.

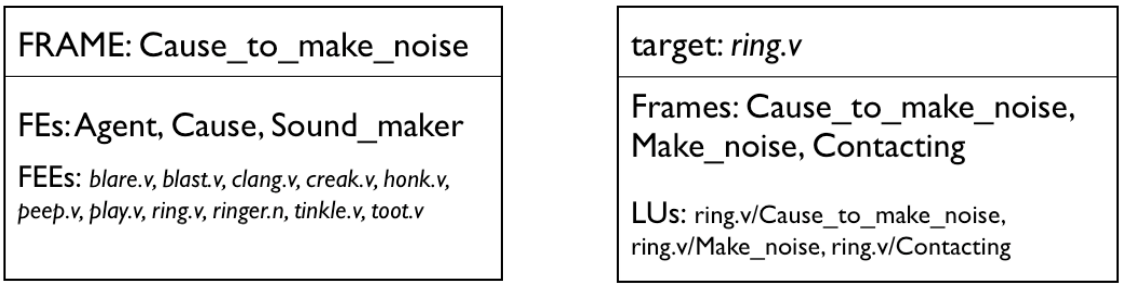
(1) [Captain Thomas Preston]$_{Defendant_i}$ was **tried**$_{Try\_defendant_i}$ for [murder]$_{Charges_{i,j}}$.

In the end [he]$_{Defendant_j}$ was **acquitted**$_{Verdict_j}$ [Ø]$_{Charges_j}$.

Performance levels obtained for full text are usually not sufficient for this kind of real-world task. FrameNet-style semantic role labeling has been shown to, in principle, be beneficial for applications that need to generalise over individual lemmas, such as recognizing textual entailment or question answering. However, studies also found that state-of-the-art FrameNet-style SRL systems perform too poorly to provide any substantial benefit to real applications (Burchardt et al., 2009; Shen and Lapata, 2007).

Extending the value of automated semantic parsing for a variety of applications requires improving the ability of systems to process unrestricted text. Several methods have been proposed to address different aspects of the coverage problem, ranging from automatic data expansion and semi-supervised semantic role labelling (Fürstenau and Lapata, 2009b; Fürstenau and Lapata, 2009a; Deschacht and Moens, 2009; Gordon and Swanson, 2007; Padó et al., 2008) to systems which can infer missing word senses (Pennacchiotti et al., 2008b; Pennacchiotti et al., 2008a; Cao et al., 2008; Burchardt et al., 2005). However, so far there has not been a detailed analysis of the problem. In this paper we provide that detailed analysis, by defining different types of coverage problems and performing analysis of both coverage and performance of an automated SRL system on three different data sets.

Section 2 of the paper provides an introduction to FrameNet and introduces the basic terminology. Section 4 describes our approach to coverage evaluation, Section 3 discusses the texts analyzed, and the analysis itself appears in Section 5. Section 6 then looks at one possibility for addressing the coverage problem. The final section presents some discussion and conclusions.



(a) (b)

Figure 1: Terminology: (a) Frame with core frame elements (FEs) and frame-evoking elements (FEEs) (b) Target with possible frame assignments and resultant lexical units (LUs)

2 FrameNet

Manual annotation of corpora with semantic argument structure information has enabled the development of statistical and supervised machine learning techniques for semantic role labeling (Toutanova et al., 2008; Moschitti et al., 2008; Gildea and Jurafsky, 2002).

The two main resources are PropBank (Palmer et al., 2005) and FrameNet (Ruppenhofer et al., 2006). PropBank aims to provide a semantic role annotation for every verb in the Penn TreeBank (Marcus et al., 1994) and assigns roles on a verb-by-verb basis, without making higher-level generalizations. Whether two distinct usages of a given verb are viewed as different senses or not is thus driven by both syntax (namely, differences in syntactic argument structure) and semantics (via basic, easily-discernable differences in meaning).

FrameNet[1] is a lexicographic project whose aim it is to create a lexical resource documenting valence structures for different word senses and their possible mappings to underlying semantic argument structure (Ruppenhofer et al., 2006). In contrast to PropBank, FrameNet is primarily semantically driven; word senses (*frames*)[2] are defined mainly based on sometimes-subtle meaning differences and can thus generalise across individual lemmas, and often also across different parts-of-speech. Because FrameNet focusses on semantics it is not restricted to verbs but also provides semantic argument annotations for nouns, adjectives, adverbs, prepositions and even multi-word expressions. For example, the sentence in (2) and the NP in (3) have identical argument structures because the verb *speak* and the noun *comment* evoke the same frame STATEMENT.

(2) [The politician]$_{Speaker}$ **spoke**$_{Statement}$ [about recent developments on the labour market]$_{Topic}$.

(3) [The politician's]$_{Speaker}$ **comments**$_{Statement}$ [on recent developments on the labour market]$_{Topic}$

Since FrameNet annotations are semantically driven they are considerably more time-consuming to create than PropBank annotations. However, FrameNet also provides 'deeper' and more informative annotations than PropBank analyses (Ellsworth et al., 2004). For instance, the fact that (2) and (3) refer to the same state-of-affairs is not captured by PropBank sense distinctions.

FrameNet Terminology

The English FrameNet data consist of an inventory of frames (i.e. word senses), a set of lexical entries, and a set of annotated examples exemplifying different syntactic realizations for selected frames (known as the *lexicographic annotations*). **Frames** are conceptual structures that describe types of situations or events together with their participants. **Frame-evoking elements (FEEs)** are predicate usages which evoke a particular frame. A given lemma can evoke different

[1] http://framenet.icsi.berkeley.edu/

[2] We follow Erk (2005) in treating frame assignment as a word sense disambiguation task. Thus in this paper we use the terms *frame* and *sense* interchangeably.

frames in different contexts; each instance of the lemma is a separate **target** for semantic analysis. For example, (4) and (5) illustrate two different frames of the lemma *speak*.

(4) [The politician]$_{Speaker}$ **spoke**$_{Statement}$ [about recent developments on the labour market]$_{Topic}$.

(5) [She]$_{Interlocutor_1}$ doesn't **speak**$_{Chatting}$ to [anyone]$_{Interlocutor_2}$.

In this paper we follow standard use of FrameNet terminology, with the possible exception of the term *lexical unit*. Figure 1 illustrates our use of FrameNet-related terminology, focussing on (a) the CAUSE_TO_MAKE_NOISE frame and (b) the target verb lemma *ring*.

The definition of a frame determines the available roles (**frame elements** or **FEs**) of the semantic argument structure for the particular use of the predicate, as well as the status—core or peripheral—of those roles. For example, the FE TOPIC is a core role under the STATEMENT frame, but a peripheral role under the CHATTING frame.

The lexical entry of a lemma in FrameNet specifies a list of frames which the lemma can evoke, and the pairing of a word with a particular frame is called a **lexical unit (LU)**. Ideally there should be annotated examples for each lexical unit, exemplifying different syntactic constructions which can realize this LU. However, as we will see later (Section 5) annotated examples can be missing. Also, because FrameNet is a lexicographic project, the examples were extracted to illustrate particular usages, i.e., they are not meant to be statistically representative.

3 Data

Having introduced the basic FrameNet terminology, we now describe in more detail the data sets used in the analysis. FrameNet Release 1.3 (FN1.3), the latest release from the Berkeley FrameNet project, includes both a corpus of lexicographic annotations (FNL), which we referred to in Section 2, and a corpus of texts fully-annotated with frames and semantic role labels (FNF). Annotations in the two corpora of course cover different sets of predicates and frames, and FNL is the corpus commonly used as the basis for training supervised FrameNet-based SRL systems (Erk and Padó, 2006).

In our analysis, we look at three data sets: the lexicographic annotations from FN1.3, the full text annotations from FN1.3, and a new data set of running text that was annotated for the SemEval 2010 Task-10 (see Table 1 for details).

FrameNet Lexicographic (FNL) FrameNet started as a lexicographic project, aiming to draw up an inventory of frames and lexical units, supported by corpus evidence, to document the range of syntactic and semantic usages of each lexical unit. The annotated example sentences in this part of FN1.3 are taken from the British National Corpus (BNC). BNC is a balanced corpus, hence FNL covers, in principle, a variety of domains.

For each LU, a subset of the sentences in which it occurs was selected for annotation, and in each extracted sentence, only the target LU was annotated. The sentences were not chosen randomly but with a set of lexicographic constraints in mind. In particular the sentences should exemplify different usage. Thus ideally selected sentences would be easy to understand and not too long or complex. As a consequence of this linguistically-driven selection procedure, the annotated sentences are not statistically representative in any way. FNL provides annotations for just under 140,000 FEEs (tokens). On average, around 20 sentences are annotated for each LU. FrameNet's frame inventory contains 722 frames.[3]

FrameNet Full Texts (FNF) Starting with release 1.3, FrameNet also provides annotations of running texts. In this annotation mode, all LUs in a sentence and all sentences in a text are annotated. FN1.3 contains two subsets of full text annotations. The first of these (**PB**) contains five texts which were also annotated by the PropBank project. While all texts come from the Wall Street Journal, they are not prototypical examples of the financial domain, rather they are longer essays covering a wide variety of general interest topics

[3] Only lexical frames are included in this number. In addition to those, FrameNet 1.3 defines another 74 frames which cannot be lexicalised but are included because they provide useful generalisations in the frame hierarchy.

Data	Genre / Domain	FEEs Tokens	FEEs Types	Frames Types
FNL	mixed	139,439	8370	722
PB	essays, general interest	1580	680	319
NTI	reports, foreign affairs	8271	1305	434
SE	fiction, crime	1530	680	320

Table 1: Statistics for the three data sets

(ranging from 'Bell Ringing' to 'Earthquakes'). The second subset (**NTI**) contains 12 texts from the Nuclear Threat Initiative website.[4] These texts are intelligence reports which summarize and discuss the status of various countries with regard to the development of weapons and missile systems. Statistics for both data sets are given in Table 1.

SemEval 2010 Task-10 Full Texts (SE) While the FrameNet full texts allow us to estimate coverage gaps that arise from limited training data, they do not allow us to gauge coverage problems arising from missing frames in the FN1.3 inventory. The reason for this is that the frame inventory reflects the annotations of both the lexicographic and the full text part of FN1.3, i.e., every frame annotated in one of these subsets will also be part of the inventory. To estimate the frame coverage problem on completely new texts, we therefore included a third (full text) data set that was annotated for the SemEval 2010 Task 10 on "Linking Events and Their Participants in Discourse" (Ruppenhofer et al., 2009).[5] The text is taken from Arthur Conan Doyle's "The Adventure of Wisteria Lodge". It thus comes from the fiction domain.

The text was manually annotated with frame-semantic argument structure by two experienced annotators. Similar to the FNF texts, the annotators aimed to annotate all LUs in the text. To do so, some new frames had to be created for previously un-encountered LUs. These new frames are not part of FN1.3 and we can thus use them to estimate coverage problems arising from missing frames. Details for the data set can be found in Table 1. This data set is very similar to the PB set in terms of size, FEE type-token ratio and number of frames (types).

[5] The data set is available from http://semeval2.fbk.eu/semeval2.php?location=data.

4 Types of Coverage Gaps

Semantic role labelling systems have to perform two sub-tasks: (i) identifying the correct frame for a given lemma and context, and (ii) identifying and labeling the frame elements. The most severe coverage problems typically arise with the first subtask. Furthermore, coverage problems related to frame identification have a knock-on effect on role identification and labeling because the choice of the correct frame determines which roles are available. Therefore, we focus on the frame identification task in this paper.

Attempts to do automated frame assignment on unrestricted text invariably encounter problems associated with limited coverage of frame-evoking elements in FrameNet. However, not every coverage gap is the same, and the precise nature of a coverage gap influences potential strategies for addressing it. In this section we describe the different types of coverage gaps. We proceed from less problematic coverage gaps to more problematic ones, in the sense that the former can be addressed more straighforwardly by automated systems than can the latter.

4.1 NOTR gaps

Some coverage gaps occur when lexical units (LUs) defined in FrameNet lack corresponding annotated examples; these gaps are the result of lacking training data, hence we call them **NOTR** gaps. To give a sense of the abundance of such gaps, of the 10,191 LUs defined in FN1.3, annotated examples are available for only 6727.

NOTR-LU: lexical unit with no training data. In many cases, an LU — a specific pairing of a target lemma with one frame — may be defined in FrameNet, thus potentially accessible to an automated system, but lacking labeled training material. For example, FrameNet defines two LUs for the noun *ringer*: with the frames CAUSE TO MAKE NOISE and SIMILARITY. It is clear that the occurrence of *ringer* in (6) belongs to the former LU, even given a very limited context. The lexicographic annotations, though, provide training material only for the SIMILARITY frame.

(6) Then, at a signal, the **ringers** begin varying the order in which the bells sound without altering the steady rhythm of the striking.

NOTR-LU gaps pose particular problems to a fully-supervised SRL system, because such a system cannot learn anything about the context in which the CAUSE TO MAKE NOISE frame is more appropriate. A NOTR-LU gap is identified for an LU even if training data is available for other senses (i.e. other LUs) of the target lemma.

NOTR-TGT: target with no training data. In other cases, a target lemma may be defined as participating in one or more LUs, but with no training data available for *any* of them. In other words, a supervised automated system trained only on the available annotated examples will fail to learn any potential frame assignments for the target lemma. Such is the case for *art*, which in FrameNet is assigned the single frame CRAFT, but for which FNL contains no training data.

(7) The **art** of change-ringing is peculiar to the English, and, like most English peculiarities, unintelligible to the rest of the world.

Whereas a NOTR-LU gap obscures a particular frame assignment for a target lemma, a NOTR-TGT gap indicates a complete absence in the lexicographic corpus of annotated data for the lemma.

4.2 UNDEF gaps

The previous coverage problems arise from a lack of annotated data, an issue which conceivably could be addressed through further annotation. More serious problems arise when a text contains word senses, words, or frames not contained in FrameNet. We call such elements 'undefined'; specifically, they receive no treatment in FN1.3.

UNDEF-LU: lexical unit not defined. Coverage gaps of this sort occur when the frame inventory for a given lemma is not complete. In other words, at least one LU for the lemma exists in FrameNet, but one or more other LUs are missing. For example, the noun *installation* occurs in FrameNet with the frames LOCALE BY USE and INSTALLING. The sense of an art installation, which is an instance of the frame PHYSICAL ARTWORKS, is missing.

UNDEF-TGT: target not addressed. In the worst case, all LUs for a target lemma might be missing, i.e., the lemma does not occur in the FrameNet lexicon at all. The noun *fabric* is an example. Though it has at least two distinct senses—that of cloth or material and that of a framework (e.g. *the fabric of society*)—FrameNet provides no help for determining appropriate frames for instances of this lemma.

UNDEF-FR: frame not defined. Finally, it may be not only that the LU is missing, but that there is no definition in FrameNet for the correct frame given the context. For example, in the sports domain the lemma *ringer* can have the sense of (*a horseshoe thrown so that it encircles the peg*); to our knowledge, this sense is not available in FrameNet.

5 Coverage gaps and automated processing

With the exception of work on extending coverage, most FrameNet-style semantic role labeling studies draw both training and evaluation data from FNL. This is an unrealistic evaluation scenario for full-text semantic analysis, as such evaluation limits the domain for which prediction can occur to those lexical entries treated in FNL. For systems which do not attempt any generalization beyond those lexical entries with training data, this limits the system to 5864 lemmas for which it can make predictions regarding frame assignment and role labeling.

Disregarding whether annotations have yet been provided for the lexical units in FNL still limits us to 8370 frame-evoking elements (targets). To better understand the potential of current frame-semantic resources for semantic analysis of unrestricted text, we evaluate coverage of the FNL annotations against the texts in FNF, as well as against the SemEval text. We then analyze the performance of an off-the-shelf, supervised SRL system, Shalmaneser (Erk and Padó, 2006), on the same texts, with a focus on the types of

Dataset	TR-LU	NOTR-LU	NOTR-TGT	UNDEF-LU	UNDEF-FR
PB	42.66	9.56	47.78	–	–
NTI	46.77	7.77	45.46	–	–
SE	51.64	6.86	26.01	3.40	12.09

Table 2: FrameNet coverage for analyzed texts

errors made and the upper bound on performance for this system.

5.1 FrameNet coverage

As described in Section 4, in many cases a lexical unit, a frame-evoking element, or a frame may simply not be represented in FrameNet. In other cases, the entity may be in FN1.3 but lacking training data. Of the 722 frames defined in FN1.3, for example, annotations exist for 502.

For the three data sets analyzed, Table 2 shows the degree of coverage provided by FNL for the gold-standard frame annotations. First, the TR-LU column shows the non-problematic cases, for which the correct frame annotation is available in FrameNet, with training data. The next two columns represent training gaps related to lack of training data: NOTR-LU are cases for which training data exists for the target, but not for the correct sense of the target, and NOTR-TGT instances are those for which no training data at all exists for the target.

Because all targets annotated in the FNF texts (i.e. PB and NTI above) are incorporated in FN1.3, gaps due to missing LUs, targets, or frames do not exist for those texts. The same does not hold for the SemEval (SE) text. For 3.4% of the annotated SemEval targets, an LU is entirely missing from the lemma's frame inventory in FrameNet, and in just over 12% of cases both the lemma and the frame are missing. In total, more than 15% of LUs appearing in the gold-standard SemEval annotations are not defined at all within FrameNet. This figure accords with that found by Baker et al. (2007).

5.2 Error analysis of full-text frame assignment

Here we examine the errors made by Shalmaneser for frame assignment on the three data sets. The upper bound on apparent performance is fixed by the number of targets for which Shalmaneser has seen training data, namely the sum of TR-LU and NOTR-LU in Table 2.[6]

Dataset	Correct	Type(i)	Type(ii)	Type(iii)
PB	36.71	5.95	9.56	47.78
NTI	41.22	5.55	7.77	45.46
SE	46.67	4.97	6.86	41.50

Table 3: Shalmaneser performance on texts

We consider three categories of errors: (i) *normal or true errors* are misclassifications when the correct label has been seen in the training data. In this category we also count errors resulting from incorrect lemmatization. (ii) *label-not-seen errors* are misclassifications when the correct label does not appear in the training data and thus is unavailable to the classifier. Finally, (iii) *no-chance errors* occur when the system has no information for either a given target or a given frame. Table 3 shows the prevalence of each error type for each data set, given as the percentage of all frame-assignment targets.

It can be seen that the frame assignment accuracy is relatively low for all three texts (between 37% and 47%). However, only a relatively small proportion of the misclassifications are due to true errors made by the system. Furthermore, a large amount of errors (41% to 48%, with an average of 46.8%) is due to cases where important information is missing from FrameNet (Type (iii) errors). Consequently, improving the semantic role labeller by optimising the feature space or the machine learning framework is going to have very little effect. A much more promising path would be to investigate methods which might enable the SRL system to deal gracefully with unseen data. One possible strategy is discussed in the next section.

[6] By 'apparent performance' we mean the system's own evaluation of its accuracy on frame assignment.

6 Frame and lemma overlap

One potential strategy for improving full-text semantic analysis without performing additional annotation is to take advantage of semantic overlap as it is represented in FrameNet. We can look at two different types of overlap in FrameNet: **lemma overlap** and **frame overlap**.

6.1 Lemma overlap

The approach of treating frame assignment as a word sense disambiguation task (as, e.g., by Shalmaneser) relies on the overlap of LUs with the same lemma and trains lemma-based classifiers on all training instances for all LUs involving that lemma. One way to consider using labeled material in FrameNet to improve performance on targets for which we have no labeled material is to generalize over lemmas associated with the same frame. The idea is to use training instances from related lemmas to build a larger training set for lemmas with little or no annotated data.

Of the 8370 lemmas in FN, 8358 share a single frame with at least one other lemma. 890 overlap on two frames with at least one other lemma, and 111 have 3-frame overlap with at least one other lemma. Only 16 lemmas show an overlap of four or more frames. These groupings are:

```
1. clang.v, clatter.v, click.v, thump.v
2. hit.v, smack.v, swing.v, turn.v
3. drop.v, rise.v
4. remember.v, forget.v
5. examine.v, examination.n
6. withdraw.v, withdrawal.n
```

The first two groupings are sets of words that are closely semantically related, the second two are opposite pairs, and the third two are verb-nominalization pairs.

The lemma overlap groups differ with respect to how much training data they make accessible.

6.2 Frame overlap

Another possibility to be considered is generalization over all instances of a given frame. For the 502 frames with annotated examples, the number of annotated instances ranges from one (SAFE SITUATION, BOARD VEHICLE, and ACTIVITY START to 6233 (SELF MOTION), with an average of 278 training instances per frame.

In future work we will examine the effectiveness of binary frame-based classifiers, abstracting away from individual predicates to predict whether a given lemma belongs to the frame in question (for a related study see Johansson and Nugues (2007)). A potential drawback to this approach is the loss of predicate-specific information. We know, for example, about verbs that they tend to have typical argument structures and typical syntactic realizations of those argument structures.

In addition to this frame-overlap approach, we will consider the impact on coverage of using coarser-grained versions of FrameNet in which frames have been merged according to frame relations defined over the FrameNet hierarchy, using the FrameNet Transformer tool described in (Ruppenhofer et al., 2010).

7 Conclusions

Although it is clear that the capability to do shallow semantic analysis on unrestricted text, and on complete documents or text passages, would help performance on a number of key tasks, currently-available resources seriously limit our potential for achieving this with supervised systems. The analysis in this paper aims for a better understanding of the precise nature of these limitations in order to address them more deliberately and with a principled understanding of the coverage problems faced by current systems.

To this end, we outline a typology of coverage gaps and analyze both coverage of FrameNet and performance of a supervised semantic role labeling system on three different full-text data sets, totaling over 150,000 frame-assignment targets. We find that, on average, 46.8% of targets are not covered under straight supervised-classification approaches to frame assignment.

Word Space Modeling for Measuring Semantic Specificity in Chinese

Abstract

The aim of this study is to use the word-space model to measure the semantic loads of single verbs, profile verbal lexicon acquisition, and explore the semantic information on Chinese resultative verb compounds (RVCs). A distributional model based on Academia Sinica Balanced Corpus (ASBC) with Latent Semantic Analysis (LSA) is built to investigate the semantic space variation depending on the semantic loads/specificity. The between group comparison of age-related changes in verb style is then conducted to suggest the influence of semantic space on verbal acquisition. Finally, it demonstrates how meaning exploring on RVCs is done with semantic space.

1 Introduction

The issue of 'word space' has been gaining attention in the field of distributional semantics, cognitive and computational linguistics. Various methods have been proposed to approximate words' meanings from linguistic distance. One of the most popular models in distributional semantics is Latent Semantic Analysis (LSA) with dimension-reduction technique, Singular Value Decomposition (SVD)(Landauer and Dumais, 1997; Karlgren and Sahlgren, 2001; Sahlgren, 2002; Widdows et al., 2002). The backbone of LSA is the co-occurrence distributional model in which words are conceived as points scattered in a texts-built n-dimensional space(Lenci, 2008). Rather than trying to predict the best performing model from a set of models, this study highlights the extent to which word space or semantic space measured from a vector-based model can access the verbal semantics and has influence on verbal acquisition.

This paper is organized as follows: Section 2 profiles the variation of semantic space affected by the semantic loads of single verbs. Section 3 discusses the correlation between the developing change in verbal lexicon and word space from the experimental data collected by M3[1] project. It will reveal how semantic space facilitates early child verbal learning. Section 4 demonstrates how to assess the meaning of Chinese resultative verb compounds (RVCs) from semantic space. The results of this work are finally concluded in Section 5.

2 The Variation of Semantic Space Between Two Verb Types (G/S) in LSA

The goal of this section is to examine the semantic variation between two verb types, generic versus specific verbs. It first creates a taxonomy for the classification of various verb groups (generic verbs versus specific verbs) based on the semantic distance with Latent Semantic Analysis (LSA) and Cluster Analysis.

2.1 Distributional Model Based on Sinica Corpus

The distributional model built in this survey is based on the Chinese texts collected in Academia

[1] Model and Measurement of Meaning: A Cross-lingual and Multi-disciplinary Approach of French and Mandarin Verbs based on Distance in Paradigmatic Graphs. Project website: http://140.112.147.149:81/m3/

Coling 2008: Poster Volume, pages 937–945,
Beijing, August 2010

Sinica Balanced Corpus (ASBC)[2]. It includes 190 files containing about 96000 word types[3]. The original matrix (M) is further decomposed into the product of three matrices (TSD^T). These matrices are then reduced into *k* dimensions. In the following reconstruction process based on *k* dimensions, it multiplies out the truncated matrices $T_k S_k D'_k$ and then gets a M_k matrix (the approximation of X)(Landauer et al., 1998; Sahlgren, 2005; Widdows and Ferraro, 2008). The following shows an example of finding the nearest neighbors of the word *da* (打 / to hit) via two methods (see Table 1). For the convenience of visualization and cluster analysis, Euclidean distance is applied in the following study.

	qu 'go'	*na* 'take'	*zhao* 'find'
Cosine	0.928	0.926	0.920
Distance	0.377	0.382	0.397

Table 1: Associating words of *da* 'hit'.

2.2 Semantic Clustering

The primary objective of cluster analysis is to examine the formation of a taxonomy: whether G verbs and S verbs form two groups separately. The clusters also help us grasp the semantic space among verbs as well as the potential semantic relation of them. Based on the distance matrix of lexical items generated in the last section, this part applied cluster analysis on the selected 150 verbs/observations[4]. For the convenience of comparison, each verb is coded with its type and a serial number like *zuo* (做/ to do) is G1 and *si* (撕/ to tear) is S27[5].

Once the similarity measure is done, the next procedure is to combine similar verbs into groups. The clustering procedure starts with each verb/observation in its own cluster, and combines two clusters together step by step until all the verbs are in a single cluster[6] The cluster dendrogram is plotted is Figure 1, in which clusters are formed from the bottom to the top.

Figure 1 demonstrates that the highest split separates these verbs into two big groups: the left branch group and right branch group drawn in different squares. The constituents of the two branches are listed in Table 2. It is clear that most of the constituent parts of the left group are G verbs whereas S verbs count as majority in the right group. If the left group is considered as a group formed with G verbs and right group with S verbs, the hit ratio[7] of G verbs (74.6%) is much higher than that of S verbs (57.1%). The clustering algorithm that we applied shows some structure, but there is no accurate separation of these two verb types. A detailed investigation of the relationship between the verb type and the distance is discussed in the next section.

	left group	right group
Generic verbs	59 (64.1%)	18 (33.3%)
Specific verbs	20 (21.7%)	24 (44.5%)
Undetermined verbs	13 (14.1%)	12 (22.2%)
Hit ratio	74.6%	57.1%

Table 2: Distribution of G/S verbs in two big clusters.

[2]ASBC website:
http://dbo.sinica.edu.tw/ftmsbin/kiwi1/mkiwi.sh

[3]The hapax legomena (words occur only once in the whole data) are not included in the matrix. The total word types including hapax amount to 220000 or so. To avoid time and computer consuming, we excluded those hapax from the co-occurrence matrix.

[4]These 150 verbs are single verbs selected from the experimental data. In the previous study of classification, these verbs are divided into two types (G:generic versus S:specific). There are 78 G verbs and 45 S verbs, along with 27 U(undetermined) verbs. It is noticeable that U verbs do not count as one type of verbs. They are floating verbs between G and S. We keep their identity as U and examine their potential characteristics in a binary cluster analysis.

[5]In fact, only 146 of 150 verbs are being classified because four words are missed in Sinica Corpus. To avoid confusion, we still call them 150 verbs in cluster analysis.

[6]Agglomerative method is implemented in the process in which single points are agglomerated into larger groups. This is termed a hierarchical cluster procedure that explores the co-relational structure of these single verbs. In complete linkage, all objects in a cluster are linked to each other with the longest distance. The use of the longest distance in complete linkage makes the least similar pair of objects group together. In other words, the maximum distance of the group results from the linkage of objects with minimum similarity.

[7]The hit ratio is calculated as follows:
hit ratio of G in the left group: $59/(59+20) = 74.6\%$
hit ratio of S in the right group: $24/(18+24) = 57.1\%$
It is noticeable that U verbs are temporarily ignored here.

2.3 Distance Variation in Small-G/S-clusters

Following the line of argumentation, this section demonstrates how distance varies within small-G-clusters and small-S-clusters. In order to examine the distance difference, small-G-cluster (or small-S-cluster) is defined as a cluster formed with the nearest twenty words of the G verb (or S verb) target.[8] In the example of one G verb *yong* (用/use) coded as G5, the closest twenty words are almost G verbs and the only one S verb is the farthest word *xie* (寫/write) (see Figure 2). The distance examination of the small cluster is applied to all of the 150 verbs studied in this survey. Table 3 has illustrated the comparison of verb types and the distance in the small cluster. As expected, the semantic distance is significantly affected by the verb type of the target word in the small cluster. The distances among words in most of the small-G-clusters range between 0.4 and 0.8. In contrast, over eighty percent small-S-clusters obtain a distance from 0.8 to 1.2. As for those U verbs which can not be decided as generic or specific in the manual tagging because of the lacking of agreement, they have distance between 0.6 and 1. Their distance shows an overlap with part of G verbs and part of S verbs. It confirms that U verbs are in a fuzzy zone between G verbs and S verbs.

In summary, G verbs are words with more senses and they appear more frequently in various context. Based on their high frequency distribution, G verbs construct a solid relation with each other in small-G-clusters. In contrast, S verbs are words with restricted meanings and they have relatively limited distributional patterns. Due to their low variety of patterns, S verbs are not easy to have tight relations with other words. It shows that words with generic meaning have high distribution variety and the distances among them are much shorter. The lack of polysemous feature makes the specific verbs be short of various distributional patterns and lose the opportunities to form close semantic relation with others. The semantic space among G verbs is short enough to form a solid cluster whereas S verbs are relatively remote from each other in semantic space. The distance of each verb cluster can help assess the verb category as generic (G) or specific (S). Approximately 75% of generic verbs form small clusters with distance lower than 0.8 while more than 80% of specific verbs acquire a

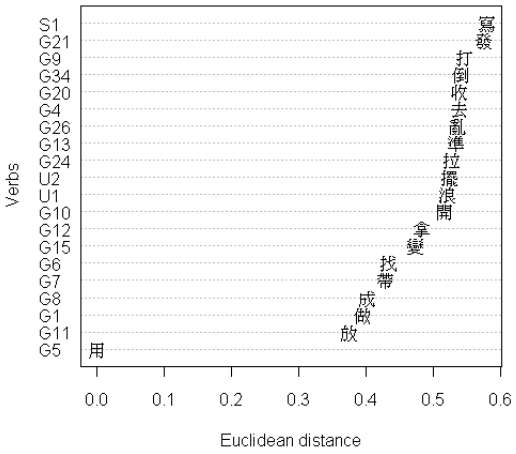

Figure 2: The small-G-cluster of *yong* (用/use).

[8] In order to test the representative power of small-clusters with 20 words, we have examined the clusters with 25 and 30 words as well. In all of the cases, the curves in 20-word cluster don't change significantly when the sample size is set to 25 or 30. The small-G/S-clusters with the sample size (N=20) is justified as representative.

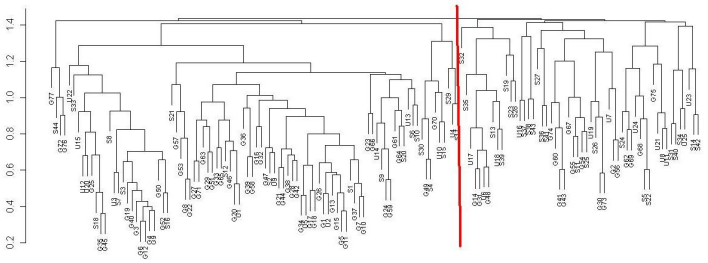

Figure 1: Agglomerative hierarchical cluster analysis of 150 verbs.

distance greater than 0.8 . As to the verbs of indeterminacy, they are averagely scattered in a fuzzy zone between G and S verbs. Over 70% U verbs are centering the distance 0.8, which suggests that words near distance 0.8 are likely to be undetermined verbs. This analysis has proved that semantic space varies in accordance with verb's meaning specificity. The distributions in context represent not only the linguistic behaviors but the semantic contents of lexical items.

3 The Influence of Specificity on Acquisition

This section assesses the influence of semantic space on the acquisition of the verbal lexicon. With the examination of Specific verb (S verb) progress, this study proposes that Generic verbs (G verbs) are acquired earlier than S verbs due to the closer semantic space. It also testifies whether the S verb development is a developing trend parallel with the acquisition of conventional verbs(Chen et al., 2008; Hsieh et al., 2009)[9] from the experimental data collected by M3 project. Based on the developing trend of conventional lexical items, the following parts analyze the relation of meaning specificity and the acquisition of lexical items.

3.1 Decreasing in Lexical Variation

The section is concerned with lexical variation among participants within the same age group. It measures type-token ratios of each group and profiles the lexical variation[10] in verbal acquisition. Data analyzed in this part include five groups of respondents' usages of verbs to four different films, each of which pictures one event. Respondents are assigned into five groups according to their age: 3-year-old, 5-year-old, 7-year-old, and 9-year-old groups have 20 respondents separately while 60 respondents are in the Adult group composed of people in their twenties. In respondents' answers, only one single verb is extracted from each respondent in this study. The number of verbs in each group is equal to the amount of participants. The first analysis begins with the lexical variation or lexical flexibility in these five groups. It is done with the ratio of lexical variation: the amount of word type is divided by the amount of word token, as shown in Table 4. The greater number of the ratio means the lexical variation is more abundant and the smaller ratio means a low diversity of word types. The ratio of lexical variation in these four films all show a decreasing trend from 3-year-old groups to adult groups. The quantity of different verbs is higher in children group (3y, 5y,7y, 9y) than that in adult group. That is, children appear more creative in event description tasks while adults are confined in the conventional usage. With the decreasing trend of lexical variety, the next step is to propose an increasing trend of specific verb

[9]They rearranged the five groups of participants into three units and then investigated the learning trend by Replacing Rate (Frequency of $V2_{freq}$ / Frequency of $V1_{freq}$). By defining adults' usages as the conventional one called V1, children's second highest frequency verb is counted as V2. Along with the increase of age, the number of V2 drops slowly whereas the amount of V1 increases gradually.

[10]Lexical diversity or sometimes called lexical variation is used to mean a combination of lexical variation and lexical sophistication. It is also referred to an indication of a combination of vocabulary size and the ability to use it effectively(Malvern et al., 2004). However, lexical variation or lexical diversity doesn't mean lexical richness in this study. In other kinds of experiment like writing tests, adults should perform better than children in lexical diversity. But the experimental data applied in this study is action-naming task. The trend of lexical variation may perform in an opposite way.

Distance	0.4-0.6	0.6-0.8	0.8-1.0	1.0-1.2
Small-G-cluster	24 (31.2%)	32 (41.6%)	17 (22.0%)	4 (5.2%)
		Total:72.8%		Total:27.2%
Small-S-cluster	0 (0)	6 (13.6%)	19 (43.2%)	19 (43.2%)
		Total:13.6%		Total:86.4%
Small-U-cluster	1 (4%)	8 (32%)	11 (44%)	5 (20%)

Table 3: Comparison of verb types (G/S) and semantic distance within small cluster.

usage when the age raises. It will show that the change is from various generic verbs to one or two specific verbs rather than various specific verbs.

Films	carrot-peel	paper-crumple	plank-saw	glass-break
3y	0.35	0.55	0.2	0.33
5y	0.25	0.47	0.2	0.2
7y	0.3	0.2	0.25	0.1
9y	0.21	0.105	0.157	0.157
Adult	0.016	0.083	0.066	0.066

Table 4: The ratio of lexical variation ($ratio$ = word type/word token).

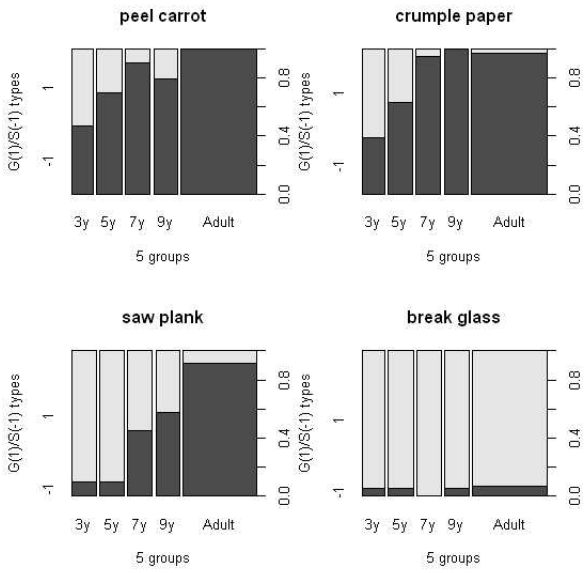

Figure 3: The proportion of S (-1) verbs to G (1) verbs from 5 groups of respondents to four events.

3.2 Increasing in Specific Verbs

With regard to the aim of the investigation, the findings reported above provide evidence of the changing trend of lexical variety in action-naming tasks. The next step is to discover the developing trend of verb type (G/S) usage. According to the annotation result of verb category, each verb in the data is now transferred into either generic (label as G or 1) or specific (S or -1) and the proportions of S verbs is plotted as Figure 3.

3.2.1 The Non-proportionality of S Verb among Age Groups

A closer investigation is then implemented for non-proportionalities by chi-squared test(Baayen, 2008). Although the proportion of S verb changes more or less in different groups, it is still need to confirm that whether S verbs are more frequently used by adults than children. The hypothesis is formulated as follows:

H_0: `The proportions of the two verb types (G verb vs. S verb ) do NOT vary in five age groups.`

With Pearson's chi-square test for four sets of data. It is reported that the small p-values (9.779e-07, 1.324e-09, and 1.191e-13) in the first three sets of data (carrot-peel (f_6), paper-crumple (f_2), and plank-saw (f_16)) suggest a non-proportionality of S verb in different age groups. However, the p-value (0.8467) obtained in the last data set (glass-break (f_3)) is too large to suggest a significant variation of S verb proportion in different age groups. It proves that the proportions of S verb change with the participant's age in the three event-naming tasks but that doesn't happen in the glass-break (f_3) event. Except for the data in glass-break (f_3) event, the null hypothesis doesn't hold in the analysis.

3.2.2 The Relationship between S Verb and Age

In order to test the correlation of S verb proportion and age variation, four groups (3y, 5y, 7y, 9y) are merged into one group called Child versus Adult group. The data are now represented by two by two contingency tables with one categorical dependent variable (verb types) and one categorical independent variable (age). Here summarizes the hypothesis:

H_0: `The frequency of the two verb types (G verb vs. S verb, the dependent variable) do NOT vary depending on participants' age (Child vs. Adult, the independent variable).`

The result has shown that the small p-values (2.803e-05, 0.001225, 1.754e-12) verify the significant difference of S verb in Child group

and Adult group with regard to the three data sets in carrot-peel (f_6), paper-crumple (f_2), and plank-saw (f_16). Along with the correlation examination, the effect size is revealed with correlation coefficient from 0 (no correlation) to 1 (perfect correlation)(Gries, 2009). According to the Phi value in this table, only the data in plank-saw (f_16) has a correlation coefficient (0.612) greater than 0.5. That is, the correlation between S verb usage and age group is considered as significantly correlated in the one data set (plank-saw (f_16)). As for the other two data sets (carrot-peel (f_6) with phi:0.379, paper-crumple (f_2) with phi: 0.297), the correlation is not particularly strong but it is still highly significant. Over half of the data sets exhibit a significant non-proportionality of S verb usage in different age groups but the correlation of S verb and participants' age requires.

In relation to the aim of this study, it has shown that meaning specificity functions as a factor in the development of verbal lexicon. The results of the analysis also show a significant variety of S verb between children and adults. It is plausible to suppose that verbs with specific meaning are acquired later than those with generic meanings. This developing trend suggests that a closer semantic space among G verbs facilitates the acquisition of verb meanings whereas a distant space among S verbs causes difficulties in meaning acquiring. Once those verbs with specific meanings are picked up, most of them will become the so-called conventional verbs. When the conventional use to an action is a specific verb, the progress of S verb usage is more obvious. The usage of verbs with specificity meaning is a developing trend of language acquisition.

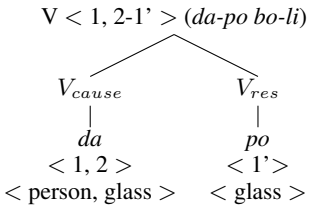
4 Meaning Exploring on Chinese Resultative Verb Compounds (RVCs)

In the verb-event co-occurrence matrix, verbs elicited from the same event are considered to be verbs have the same object in a verb-object co-occurrence matrix. With the distributional model, it then shows how meaning specificity affects the linguistic behavior and semantic content of Chinese resultative verb compounds (RVCs). Those RVCs with similar distributional patterns will present a high semantic relation. This semantic relation could result from the meaning of the first verbal morpheme (V_{caus}) or the second one (V_{res}). It is further proposed that the verb type (generic or specific) of V_{caus} would affect the whole meaning content of V-V compounds.

4.1 The RVC Structure in the Data

A Chinese resultative verb compound (RVC) consists two main elements: the first element (V_{caus}) expresses a causing event or a state while the second element (V_{res}) denotes a resulting event or the aspectual properties of the object. According to the Aspectual Interface Hypothesis(Tenny, 1989), the property of an internal argument can measure out the event. In the Chinese example, *da-po bo-li* (打破玻璃 / hit-break glass), the state of the object *bo-li* (玻璃 / glass) is changed into smashed and this change points out an end point of the event. The resultative *po* (破 / broken) is an delimiting expression which refers to the property of the object. In addition to defining the second element of an RVC as a delimiting expression, other surveys label it as V_{res} which requires the saturation of arguments. Four possible V-V compound argument structures are proposed in Li's (1990) works. In the following studies, most of RVCs require an argument structure like (1). The first verbal morpheme (V_{caus}) has a theta-grid $<$1, 2$>$ and the second morpheme (V_{res}) has $<$1'$>$. V_{caus} requires an external argument (a person) and an internal argument (a glass). The internal argument (a glass) is identified with the argument of V_{res}. Since the internal argument of V_{caus} has to be identified with the argument of V_{res}, it raises the issue that which one functions more prominent in choosing the object of a V-V compound. From the study of RVCs' distributional pattern, it examines which one (V_{caus} or V_{res}) is more salient and also dominates the argument selection of a V-V compound.

(1)



4.2 Semantic Assessment

The semantic links among words are built by measuring the linguistic distances among them. In order to examine the semantic information of RVCs, a sub-sample with thirty-six verbs is selected to do cluster tasks. The semantic relationships of word in the sub-sample is visualized as a clustering tree, as shown in Figure 4. The figure shows that an RVC with a G verb as its V_{caus} ($GV_{caus} - V_{res}$) build a close relation with other RVCs which have the same V_{res} with it. Take the most extreme G verb *da* (打/hit)as an example, *da-lan* (打爛/hit-ruin) is closer to *pai-lan* (拍爛/hit with palm and ruin) than *da* (打/hit). On the other hand, an RVC with an S verb as its V_{caus} ($SV_{caus} - V_{res}$), are grouped with those having the same V_{caus}. The RVC, *ju-kai* (鋸開/saw-open), with a S verb *ju* (鋸/saw) as its head, forms a cluster with *ju* (鋸/saw) and *ju-duan* (鋸斷/saw-crack).

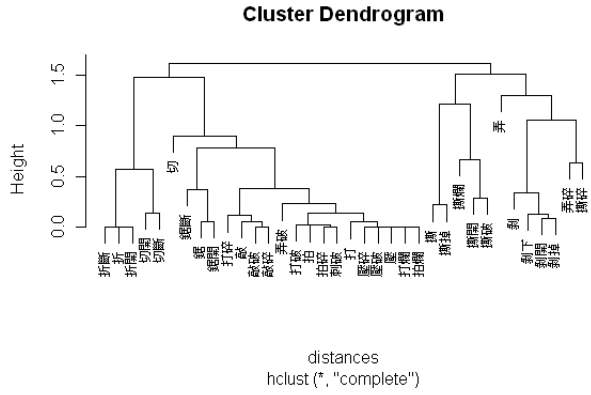


Figure 4: Semantic clustering of selected verbs.

With regard to the semantic relation of RVCs shown in the cluster plot, the next step is to justify the proportion of RVCs with the structure $GV_{caus} - V_{res}$ in which V_{res} selects a G verb as its V_{cause}. As Table 5 shows, the proportion of $GV_{caus} - V_{res}$ and $SV_{caus} - V_{res}$ is 50% respectively. That is, half of the selected seven V_{res} pick up a G verbs as its head while the other half words go with S verbs. Those V_{res} preferring a G head to a S head are *sui*, *po*, *lan*, *duan*; those preferring a S verb to a G verb head are *kai*, *diao*, *xia*. According to the semantic content these resultative verbs, *kai*, *diao*, *xia* describes the direction of the action and the motion of objects and they are defined as 'path' V_{res} in Ma and Lu's (1997) work. As for *sui*, *po*, *lan*, *duan* called as 'result' V_{res}, they mainly express the result of the object affected by the action. The outcome reported here suggests that 'result' V_{res} is apt to have a G verb as its head verb whereas 'path' V_{res} tends to pick up a S head verb. The proposal in literatures that V_{res} tends to choose a G head verb is justified as valid when the V_{res} expresses the meaning of 'result' rather than 'path.'

	GV_{caus}	**S**V_{caus}
'result' V_{res}		
sui (碎/smash)	da, nong, pai, ya, qiao	si
po (破/break)	da, nong, ya, qiao	si, ci
lan (爛/ruin)	da, pai	si
duan (斷/crack)	qie	
Proportion	47%	15%
'path' V_{res}		
kai (開/open)	qie	zhe, ju, si, bo
diao (掉/fall)		zhe, ju, si, bo
xia (下/down)		bo
Proportion	3%	35%

Table 5: $GV_{caus} - V_{res}$ versus $SV_{caus} - V_{res}$.

In summary, words with small distance resulting from their similar distributional patterns can be interpreted to be semantically similar in a semantic cluster. The result of semantic clustering has suggested that the meaning of RVCs depend on either the V_{caus} or the V_{res}. The meaning of $GV_{caus} - V_{res}$ is more determined by V_{res} because GV_{caus} is more polysemous and the V_{res} becomes a prominent role to dominate the meaning of $GV_{caus} - V_{res}$. In contrast, $SV_{caus} - V_{res}$ focuses on the part of SV_{caus} since

SV_{caus} expresses its meaning specific enough. In addition, the property of V_{res} also affects the category of its head verb. When V_{res} like *sui* belong to the 'result' V_{res}, it tend to choose a G verb as its V_{caus}. On the other hand, the 'path' V_{res} like *xia*, its head verb is apt to be a S verb. It is suggested that 'path' V_{res} is more likely to have a G verb than 'path' V_{res}. As the empirical study illustrates the semantic information on Chinese RVCs are affected by the semantic space of words.

5 Conclusion

In this paper, we argue the following points: firstly, the distributional model shows that the semantic space differ clearly in accordance with the specificity of verbs. The G verbs form tight relations with each other and become a larger cluster whereas the semantic space among S verbs is too distant to become a solid group. Secondly, semantic space has influence on the acquiring of words' meanings. Generic verbs are earlier and easier acquired due to the closer semantic space among words. The developing trend of specific verb lexicon parallel with conventional usage suggests a language acquisition phenomenon. Finally, the G/S verbs play an influential role in Chinese resultative compounds. The resultative verb becomes more prominent when the first verb is with a generic meaning. The 'result' V_{res} is apt to have a G verb as its head verb whereas 'path' V_{res} tends to pick up a S head verb. We believe that results of our analysis will shed light on semantic assessment and make predictions for lexical acquisition.

MT Error Detection for Cross-Lingual Question Answering

Abstract

We present a novel algorithm for detecting errors in MT, specifically focusing on content words that are deleted during MT. We evaluate it in the context of cross-lingual question answering (CLQA), where we try to correct the detected errors by using a better (but slower) MT system to retranslate a limited number of sentences at query time. Using a query-dependent ranking heuristic enabled the system to direct scarce MT resources towards retranslating the sentences that were most likely to benefit CLQA. The error detection algorithm identified spuriously deleted content words with high precision. However, retranslation was not an effective approach for correcting them, which indicates the need for a more targeted approach to error correction in the future.

1 Introduction

Cross-lingual systems allow users to find information in languages they do not know, an increasingly important need in the modern global economy. In this paper, we focus on the special case of cross-lingual tasks with result translation, where system output must be translated back into the user's language. We refer to tasks such as these as *task-embedded machine translation*, since the performance of the system as a whole depends on both task performance and the quality of the machine translation (MT).

Consider the case of cross-lingual question answering (CLQA) with result translation: a user enters an English question, the corpus is Arabic, and the system must return answers in English. If the corpus is translated into English before answer extraction, an MT error may cause the system to miss a relevant sentence, leading to decreased recall. Boschee et al. (2010) describe six queries from a formal CLQA evaluation where none of the competing systems returned correct responses, due to poor translation. In one example, the answer extractor missed a relevant sentence because the name "Abu Hamza al-Muhajir" was translated as "Zarqawi's successor Issa." However, even if answer extraction is done in Arabic, errorful translations of the correct answer can affect precision: if the user cannot understand the translated English sentence, the result will be perceived irrelevant. For instance, the user may not realize that the mistranslation "Alry$Awy" refers to Al-Rishawi.

Our goal was not to improve a specific CLQA system, but rather to find MT errors that are likely to impact CLQA and correct them. We introduce an error detection algorithm that focuses on several common types of MT errors that are likely to impact translation adequacy:

- content word deletion
- out-of-vocabulary (OOV) words
- named entity missed translations

The algorithm is language-independent and MT-system-independent, and generalizes prior work by detecting errors at the word level and detecting errors across multiple parts of speech.

We demonstrate the utility of our algorithm by applying it to CLQA at query time, and investigate using a higher-quality MT system to correct the errors. The CLQA system translates the full corpus, containing 119,879 text documents and 150 hours of speech, offline using a production MT system, which is able to translate quickly (5,000 words per minute) at the cost of lower quality translations. A research MT system has higher quality but is too slow to be practical for a large amount of data (at 2 words per minute,

Coling 2008: Poster Volume, pages 946–954,
Beijing, August 2010

it would take 170 days on 50 machines to translate the corpus). At query-time, we can call the research MT system to retranslate sentences, but due to time constraints, we can only retranslate k sentences (we set k=25). In order to choose the sentences to best improve CLQA performance, we rank potential sentences using a relevance model and a model of error importance.

Our results touch on three areas:

- Evaluation of our algorithm for detecting content word deletion shows that it is effective, accurately pinpointing errors 89% of the time (excluding annotator disagreements).
- Evaluation of the impact of re-ranking shows that it is crucial for directing scarce MT resources wisely as the higher-ranked sentences were more relevant.
- Although the research MT system was perceived to be significantly better than the production system, evaluation shows that it corrected the detected errors only 39% of the time. Furthermore, retranslation seems to have a negligible effect on relevance. These unexpected results indicate that, while we can identify errors, retranslation is not a good approach for correcting them. We discuss this finding and its implications in our conclusion.

2 Task-Embedded MT

A variety of cross-lingual applications use MT to enable users to find information in other languages: e.g., CLQA, cross-lingual information retrieval (CLIR), and cross-lingual image retrieval. However, cross-lingual applications such as these typically do not do result translation – for instance, an English-French CLIR system would take an English query and return French documents, assuming that result translation is a separate MT problem. Part of the reason for the separation between cross-lingual tasks and MT is that evaluating task performance on MT is often difficult. For example, for a multilingual summarization task combining English and machine translated English, Daumé and Marcu (2006) found that doing a pyramid annotation on MT was difficult due to the poor MT quality.

Assessing cross-lingual task performance without result translation is problematic, because in a real-world application, result translation would affect task performance. For instance, in English-Arabic CLIR, a poorly translated relevant Arabic document may appear to be irrelevant to an English speaker. Decoupling the cross-lingual application from the MT system also limits the opportunity for feedback between the application and the MT system. Ji and Grishman (2007) exploited a feedback loop between Chinese and English named entity (NE) tagging and Chinese-English NE translation to improve both NE extraction and NE translation.

In this paper, error detection is done at query time so that query context can be taken into account when determining which sentences to retranslate. We also use the task context to detect errors in translating NEs present in the query.

3 Related Work

There is extensive prior work in describing MT errors, but they usually involve post-hoc error analysis of specific MT systems (e.g., (Kirchhoff et al., 2007), (Vilar et al., 2006)) rather than online error detection. One exception is Hermjakob et al. (2008), who studied NE translation errors, and integrated an improved on-the-fly NE transliterator into an SMT system.

Content word deletion in MT has been studied from different perspectives. Li et al. (2008) and Menezes and Quirk (2008) explored ways of modeling (intentional) source-word deletion in MT and showed that it can improve BLEU score. Zhang et al. (2009) described how errors made during the word-alignment and phrase-extraction phases in training phrase-based SMT often lead to spurious insertions and deletions during translation decoding. This is a common error – Vilar et al. (2006) found that 22% of errors produced by their Chinese-English MT system were due to missing content words. Parton et al. (2009) did a post-hoc analysis on the cross-lingual 5W task and found that content word deletion accounted for 17-22% of the errors on that task.

Some work has been done in addressing MT errors for different cross-lingual tasks. Ji and

Table 1: Two examples of content word deletion during MT.

Grishman (2007) detected NE translation errors in the context of cross-lingual entity extraction, and used the task context to improve NE translation. Ma and McKeown (2009) investigated verb deletion in Chinese-English MT in the context of CLQA. They tested two SMT systems, and found deleted verbs in 4-7% of the translations. After using post-editing to correct the verb deletion, QA relevance increased for 7% of the sentences, showing that an error that may have little impact on translation metrics such as BLEU (Papineni et al., 2002) can have a significant impact on cross-lingual applications.

Our work generalizes Ma and McKeown (2009) by detecting content-word deletions and other MT errors rather than just verb deletions. We also relax the assumption that translation preserves part of speech (i.e., that verbs must translate into verbs), assuming only that a phrase containing a content word should be translated into a phrase containing a content word. Instead of post-editing, we use an improved MT system to retranslate sentences with detected errors.

Using retranslation to correct errors exploits the fact that some sentences are harder to translate than others. In a resource-constrained setting, it makes sense to apply a better MT system only to sentences for which the fast MT system has lower confidence. We do not know of other systems that do multi-pass translation, but it is an interesting area for further work.

4 MT Error Detection

Most MT systems try to balance translation fluency with adequacy, which refers to the amount of meaning expressed in the original that is also expressed in the translation. For task-embedded MT, errors in adequacy are more likely to have an impact on performance than errors in fluency. Many MT metrics (such as BLEU) treat all tokens equally, so deleting a verb is penalized the same as deleting a comma. In contrast, we focus on errors in translating **content words**, which are words with open-class parts of speech (POS), as they are more likely to impact adequacy. First we describe how MT deletion errors arise and how we can detect them, and finally we describe detection of other types of errors.

4.1 Deletion in MT

The simplest case of content word deletion is a complete deletion by the translation model – in other words, a token was not translated. We assume the MT system produces word or phrase alignments, so this case can be detected by checking for a null alignment. However, it is necessary to distinguish correct deletion from spurious deletion. Some content words do not need to be translated – for example the Arabic copular verb "kAn" ("to be") is often correctly deleted when translating into English.

A more subtle form of content word deletion occurs when a content word is translated as a non-content word. This can be detected by comparing the parts of speech of aligned words. Consider the production MT System (Prod. MT) example in Table 1: the verb "tHdv"[1] ("spoke") has been translated as the expletive "there."

Finally, another case of content word deletion occurs when a content word is translated as part of a larger MT phrase, but the content word is not translated. In the second example in Table 1, an Arabic phrase consisting of a noun and preposition is translated as just the preposition "to."

[1] Arabic examples in this paper are shown in Buckwalter transliteration (Buckwalter, 2002).

The latter two kinds of content word deletion are considered mistranslations rather than deletions by the translation model, since the deleted source-language token does produce one or more target-language tokens. However, from the perspective of a cross-lingual application, there was a deletion, since some content that was present in the original is not present in the translation.

4.2 Detecting Deleted Content Words

The deletion detection algorithm is motivated by the assumption that a source-language phrase containing one or more meaning-bearing words should produce a phrase with one or more meaning-bearing words in the translation. (Phrase refers to an n-gram rather than a syntactic phrase.) Note that this does not assume a one-to-one correspondence between content words – for example, translating the phrase "spoke loudly" as the single word "yelled" satisfies the assumption. This hypothesis favors precision over recall, since it may miss cases where two content words are incorrectly translated as a single content word (for instance, if "coffee table" is translated as "coffee").

The algorithm takes as input POS tags in both languages and word alignments produced by the MT system during translation. The exact definition of "content word" will depend upon the language and POS tagset. The system iterates over all content words in the source sentence, and, for each word, checks whether it is aligned to one or more content words in the target sentence. If it has no alignment, or is aligned to only function words, the system reports an error. This rule-based approach has poor precision because of content words that are correctly deleted. For example, in the sentence "I am going to watch TV," "am" and "going" are tagged as verbs, but may be translated as function words. To address this, frequent content words were heuristically filtered using source-language IDF (inverse-document frequency) over the QA corpus. The cut-off was tuned on a development set.

This algorithm is a lightweight, language-independent and MT-system-independent way to find errors in MT. The only requirement is that the MT system produce word or phrase alignments. This algorithm generalizes Ma and McKeown (2009) in several ways. First, it detects any deleted content words, rather than just verbs. The previous work only addresses complete deletions, where the deleted token has a null alignment, whereas this approach finds cases where content words are mistranslated as non-content words. Finally, this error detection algorithm is more fine-grained, since it is at the word level rather than the phrase level.

4.3 Additional Error Detection Heuristics

For the CLQA task, we extended our MT error detection algorithm to handle two additional types of MT errors, OOV words and NE mistranslations, and to rank the errors. The production MT system was explicitly set to not delete OOV words, so they were easy to detect as source-language words left in the target language. The CLIR system was used to find occurrences of query NEs in the corpus, and then word alignments were used to extract the corresponding translations. If the translations were not a fuzzy match to the query, then it was flagged as a possible NE translation error. For instance, in a query about al-Rishawi, the CLIR would return Arabic-language matches to the Arabic word Alry$Awy. If the aligned English translation was al-Ryshoui instead of al-Rishawi, it would be flagged as an error.

Even if the retranslation corrects the errors in MT, if the sentences are not relevant, they will have no impact on CLQA. To account for relevance, we implemented a bilingual bag-of-words matching model, and ranked sentences with more keyword matches to the query higher. Sentences with the same estimated relevance were further sorted by potential impact of the MT error on the task. Errors affecting NEs (either via source-language POS tagging or source-language NE recognition) were ranked highest, since our particular CLQA task is focused on NEs. The final output of the algorithm is a list of sentences with MT errors, ranked by relevance to the query and importance of the error.

5 Experimental Setup

We begin by describing the MT systems, which motivate the need for time-constrained MT. Then we describe the CLQA task and the baseline CLQA system, and finally how the error detection algorithm is used by the CLQA system.

5.1 MT Systems

Both the research and production MT systems used in our evaluation were based on Direct Translation Model 2 (Ittycheriah and Roukos, 2007), which uses a maximum entropy approach to extract minimal translation blocks (one-to-M phrases with optional variable slots) and train system parameters over a large number of source- and target-language features. The research system incorporates many additional syntactic features and does a deeper (and slower) beam search, both of which cause it to be much slower than the production system. In addition, the research MT system filters the training data to match the test data, as is customary in MT evaluations, whereas the production system must be able to handle a wide range of input data. Part of the reason for the slower running time is that the research system has to retrain; the advantage is that more test-specific training data can be used to tailor the MT system to the input.

Overall, the research MT system performs 4 BLEU points better than the production MT system on a standard MT evaluation test corpus, but at a great cost: the production MT handles 5,000 words per minute, while the research MT system handles 2 words per minute. Using 50 machines, the production MT system could translate the corpus in under 2 hours, whereas the research MT system would take 170 days. This vast difference succinctly captures the motivation behind the time-constrained retranslation step.

5.2 CLQA Task

The CLQA task was designed for the DARPA GALE (Global Autonomous Language Exploitation) project. The questions found are open-ended, non-factoid information needs. There are 22 question types, and each type has its own relevance guidelines. For instance, one type is "Describe the election campaign of [PERSON]," and a question could be about Barack Obama. Queries are in English, the corpus is in Arabic, and the system must output comprehensible English sentences that are relevant to the question.

The Arabic corpus was created for the evaluation and consists of four genres: formal text (72,677 documents), informal text (47,202 documents), formal speech (50 hours), and informal speech (80 hours). The speech data was story segmented and run through a speech recognition system before translation. We used 31 text queries developed by the Linguistic Data Consortium (LDC), and 39 speech queries developed by other researchers working on the CLQA task.

5.3 CLQA System

The baseline CLQA system translates the full corpus offline before running further processing on the translated sentences (parsing, NE recognition, information extraction, etc.) and indexing the corpus. At query-time, CLIR (implemented with Apache Lucene) returns documents relevant to the query, and the CLQA answer extraction system is run over the translated documents. The answer extraction system relies on target-language annotations, but any MT errors will propagate to target-language processing, and therefore affect answer extraction.

5.4 CLQA System with MT Error Detection

The error detection and retranslation module was added to the baseline system after CLIR, but before answer extraction. The inputs to the detection algorithm are the query and a list of ranked documents returned by CLIR. The detection algorithm has access to the indexed (bilingual) corpus, source- and target-language annotations (POS tagging and NE recognition), and MT word alignments. The error detection algorithm has two stages: first it runs over sentences in documents related to the query, and after it finds $2k$ sentences with errors (or exhausts the document list), it reranks the errors as described in section 4.3 and retranslates the top k=25 sentences. Then the merged set of original and retranslated relevant sentences are passed to the

answer extraction module.

By doing retranslation before answer extraction, the algorithm has the potential to improve precision and recall. An improved translation of a relevant Arabic sentence is more likely to be selected by the answer extraction system and increase recall, as in Boschee et al. (2010), where answers were missed due to mistranslation. A better translation of a relevant sentence is also more likely to be perceived as relevant, as shown by Ma and McKeown (2009).

6 Evaluation

Amazon Mechanical Turk (AMT) was used to conduct a large-scale evaluation of the impact of error detection and retranslation on relevance. An intrinsic evaluation of the error detection was run on a subset of the sentences, since it required bilingual annotators.

6.1 Task-Based Evaluation

Each sentence was annotated in the production MT version and the research MT version. The annotators were first presented with template relevance guidelines and an example question, along with 3 – 4 example sentences and expected judgments. Then the actual question was presented to the annotator, along with 5 sentences (all from a single MT system). For each sentence, the annotators were first asked to judge perceived adequacy and then relevance.

The *perceived adequacy* rating was loosely based upon MT adequacy evaluations – in other words, annotators were told to ignore grammatical errors and focus on perceived meaning. However, since there were no reference translations, annotators were asked to rate how much of the sentence they believed they understood by selecting one of (All, More than half, About half, Less than half, and None).

The *relevance* rating was based on the template relevance guidelines, and annotators could select one of (Relevant, Maybe relevant, Not relevant, Can't tell due to bad translation and Can't tell due to other reason).

Genre	# detected errors per sentence	# detected errors per 1,000 tokens
Newswire	0.16	56
Broadcast news	0.23	105
Broadcast conversation	0.14	84

Table 2: Number of errors detected across different genres.

6.2 Amazon Mechanical Turk (AMT)

The evaluation was run on AMT, which has been extensively used in NLP and has been shown to have high correlation with expert annotators on many NLP tasks at a lower cost (Snow et al., 2008). It has also been used in MT evaluation (Callison-Burch, 2009), though that evaluation used reference translations.

For 70 queries, the top 25 ranked sentences in both the production and research MT versions were evaluated. Each sentence was judged for both relevance and perceived adequacy by 5 annotators, for a total of 35,000 individual judgments. As is standard, some of the judgments were filtered due to noise by using the percent of time that an annotator disagreed with all other annotators, and the relative time spent on a given annotation. The percent of sentences with majority agreement was 91% for relevance and 72% for perceived adequacy.

6.3 Intrinsic Evaluation

Annotators were presented with an Arabic sentence with a single token highlighted, and asked whether the token was a "content word" or not. Then annotators were asked to decide which of two translations (in random order) translated the highlighted Arabic word best, or whether they were equal. In total, 150 sentences were judged by annotators with knowledge of Arabic. For both questions, kappa agreement was moderate.

7 Results

Table 2 shows how many errors were found by the error detection algorithm for each genre. Not surprisingly, more errors are detected in the speech genres (84 and 105 errors per 1,000 tokens) than in formal text (56 errors per 1,000 tokens). We attribute the large difference between broadcast news and broadcast conversa-

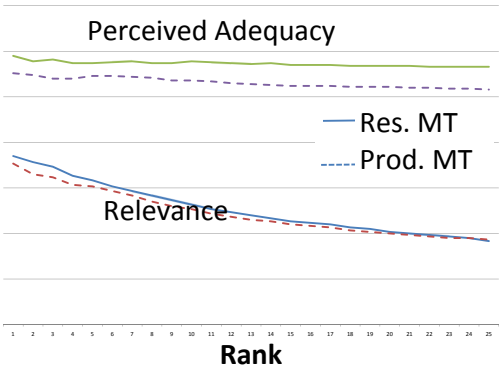

Figure 1: Average normalized cumulative sentence perceived adequacy and relevance versus rank of the sentence, by the ranking heuristic.

tion to the large number of short sentences without content words in informal speech (such as "hello", "thank you", etc.).

7.1 Perceived MT Adequacy

The research MT significantly outperformed the production MT in perceived adequacy (according to ANOVA with p=0.001). Of the production MT translations, 58% were considered "more than half" or "all" understandable, whereas 69% of the research MT were. Overall, retranslation increased perceived adequacy in 17% of the sentences, and decreased it in only 5% of sentences.

7.2 Ranking Algorithm

Figure 1 show the average cumulative sentence relevance and perceived adequacy, as ranked by the error detection algorithm. In other words, at each rank i, the average relevance (or perceived adequacy) of sentences $(1 - i)$ was calculated. On the perceived adequacy chart, the research MT system consistently outperforms the production MT system by a statistically significant margin. For relevance, the research MT curve is only marginally higher than the production MT curve.

The shape of the relevance curves shows that ranking sentences by a simple bilingual bag-of-words model did affect sentence relevance, since sentences that are higher ranked have higher cumulative average relevance. By ranking sentences with a basic relevance model, we were able to focus the scarce MT resources on sentences that are most likely to help the CLQA task. This underscores the importance of using the task context to guide MT error detection, especially in the case of time-constrained MT.

	Relevance				
	⇑	Same	⇓	No maj./ Don't know	
MT ⇑	20	201	9	56	17%
MT same	93	919	72	212	78%
MT ⇓	2	56	4	28	5%
	7%	70%	5%	18%	

Table 3: The relationship between changes in perceived adequacy and changes in relevance.

7.3 CLQA Relevance

Annotators judged 14.5% of the production MT sentences relevant. After retranslation, the overall number of sentences considered relevant increased to 14.7%. Although the overall numbers are similar, the relevance of many individual sentences did change. Table 3 shows the results of comparing annotations on the original MT with annotations on the retranslated MT. Relevance was classified as ⇑ or ⇓ by comparing the majority judgment of the production MT to the research MT. Changes in MT were based on comparing the average rating of both versions, with a tolerance of 1.0.

Of the sentences with better perceived MT, 7% increased in relevance, and 3% decreased in relevance. When the retranslated sentence was considered worse, there was a 2% increased in relevance and a 4% decrease. In other words, when retranslation had a positive effect, it more often led to increased relevance. However, the impact of retranslation was mixed, and none of the changes was statistically significant.

7.4 Intrinsic Evaluation

While the extrinsic evaluation focused on the impact on CLQA relevance, the goal of the intrinsic evaluation was to measure the precision of the error detection algorithm, and whether retranslation addressed the detected errors.

Of the 82% of sentences where both judges agreed, 89% of the detected errors were considered content words. All of the OOV tokens were content words (except for one disagree-

ment). Surprisingly, for the errors involving content words, 60% of the time both systems were judged the same with regard to the highlighted error. The research system was better 39% of the time, and the original was better only 1% of the time (excluding 26% disagreements).

8 Discussion

The CLQA evaluation was based on three hypotheses:

- That we could detect errors in MT with high precision.
- That retranslating errorful sentences with a much better MT system would correct the errors we detected.
- That correcting errors would cause some sentences to become relevant which were not previously relevant, as in (Ma and McKeown, 2009).

The intrinsic evaluation confirmed that we can identify content word deletions in MT with high precision, thus validating the first hypothesis. However, detecting the errors and retranslating them did not lead to large improvements in CLQA relevance – the impact of increased perceived adequacy on relevance was mixed and not significant. The intrinsic evaluation explains this negative result: even though the retranslated sentences were judged significantly better, the retranslation only corrected the detected error 39% of the time. In other words, the better research MT system was making many of the same mistakes as the production MT system, despite using syntactic features and a much deeper search space during decoding. Since the second hypothesis did not hold, we need to improve our error correction algorithm before we can tell whether the third hypothesis holds.

This result directly motivates the need for targeted error correction of MT. Automatic MT post-editing has been successfully used for selecting determiners (Knight and Chander, 1994), reinserting deleted verbs (Ma and McKeown, 2009), correcting NE translations (Parton et al., 2008), and lexical substitutions (Elming, 2006). Since Arabic and English word order differ significantly, straightforward re-insertion of the deleted words is not sufficient for error correction, so we are currently working on more sophisticated post-editing techniques.

9 Conclusions

We presented a novel online algorithm for detecting MT errors in the context of a question, and a heuristic for ranking MT errors by their potential impact on the CLQA task. The error detection algorithm focused on content word deletion, which has previously been shown to be a significant problem in SMT. The algorithm is generally applicable to any MT system that produces word or phrase alignments for its output and any language pair that can be POS-tagged, and it is more fine-grained and covers more types of errors than previous work. It was able to detect errors in Arabic-English MT across multiple text and speech genres, and the intrinsic evaluation showed that the large majority of tokens flagged as errors were indeed content words.

The large-scale CLQA evaluation confirmed that the slower research MT system was significantly better than the production MT system. Relevance judgments showed that the ranking component was crucial for directing scarce MT resources wisely, as the higher-ranked sentences were most likely to be relevant to the query, and therefore most likely to benefit the CLQA system by being retranslated.

Although we correctly identified MT errors, retranslating the sentences with the errors had a negligible effect on CLQA relevance. This unexpected result may be explained by the fact that only 39% of the errors were actually corrected by the research MT system, so re-translation was not a good approach for error correction. We are currently working on correcting content word deletion in MT via post-editing.

Acknowledgments The authors are grateful to Radu Florian, Salim Roukos, Vittorio Castelli, Dan Bikel and the whole GALE IBM team for providing the experimental testbed, including the CLQA and MT systems. This research was partially supported by DARPA grant HR0011-08-C-0110.

The Role of Queries in Ranking Labeled Instances Extracted from Text

Marius Paşca
Google Inc.
mars@google.com

Abstract

A weakly supervised method uses anonymized search queries to induce a ranking among class labels extracted from unstructured text for various instances. The accuracy of the extracted class labels exceeds that of previous methods, over evaluation sets of instances associated with Web search queries.

1 Introduction

Classes pertaining to unrestricted domains (e.g., *west african countries*, *science fiction films*, *slr cameras*) and their instances (*cape verde*, *avatar*, *canon eos 7d*) play a disproportionately important role in Web search. They occur prominently in Web documents and among search queries submitted most frequently by Web users (Jansen et al., 2000). They also serve as building blocks in formal representation of human knowledge, and are useful in a variety of text processing tasks.

Recent work on offline acquisition of fine-grained, labeled classes of instances applies manually-created (Banko et al., 2007; Talukdar et al., 2008) or automatically-learned (Snow et al., 2006) extraction patterns to large document collections. Although various methods exploit additional textual resources to increase accuracy (Van Durme and Paşca, 2008) and coverage (Talukdar et al., 2008), some of the extracted class labels are inevitably less useful (*works*) or spurious (*car makers*) for an associated instance (*avatar*). In Web search, the relative ranking of documents returned for a query directly affects the outcome of the search. Similarly, the relative ranking among class labels extracted for a given instance influences any applications using the labels.

Our paper proposes the use of features other than those computed over the underlying document collection, such as the frequency of co-occurrence or diversity of extraction patterns producing a given pair (Etzioni et al., 2005), to determine the relative ranking of various class labels, given a class instance. Concretely, the method takes advantage of the co-occurrence of a class label and an instance within search queries from anonymized query logs. It re-ranks lists of class labels produced for an instance by standard extraction patterns, to promote class labels that co-occur with the instance. This corresponds to a soft ranking approach, focusing on the ranking of candidate extractions such as the less relevant ones are ranked lower, as opposed to removed when deemed unreliable based on various clues.

By using queries in ranking, the ranked lists of class labels available for various instances are instrumental in determining the classes to which given sets of instances belong. The accuracy of the class labels exceeds that of previous work, over evaluation sets of instances associated with Web search queries. The results confirm the usefulness of the extracted IsA repository, which remains general-purpose and is not tailored to any particular task.

2 Instance Class Ranking

2.1 Extraction of Instances and Classes

The initial extraction of labeled instances relies on hand-written patterns from (Hearst, 1992), widely used in work on extracting hierarchies from text (Snow et al., 2006; Ponzetto and Strube,

Coling 2008: Poster Volume, pages 955–962,
Beijing, August 2010

2007):

⟨[..] $\mathcal{C}$ [such as|including] $\mathcal{I}$ [and|,|.]⟩,

where $\mathcal{I}$ is a potential instance (e.g., *diderot*) and $\mathcal{C}$ is a potential class label (e.g., *writers*).

Following (Van Durme and Paşca, 2008), the boundaries of potential class labels $\mathcal{C}$ are approximated from the part-of-speech tags of the sentence words, whereas the boundaries of instances $\mathcal{I}$ are identified by checking that $\mathcal{I}$ occurs as an entire query in query logs. Since users type many queries in lower case, the collected data is converted to lower case.

When applied to inherently-noisy Web documents, the extraction patterns may produce irrelevant extractions (Kozareva et al., 2008). Causes of errors include incorrect detection of possible enumerations, as in *companies such as Procter and Gamble* (Downey et al., 2007); incorrect estimation of the boundaries of class labels, due to incorrect attachment as in *years* from *on a limited number of vehicles over the past few years, including the Chevrolet Corvette*; subjective (*famous actors*) (Hovy et al., 2009), relational (*competitors*, *nearby landmarks*) and otherwise less useful (*others*, *topics*) class labels; or questionable source sentences, as in *Large mammals such as deer and wild turkeys can be [..]* (Van Durme and Paşca, 2008).

As a solution, recent work uses additional evidence, as a means to filter the pairs extracted by patterns, thus trading off coverage for higher precision. The repository extracted from a similarly-sized Web document collection using the same initial extraction patterns as here, after a weighted intersection of pairs extracted with patterns and clusters of distributionally similar phrases, contains a total of 9,080 class labels associated with 263,000 instances in (Van Durme and Paşca, 2008). Subsequent extensions of the repository, using data derived from tables within Web documents, increase instance coverage and induce a ranking among class labels of each instance, but do not increase the number of class labels (Talukdar et al., 2008). Due to aggressive filtering, the resulting number of class labels is higher than the often-small sets of entity types studied previously, but may still be insufficient given the diversity of Web search queries.

2.2 Ranking of Classes per Instance

As an alternative, the soft ranking approach proposed here attempts to rank better class labels higher, without necessarily removing class labels deemed incorrect according to various criteria. For each instance $\mathcal{I}$, the associated class labels are ranked in the following stages:

1) Apply the scoring formula below, resulting in a ranked list of class labels $\mathrm{L}_1(\mathcal{I})$:

$$Score(\mathcal{I},\mathcal{C}) = Size(\{Pattern(\mathcal{I},\mathcal{C})\})^2 \times Freq(\mathcal{I},\mathcal{C})$$

Thus, a class label $\mathcal{C}$ is deemed more relevant for an instance $\mathcal{I}$ if $\mathcal{C}$ is extracted by multiple extraction patterns and its original frequency-based score is higher.

2) For each term within any class label from $\mathrm{L}_1(\mathcal{I})$, compute a score equal to the frequency sum of the term within anonymized queries containing the instance $\mathcal{I}$ as a prefix, and the term anywhere else in the queries. Each class label is assigned the geometric mean of the scores of its terms, after ignoring stop words. The class labels are ranked according to the means, resulting in a ranked list $\mathrm{L}_2(\mathcal{I})$. In case of ties, $\mathrm{L}_2(\mathcal{I})$ preserves the relative ranking from $\mathrm{L}_1(\mathcal{I})$. Thus, a class label is deemed more relevant if its individual terms occur in popular queries containing the instance.

3) Compute a merged ranked list of class labels out of the ranked lists $\mathrm{L}_1(\mathcal{I})$ and $\mathrm{L}_2(\mathcal{I})$, by sorting the class labels in decreasing order of the inverse of the average rank, computed with the following formula:

$$MergedScore(\mathcal{C}) = \frac{2}{Rank(\mathcal{C},L_1) + Rank(\mathcal{C},L_2)}$$

where 2 is the number of input lists of class labels, and Rank($\mathcal{C}$, L_i) is the rank of $\mathcal{C}$ in the list L_i of class labels computed for the corresponding input instance. The rank is set to 1000, if $\mathcal{C}$ is not present in the list L_i. By using only the relative ranks of the class labels within the input lists, and not on their scores, the outcome of the merging is less sensitive to how class labels of a given instance are scored within the IsA repository. In case of ties, the scores of the class labels from $\mathrm{L}_1(\mathcal{I})$ serve as a secondary ranking criterion.

Note that the third stage is introduced because relying on query logs to estimate the relevance of

class labels exposes the ranking method to significant noise. On one hand, arguably useful class labels (e.g., *authors*) may not occur in queries along with the respective instances (*diderot*). On the other hand, for each query containing an instance and (part of) useful class labels, there are many other queries containing, e.g., attributes (*diderot biography* or *diderot beliefs*) or the name of a book in the query *diderot the nun*. Therefore, the ranked lists $L_2(\mathcal{I})$ may be too noisy to be used directly as rankings of the class labels for $\mathcal{I}$.

3 Experimental Setting

3.1 Textual Data Sources

The acquisition of the IsA repository relies on unstructured text available within Web documents and search queries. The collection of queries is a sample of 50 million unique, fully-anonymized queries in English submitted by Web users in 2009. Each query is accompanied by its frequency of occurrence in the logs. The document collection consists of a sample of 100 million documents in English. The textual portion of the documents is cleaned of HTML, tokenized, split into sentences and part-of-speech tagged using the TnT tagger (Brants, 2000).

3.2 Experimental Runs

The experimental runs correspond to different methods for extracting and ranking pairs of an instance and a class:

- as available in the repository from (Talukdar et al., 2008), which is collected from a document collection similar in size to the one used here plus a collection of Web tables, in a run denoted R_g;
- from the repository extracted here, with class labels of an instance ranked based on the frequency and the number of extraction patterns (see $Score(\mathcal{I}, \mathcal{C})$ in Section 2), in run R_s;
- from the repository extracted here, with class labels of an instance ranked based on the $MergedScore$ from Section 2, in run R_u.

3.3 Evaluation Procedure

The manual evaluation of open-domain information extraction output is time consuming (Banko et al., 2007). Fortunately, it is possible to implement an automatic evaluation procedure for ranked lists of class labels, based on existing resources and systems. Assume that a gold standard is available, containing gold class labels that are each associated with a gold set of their instances. The creation of such gold standards is discussed later. Based on the gold standard, the ranked lists of class labels available within an IsA repository can be automatically evaluated as follows. First, for each gold label, the ranked lists of class labels of individual gold instances are retrieved from the IsA repository. Second, the individual retrieved lists are merged into a ranked list of class labels, associated with the gold label. The merged list is computed using an extension of the $MergedScore$ formula described earlier in Section 2. Third, the merged list is compared against the gold label, to estimate the accuracy of the merged list. Intuitively, a ranked list of class labels is a better approximation of a gold label, if class labels situated at better ranks in the list are closer in meaning to the gold label.

3.4 Evaluation Metric

Given a gold label and a list of class labels, if any, derived from the IsA repository, the rank of the highest class label that matches the gold label determines the score assigned to the gold label, in the form of the reciprocal rank, max(1/rank$_{match}$). Thus, if the gold label matches a class label at rank 1, 2, 3, 4 or 5 in the computed list, the gold label receives a score of 1, 0.5, 0.33, 0.25 or 0.2 respectively. The score is 0 if the gold label does not match any of the top 20 class labels. The overall score over the entire set of gold labels is the mean reciprocal rank (MRR) score over all gold labels from the set. Two types of MRR scores are automatically computed:

- MRR$_f$ considers a gold label and a class label to match if they are identical;
- MRR$_p$ considers a gold label and a class label to match if one or more of their tokens that are not stop words are identical.

During matching, all string comparisons are case-insensitive, and all tokens are first converted to their singular form (e.g., *european countries* to *european country*) when available, by using WordNet's morphological routines. Thus, *insurance carriers* and *insurance companies* are considered to not match in MRR_f scores, but match in MRR_p scores, whereas *insurance companies* and *insurance company* match in both MRR_f and MRR_p scores. Note that both MRR_f and MRR_p scores fail to give any credit to arguably valid and useful class labels, such as *insurers* for the gold label *insurance carriers*, or *asian nations* for the gold label *asia countries*. On the other hand, MRR_p scores may give credit to less relevant class labels, such as *insurance policies* for the gold label *insurance carriers*. Therefore, MRR_p is an approximate, and MRR_f is a conservative, lower-bound estimate of the actual usefulness of the computed ranked lists of class labels as approximations of the semantics of the gold labels.

4 Evaluation Results

4.1 Evaluation Sets of Queries

A random sample of anonymized, class-seeking queries (e.g., *video game characters* or *smartphone*) submitted by Web users to Google Squared [1] over a 30-day interval is filtered, to remove queries for which Google Squared returns fewer than 10 instances at the time of the evaluation. The resulting evaluation set of queries, denoted Q_e, contains 807 queries, each associated with a ranked list of between 10 and 100 instances automatically extracted by Google Squared.

Since the instances available as input for each query as part of Q_e are automatically extracted, they may (e.g., *acorn a7000*) or may not (e.g., *konrad zuse*) be true instances of the respective queries (e.g., *computers*). A second evaluation set Q_m is assembled as a subset of 40 queries from Q_e, such that the instances available for each query in Q_m are correct. For this purpose, each instance returned by Google Squared for the 40 queries from Q_m is reviewed by at least three human annotators. Instances deemed highly relevant (out of 5 possible grades) with high inter-annotator agreement are retained. As a result, the 40 queries from Q_m are associated with between 8 and 33 human-validated instances.

Query Set: Sample of Queries
Q_e (807 queries): 2009 movies, amino acids, asian countries, bank, board games, buildings, capitals, chemical functional groups, clothes, computer language, dairy farms near modesto ca, disease, egyptian pharaohs, eu countries, french presidents, german islands, hawaiian islands, illegal drugs, irc clients, lakes, macintosh models, mobile operator india, nba players, nobel prize winners, orchids, photo editors, programming languages, renaissance artists, roller costers, science fiction tv series, slr cameras, soul singers, states of india, taliban members, thomas edison inventions, u.s. presidents, us president, water slides
Q_m (40 queries): actors, airlines, birds, cars, celebrities, computer languages, digital camera, dog breeds, drugs, endangered animals, european countries, fruits, greek gods, horror movies, ipods, names, netbooks, operating systems, park slope restaurants, presidents, ps3 games, religions, renaissance artists, rock bands, universities, university, vitamins

Table 1: Size and composition of evaluation sets of queries associated with non-filtered (Q_e) or manually-filtered (Q_m) instances

Table 1 shows a sample of the queries from Q_e and queries from Q_m. A small number of queries are slight lexical variations of one another, such as *u.s. presidents* and *us presidents* in Q_e, or *universities* and *university* in Q_m. In general, however, the sets cover a wide range of domains of interest, including entertainment for *2009 movies* and *rock bands*; biology for *endangered animals* and *amino acids*; geography for *asian countries* and *hawaiian islands*; food for *fruits*; history for *egyptian pharaohs* and *greek gods*; health for *drugs* and *vitamins*; and technology for *photo editors* and *ipods*. Some of the queries from Table 1 are specific enough that computing them exactly,

[1] Google Squared (http://www.google.com/squared) is a Web search tool taking as input class-seeking queries (e.g., *insurance companies*) and returning lists of instances (e.g., *allstate*, *state farm insurance*), along with attributes (e.g., *industry*, *headquarters*) and values for each instance.

Table 2: Accuracy of instance set labeling, as full-match (MRR_f) or partial-match (MRR_p) scores over the evaluation sets of queries associated with non-filtered instances (Q_e) or manually-filtered instances (Q_m), for various experimental runs (I_Q=number of instances available in the input evaluation sets that are used for retrieving class labels; C_I=number of class labels retrieved from IsA repository per input instance)

even from a comprehensive, perfect list of extracted instance, would be very difficult whether done automatically or manually. Examples of such queries are *dairy farms near modesto ca* and *science fiction tv series*, but also *mobile operator india* (phrase expressed as keywords) in Q_e, or *park slope restaurants* (specific location) in Q_m.

Access to a system such as Google Squared is useful, but not necessary to conduct the evaluation. Given other sets of queries, it is straightforward, albeit time consuming, to create evaluation sets similar to Q_m, by manually compiling correct instances, for each selected query or concept.

Following the general evaluation procedure, each query from the sets Q_e and Q_m acts as a gold class label associated with its set of instances. Given a query and its instances $\mathcal{I}$ from the evaluation sets Q_e or Q_m, we compute merged, ranked lists of class labels, by merging the ranked lists of class labels available in the underlying IsA repository for each instance $\mathcal{I}$. The evaluation compares the merged lists of class labels, on one hand, and the corresponding queries from Q_e or Q_m, on the other hand.

4.2 Accuracy of Class Labels

Table 2 summarizes results from comparative experiments, quantifying a) horizontally, the impact of alternative parameter settings on the computed lists of class labels; and b) vertically, the comparative accuracy of the experimental runs over the query sets. The experimental parameters are the number of input instances from the evaluation sets that are used for retrieving class labels, I_Q, set to 3, 5, 10 and 15; and the number of class labels retrieved per input instance, C_I, set to 5, 10 and 20.

The scores over Q_m are higher than those over Q_e, confirming the intuition that the higher-quality input set of instances available in Q_m relative to Q_e should lead to higher-quality class labels for the corresponding queries. When I_Q is fixed, increasing C_I leads to small, if any, score improvements. Conversely, when C_I is fixed,

even small values of I_Q, such as 3 or 5 (that is, very small sets of instances provided as input) produce scores that are competitive with those obtained with a higher value like. This suggests that useful class labels can be generated even in extreme scenarios, where the number of instances available as input is as small as 3 or 5.

For most combinations of parameter settings and on both query sets, run R_u produces the highest scores. In particular, when I_Q is set to 10 and C_I to 20, run R_u identifies the original query as an exact match among the top four class labels returned; and as a partial match among the top two class labels returned, as an average over the Q_e set. In this case, the original query is identified at ranks 1, 2, 3, 4 and 5 for 16.8%, 8.7%, 6.1%, 3.7% and 1.7% of the queries, as an exact match; and for 48.8%, 14.2%, 6.1%, 3.6% and 1.9% respectively, as a partial match. The corresponding MRR_f score of 0.257 over the Q_e set obtained with run R_u is higher than with run R_s, and much higher than with run R_g. In all experiments, the higher scores of R_u can be attributed to higher coverage of class labels, relative to R_g; and higher-quality lists of class labels, relative to R_s but also to R_g, despite the fact that R_g combines high-precision seed data with using both unstructured and structured text as sources of class labels (cf. (Talukdar et al., 2008)). Among combinations of parameter settings described in Table 2, values around 15 for I_Q and 20 for C_I give the highest scores over both Q_e and Q_m.

5 Related Work

5.1 Extraction of IsA Repositories

Knowledge including instances and classes can be manually compiled by experts (Fellbaum, 1998) or collaboratively by non-experts (Singh et al., 2002). Alternatively, classes of instances acquired automatically from text are potentially less expensive to acquire, maintain and grow, and their coverage and scope are theoretically bound only by the size of the underlying data source. Existing methods for extracting classes of instances acquire sets of instances that are each either unlabeled (Wang and Cohen, 2008; Pennacchiotti and Pantel, 2009; Lin and Wu, 2009), or associated with a class label (Pantel and Pennacchiotti, 2006; Banko et al., 2007; Wang and Cohen, 2009). When associated with a class label, the sets of instances may be organized as flat sets or hierarchically, relative to existing hierarchies such as WordNet (Snow et al., 2006) or the category network within Wikipedia (Wu and Weld, 2008; Ponzetto and Navigli, 2009). Semi-structured text was shown to be a complementary resource to unstructured text, for the purpose of extracting relations from Web documents (Cafarella et al., 2008).

The role of anonymized query logs in Web-based information extraction has been explored in the tasks of class attribute extraction (Paşca and Van Durme, 2007) and instance set expansion (Pennacchiotti and Pantel, 2009). Our method illustrates the usefulness of queries considered in isolation from one another, in ranking class labels in extracted IsA repositories.

5.2 Labeling of Instance Sets

Previous work on generating relevant labels, given sets or clusters of items, focuses on scenarios where the items within the clusters are descriptions of, or full-length documents within document collections. The documents are available as a flat set (Cutting et al., 1993; Carmel et al., 2009) or are hierarchically organized (Treeratpituk and Callan, 2006). Relying on semi-structured content assembled manually as part of the structure of Wikipedia articles, such as article titles or categories, the method introduced in (Carmel et al., 2009) derives labels for clusters containing 100 full-length documents each. In contrast, our method relies on IsA relations automatically extracted from unstructured text within arbitrary Web documents, and computes labels given textual input that is orders of magnitude smaller, i.e., around 10 phrases (instances). The experiments described in (Carmel et al., 2009) assign labels to one of 20 sets of newsgroup documents from a standard benchmark. Each set of documents is associated with a higher-level, coarse-grained label used as a gold label against which the generated labels are compared. In comparison, our experiments compute text-derived class labels for finer-grained, often highly-specific gold labels.

Reducing the granularity of the items to be labeled from full documents to condensed document descriptions, (Geraci et al., 2006) submits arbitrary search queries to external Web search engines. It organizes the top 200 returned Web documents into clusters, by analyzing the text snippets associated with each document in the output from the search engines. Any words and phrases from the snippets may be selected as labels for the clusters, which in general leads to labels that are not intended to capture any classes that may be associated to the query. For example, labels of clusters generated in (Geraci et al., 2006) include *armstrong ceilings*, *italia*, *armstrong sul sito* and *louis jazz* for the query *armstrong*; and *madonnaweb*, *music*, *madonna online* and *madonna* itself for the query *madonna*. The amount of text available as input for the purpose of labeling is at least two orders of magnitude larger than in our method, and the task of selecting any phrases as labels, as opposed to selecting only labels that correspond to classes, is more relaxed and likely easier.

Another approach specifically addresses the problem of generating labels for sets of instances, where the labels are extracted from unstructured text. In (Pantel and Ravichandran, 2004), given a collection of news articles that is both cleaner and smaller than Web document collections, a syntactic parser is applied to document sentences in order to identify and exploit syntactic dependencies for the purpose of selecting candidate class labels. Such methods are comparatively less applicable to Web document collections, due to scalability issues associated with parsing a large set of Web documents of variable quality. Moreover, the class labels generated in (Pantel and Ravichandran, 2004) tend to be rather coarse-grained. For example, the top labels generated for a set of Chinese universities (*qinghua university*, *fudan university*, *beijing university*) are *university*, *institution*, *stock-holder*, *college* and *school*.

6 Conclusion

The method presented in this paper produces an IsA repository whose class labels have higher coverage and accuracy than with recent methods operating on document collections. This is done by injecting useful ranking signals from inherently-noisy queries, rather than making binary, coverage-reducing quality decisions on the extracted data. Current work investigates the usefulness of the extracted class labels in the generation of flat or hierarchical query refinements for class-seeking queries.

Abstract

This article presents an original lexical unit extraction system for Chinese. The method is based on an incremental process driven by an association score featuring a minimal resources statistically aided linguistic approach. We also introduce a linguistics-based lexical unit definition and use it to describe an evaluation protocol dedicated to the task. The experimental results on a domain specific corpus show that the method performs better than other approaches. The extraction results, evaluated on a random sample of the working corpus, show a recall of 68.4 % and precision of 37.1 %.

1 Introduction

Lexical resources are all the more fundamental to NLP systems since domain specific corpora are multiple and various. The performance of common tasks, such as Information Retrieval or Information Extraction, can be improved by comprehensive and updated domain specific lexicon (i.e. terminology). However the constitution of lexicons raises pragmatic issues, such as development cost or re-usability, which have a great importance in an industrial context ; and also theoretical issues, such as the definition of the lexical unit or evaluation protocol, which are crucial for the relevance of the results. In Chinese text processing context, lexicons are particularly important for dictionary-based word segmentation techniques in which out-of-vocabulary words are an important cause of errors (Sproat and Emerson, 2003).

In this paper we consider the lexicon extraction task independent of the word segmentation, this position differs from Zhao and Kit's (2004) point of view. Generally speaking, word segmentation aims at delimiting units in a sequence of characters. The delimited units are usually morphological lexical units (i.e. words) and internal composition of the unit is not considered. The evaluation process checks whether each word occurrence is well delimited. On the opposite, lexicon extraction aims at extracting lexicon entries from a corpus. The extracted units are morphological or syntactic units and the internal components are also considered. The evaluation process checks the extracted candidates list considering the corpus global scope.

Many approaches for Chinese lexicon extraction rely on a supervised word segmenter (Wu and Jiang, 2003; Li et al., 2004) or a morpho-syntactic tagger (Piao et al., 2006) to extract unknown words. These techniques perform well but suffer from a major drawback, they cannot be applied efficiently to corpora that cover different domains than the calibration corpus. Some approaches are nested in an unsupervised word segmentation process and aim at improving its effectiveness. Fung and Wu (1994) try to select segments using mutual information on bigram. Chang and Su (1997) present an iterative unsupervised lexicon extraction system driven by the quality of segmentation obtained with the discovered lexicon. This approach, although efficient, imposes an arbitrarily 4-character length restriction on candidates. Other works, like this approach, focus on the lexicon or terminology extraction as standalone task. Feng et al. (2004) introduce a lexicon extraction unsuper-

Coling 2008: Poster Volume, pages 963–971,
Beijing, August 2010

vised method based on context variation with very convincing results. Yang et al. (2008) focus on terminology extraction using delimiters extracted from a training corpus with good results.

This study proposes an original answer to the Chinese lexicon extraction task using an incremental minimal resources method to extract and rank lexical unit candidates. An annotated reference corpus is required to extract a common-word dictionary and to prepare the data. The method has the advantage of proposing structured candidates, which allow interactive candidate filtering. In addition the candidate maximum length is determined by the number of associations that allow the detection of the longer lexical units. We extend the association measure method introduced by Sun et al. (1998) for word segmentation without lexical resources. This paper starts with a linguistic definition of the lexical unit which drives the method. We also build on it to propose an improvement of the evaluation protocol for the Chinese lexicon extraction task.

2 Lexical Unit Definition

Although defining the Chinese lexical unit is not a trivial task, we think that it is absolutely necessary for the understanding of the kind of linguistic phenomena we are dealing with. Without this knowledge we may miss important features and may not be able to efficiently evaluate the extraction process. We introduce two linguistic concepts to define the lexical units focusing on contemporary written Chinese: the *morpho-syntactic unit* and the *lexical content*. These definitions use concepts introduced by Polguère (2003) applied to the Chinese case by Nguyen (2008).

2.1 Morpho-syntactic Unit

A *graphy* is the Chinese minimal autonomous orthographic unit and it approximatively matches the glyph concept in computer science. The following glyphs are different Chinese graphies: 猫, 貓, 寿, 葡, 萄. A *morph* (noted | m |) is the smallest meaningful unit representable by a sequence of graphies. Morphs are atomic so that they cannot be representable by a smaller sequence of morphs. The following sequences of graphies are different morphs : |longevity 寿|, |grape 葡萄|, |aspirin 阿司匹林|, |buy 买|. Note that the graphy 萄 does not carry any meaning and is not a morph. A *morpheme* (noted ‖M‖[1]) is a set of morphs sharing the same lexical content ignoring grammatical inflection or variants (Table 1). Chinese morphs cannot be inflected, unlike European languages, but some graphies have variants.

Morpheme	***Morph***
‖protect 保‖	|protect 保|
‖aspirin 阿司匹林‖	|aspirin 阿司匹林|
‖cat 猫‖	|cat 猫| |cat 貓|

Table 1: *Morphemes and related morphs*

A *word-form* (noted (w)) is an autonomous and inseparable sequence of morphs. Autonomy means that it can be enunciated individually and can take place in a syntactic paradigm. Inseparability means that breaking the sequence causes the loss of the relationship between elements. A *lexeme* (noted ⟪ w ⟫) is a set of word-forms sharing the same lexical content ignoring inflection or variants (Table 2).

Lexeme	***Word-form***
⟪aspirin 阿司匹林⟫	(|aspirin 阿司匹林|)
⟪take 拿⟫	(|take 拿|) (|take /prefect/ 拿|了|) (|take /progressive/ 拿|着|) (|take /experience/ 拿|过|)
⟪insurance 保险⟫	(|insurance 保|险|)
⟪|panda 熊|猫|⟫	(|panda 熊|猫|) (|panda 熊|貓|)

Table 2: *Lexemes and associated word-forms*

A *phrase* (noted [s]) is a syntactic combination of word-forms. The syntactic nature of the combination implies that the phrase components are relatively free. A *locution* (noted ⟦ s ⟧) is a set of lexicalized phrases sharing the same lexical content ignoring inflection or variants (Table 3).

Locution	***Phrase***
⟦shoot 开枪⟧	[(shoot 开)(枪)] [(shoot /prefect/ 开了)(枪)] ...
⟦be jealous 吃醋⟧	[(be jealous 吃)(醋)]
⟦insurance company 保险公司⟧	[(insurance company 保险)(公司)]

Table 3: *Locutions and associated phrases*

[1]The standard simplified form is used to represent morphemes.

The morphs, word-forms and phrases are the morpho-syntactic units, they describe the composition of lexemes and locutions.

2.2 Lexical Content

The lexical units we look for are lexemes and locutions. Finding lexical units means identifying words-forms and phrases having a lexical content. We use two criteria to define the lexical content: the *compositionality criterion* and the *referentiality criterion* (Table 4). Units which fulfill at least one of these criteria are said to have a lexical content.

The compositionality criterion (or lexicalization criterion) is relative to the relationship between the sense of the unit and the sense of its components. The question is whether or not the sense of the unit can be deduced from the combination of its components. The referentiality criterion is related to the relationship between the unit and the referent concept or object. The question is whether or not the referent has specific properties for the speakers. This criterion is strongly dependent on human judgment and the working domain.

	Referential	***No-Referential***
Compositional	《Chinese food 中餐》	(anticization 古代化)
	⟦insurance company 保险公司⟧	[African car 非洲汽车]
Lexicalized	《disinfect 消毒》	⟦everyone 大家⟧
	⟦dividend product 分红产品⟧	⟦selling vinegar as wine 挂羊头卖狗肉⟧

Table 4: *Referential and Compositional units*

The Table 4 presents examples of four criterion combinations. Referentiality and compositionality criteria are always applied at the highest association level, thus ⟦insurance company 保险公司⟧) is compositional, although 《insurance 保险》 and 《company 公司》 are not compositional. Word-forms are not necessarily compositional or referential, thus the unit (anticization 古代化) does not refer to any concept and we can use the combination of its components to interpret it: 《antiquity 古代》 + ‖-ation 化‖. Referentiality does not imply lexicalization, thus the compositional unit ⟦German car 德国汽车⟧ is referential because it refers to the German car brands or characteristics in the automobile context.

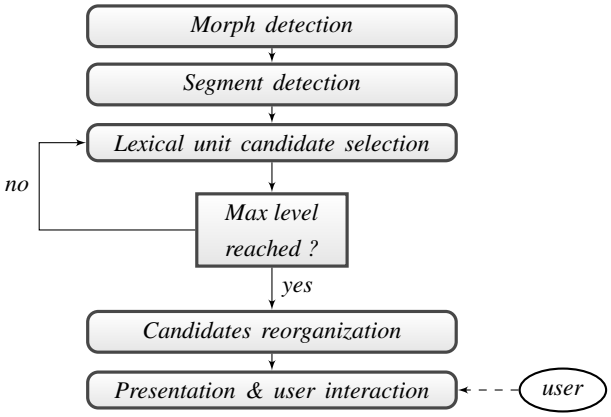

Figure 1: *Method overview*

3 Methodology

The method (Figure 1) follows the linguistic intuitions developed in the previous section. We identify morpho-syntactic units and select those that are likely to have a lexical content to obtain *lexical unit candidates* (LUCs). The word-forms and phrases are respectively generated by associations of morphs or word-forms and association of word-forms or phrases. We consequently use an incremental process, which associates LUCs as they are selected. The incremental process is initiated by detecting every morph and spliting the corpus into segments. Then we enumerate all the morpho-syntactic unit couples and use lexical content criteria to select the couples to associate. This process is repeated until the maximum number of associations is reached. At the end, the LUCs are reorganized and submitted to the user. The user's answers are used to filter the remaining LUCs.

3.1 Morphs Detection

As stated in Section 2.1, we consider that the morph is the minimal morpho-syntactic unit. Every glyph is considered as a morph unless it can be included in an ancient loanword morph (《butterfly 蝴蝶》 《garbage 垃圾》) or a foreign transcription morph (《Italy 意大利》, 《microphone 麦克风》). In an ambiguous case the longest possibility is accepted. Foreign transcriptions are phonetic interpretations of foreign words using the pronunciation of the Chinese graphies. The set of graphies used for transcription is well-

known and closed. We trained a CRF tagger[2] using simple features based on current, next and previous graphies to extract foreign transcriptions (the training corpus is described in Section 4.1). Ancient loanwords importation process is not productive anymore, thus they are detected using a loanword list.

3.2 Segment Detection

The aim of the segment detection step is to split the corpus into segments (i.e. a succession of Chinese graphies). Chinese texts contain two kinds of delimiters which are not likely to be components of a lexical unit, delimiter-words and delimiter-expressions. Delimiter-words are enumerable with a common word dictionary[3] and include prepositions (对, 使), adverbs (很, 也, 都), pronouns (我, 其他, 那儿), interrogative pronouns (哪里, 谁), conjunctions (而且, 但, 因此), discourse structure words (目前, 按照, 由), tonal particles (啊, 吧) and tool-words (的). Delimiter-expressions include numerical expressions (六万美元, 三个), temporal expressions (今天晚上, 八点左右), circumstantial expressions (从...开始, 在...中) , which are easily describable using shallow context-free grammars. Delimiters are removed from the corpus and used to delimit the segments. The inflexions (了, 过, 着), which introduce inflectional variations, are also removed from the corpus but do not delimit the segments. The delimiters identification is controlled by rules. For instance tonal particles are removed only if they are the end of a segment, discourse structure words are removed only if they are the beginning of a segment. Delimiters and inflexions are not removed if they are inside a sequence of graphies which is present in a common-word dictionary.

3.3 Selection of Lexical Unit Candidates

In this step, *lexical unit candidates* (LUCs) are extracted by selecting morpho-syntactic unit couples, which are likely to have a lexical content. The first assumption is that lexical units can always be decomposed into binary trees. Only a small number of lexical units do not satisfy this assumption (e.g. 乌漆墨黑), in such case it is possible to select a non-linguistically motivated way to decompose the unit into binary associations. Thus, every couples of contiguous morpho-syntactic units are iteratively enumerated for each segment. The second assumption is that *association measures* are good statistical evidence to detect lexical content. Thereby, the association strength of morpho-syntactic couples is used as a main criterion to identify relevant candidates.

Sentence with delimiters noted {delimiter}:

公司银代主力产品“新红A”、“新红C”两款分红产品适应{了}今年资本市场{的}现状，产品设计、分红水平、特殊红利分配{等}方面{都}得到合作银行{和}客户{的}认同，充分满足{了}客户{的}预期利益，{在}市场{上}得到{了}{很}高{的}美誉度。

Obtained segments noted [segment]:

[公司银代主力产品] [新红] [新红] [两款分红产品适应今年资本市场] [现状] [产品设计] [分红水平] [特殊红利分配] [方面] [得到合作银行] [客户] [认同] [充分满足客户] [预期利益] [市场] [得到] [高] [美誉度]

Figure 2: *Segment detection example*

Consider G the alphabet of all Chinese graphies, $M = G^+$ the language describing the morpho-syntactic units, S_n a set of segments at step n, $s_n^i = m_1, m_2, ..., m_n$ the i^{th} segment of S_n where $\forall m \in s_n^i \mid m \in M$ and S_n^* the set of all morpho-syntactic unit couples in S_n segments. Given the morpho-syntactic unit couple m_i, $m_{i+1} \in S_n^*$ (denoted as $m_{i,i+1}$), the *lexical content criteria* ($LCC(m_{i,i+1})$) matches if the following conditions are fulfilled:

1. Neither m_i nor m_{i+1} has not been associated at the current step n.
2. $Nb(m_i) \neq 1$ or $Nb(m_{i+1}) \neq 1$.
3. $AS(m_{i,i+1}) > T$.
4. $AS(m_{i,i+1}) > AS(m_{i-1,i})$ or not $LCC(m_{i-1,i})$
5. $AS(m_{i,i+1}) > AS(m_{i+1,i+2})$ or not $LCC(m_{i+1,i+2})$

where $Nb(x)$ is the number of occurrences of x, $AS(x, y)$ returns the association score of the cou-

[2] CRF++ implementation of Conditional Random Fields

[3] We assert that this kind of dictionary is easily available

ple x, y computed with a given association measure, and T is the association threshold relative to the association measure (cf. 4.1).

Let S_0 the initial set of segments where $\forall s_0^i \in S_0$, s_0^i is a segment (cf. 3.2) such that $\forall m \in s_0^i$, m is a morph (cf. 3.1). The LUC list is composed of morpho-syntactic couples produced by the association operator $\oplus$ to compute S_{max} (algorithm 1) with max the maximum number of iteration.

$$
\begin{aligned}
&S \leftarrow S_{n-1} \\
&\textbf{while} \quad \exists\, m_{i,i+1} \in S^* |\ LCC(m_{i,i+1}) \\
&\quad S \leftarrow S[m_i \oplus m_{i+1}] \qquad (1) \\
&\textbf{end} \\
&S_n \leftarrow S
\end{aligned}
$$

with $\oplus$ the association operator whose result is a morpho-syntactic unit, $S_n[m_1 \oplus m_2]$ the replacement of m_1 and m_2 by the morpho-syntactic unit $m_1 \oplus m_2$ in the corresponding segment. See the Section 5 for more details about the maximum number of iteration setting.

3.4 Candidates Reorganization

Once LUCs are extracted, we map every LUC to the couple of morpho-syntactic units it is composed of. These units are called *components*. Some LUCs are generated from two different couples at the candidate selection step. For instance, 旅游业者 is discovered in two ways: 旅游⊕业者 or 旅游业⊕者. We always choose the most frequent option. When the "LUC/couple" map is created, we sort the LUCs by their corresponding couple association scores. Finally, if a LUC is ranked in the list before its components we move the components to the position just before it in the list and use the same rule to recursively check the moved components. The candidates list is expected to be ordered by likelihood deduced by an association measure and compositional order.

3.5 Presentation and User Interaction

The lexicon extraction task aims at submitting a ranked list of candidates to the user in order to help him produce lexical resources. The user is expected to check the list in this order and the method uses the user answers to discard not yet verified candidates. To do so, the user is asked to answer the following questions for each LUC according to the definition given in the Section 2:

1. Does the unit have a lexical content ?
2. Is the unit a part of a lexical unit ?

If answers to both these questions are 'no' then all the candidates having this component are removed from the remaining list.

4 Evaluation

Since the submitted candidates are progressively modified according to the user answers, the evaluated candidates are only the ones submitted to the user. We used three measures to evaluate the method: recall, precision and precision at rank n. Since producing large annotated corpora is costly, we perform the evaluation using a sample of texts from the evaluation corpus. Therefore the scores obtained are an estimation of the true scores. The inter-human variation is not considered here and should be integrated in further works.

4.1 Evaluation parameters

The morphs and the segment detection step use data from a *reference corpus*: *The Lancaster Corpus of Mandarin Chinese* (McEnery and Xiao, 2004). The corpus is composed of text samples choose in various domain and genre corpora, it contains two millions of glyphs and it is annotated according to the Beijing University annotation guideline[4]. This corpus is mainly used to extract delimiter-words, to produce the grammar for delimiter-expressions and to extract a common-word dictionary. All foreign transcriptions are also annotated for the CRF tagger training (cf. 3.1).

The lexical unit detection step is evaluated using four well-known association measures: Pointwise Mutual Information (PMI), Poisson-Striling (PS) (Quasthoff and Wolff, 2002), Log-likelihood (LL), Pointwise Mutual Information Cube (PMI^3) (Daille, 1994). These measures are detailed in table 5. The significant association threshold is intuitively given by the statistical interpretation of

[4] *http://icl.pku.edu.cn/icl_groups/corpus/coprus-annotation.htm*

AM	*Formulas*	*Variables*
PMI	$\log \frac{p_{xy}}{p_{x*}p_{*y}}$	x, y : words $\overline{x}$: all words but x $*$: all words p_x : x probability f_x : x frequency N : nb. of bigram $\lambda = N \cdot p_x \cdot p_y$ $k = f_{xy}$ $\hat{f}_{xy} = \frac{f_{x*}f_{*y}}{N}$
LL	$2 \sum_{i,j}^{\{x,\overline{x}\},\{y,\overline{y}\}} f_{ij} \log \frac{f_{ij}}{\hat{f}_{ij}}$	
PS	$\frac{k(\log k - \log \lambda - 1)}{\log N}$	
PMI^3	$\log \frac{N {f_{xy}}^3}{f_{x*}f_{*y}}$	

Table 5: *Association score calculation*

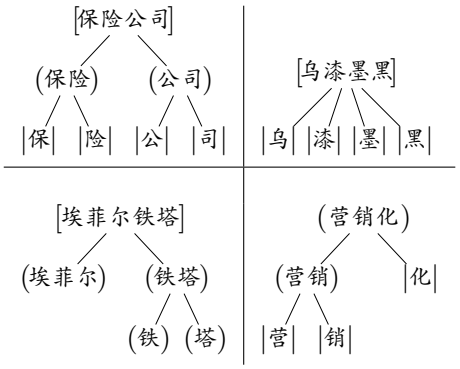

Figure 3: *Lexical unit trees*

the formulas for MI and PS. Thus, these measures are used for LCC's *selection criterion 2* and T is set to 0 (cf. 3.3). A threshold can not be deduced from PS and PMI^3, therefore they are only used for LCC's *comparison criteria 3 & 4*.

4.2 Evaluation Process

To prepare the evaluation we randomly selected twenty texts in an evaluation corpus and annotated lexical units according to the linguistic description given in Section 2. For each sample text, we obtained a set of lexical unit trees (Table 3) corresponding to all the encountered lexical units. N-trees are used for units which can not be transformed into binary tree. Two evaluation sets are defined, the *shallow set* which contains the root nodes of the lexical unit trees and the *deep set* which contains the inner nodes[5] of the lexical unit trees. Given the four examples of Figure 3, the shallow set contains [保险公司], [乌漆墨黑], [埃菲尔铁塔] and (营销化) ; and the deep set contains [保险公司], (保险), (公司), [乌漆墨黑], [埃菲尔铁塔], (铁塔), (营销化) and (营销).

Experiments with different parameters produce different candidate lists and an expert intervention is required to evaluate each candidate list. To avoid this problem, all the repeated sequences of non-inflectional graphies are generated from the annotated sample texts and intersected with the LUC list. The obtained list is a projection of the candidate list on the sample texts. This trick allows us to extract all LUCs appearing in the sample texts and evaluate them automatically.

[5] All nodes excluding leaves.

5 Experiments

The experiments are conducted on insurance domain corpus containing ten million graphies. This evaluation corpus is composed of news and articles collected automatically from Chinese insurance companies websites. The text fields are extracted with an xhtml parser. Several text fields, such as menus or buttons, are repeated and duplicates are removed to avoid noise. The presented method, referred as ILex (Incremental Lexicon Extractor), is applied using the previously mentioned 4 measures (cf. 4.1). The evaluation is based on couple of measures, the first measure is dedicated to candidates selection (LCC 2.) and the second to candidates comparison (LCC 3. & 4.). The comparison measure is also used to sort the candidates (cf. 3.4). The maximal number of iterations is set to 3 (for a maximal depth of 4), which is the maximum number of associations required to compose the majority of lexical units in the reference corpus. The precision and recall are computed on the deep set in order to consider all valid lexical units, the recall on the shallow set is given to see the results on wider lexical units (Table 6). The results show that PMI-LL couple performs better overall than the other measures. It can be noticed that the scores are relatively close ($\pm$1.8% for precision and $\pm$7.0% for deep recall) meaning that the choice of the association measure has a low influence over the results. For the further experiments are conducted with PMI-LL, which achieves the best recall score.

Selection	PMI		PS	
Comparison	LL	PMI^3	LL	PMI^3
Precision	37.1	38.9	37.3	38.1
Deep recall	68.4	65.6	62.3	61.4
Shallow recall	75.1	74.2	70.6	70.6

Table 6: *Measure combinations results*

The method extracted 585,794 LUCs from the whole corpus using the PMI-LL couple before applying the user interaction step. The *candidate list projection* (cf. 4.2) contains 4,539 LUCs. The user decisions are simulated with the lexical unit trees obtained from sample texts. In total 312 LUCs were removed in consequence of the user interaction (cf. 3.5), without this step the precision decreases to 33.7%. The 1,246 LUCs present in the common-word dictionary are ignored. Finally 1,886 invalid candidates and 1,105 valid lexical units are submitted to the user, the evaluation is based on these 3,059 LUCs.

Lexical unit	**Rank**	**Nb.**
⟦政策性农业保险⟧ (policy agricultural insurance)	155	1798
⟦泰康人寿⟧ (Tai Kang Life Insurance)	453	1,854
⟪保险人⟫ (insurer)	1,048	4,999
⟦南开大学⟧ (Nan Kai University)	2,828	111
⟦洛杉矶旅游业者⟧ (Los Angeles tourism professionals)	9,647	3
⟦人寿保险⟧ (life insurance)	11,647	871
⟪王恩韶⟫ (Wang Enshao (person))	14,617	2
⟦有偿使用⟧ (compensated use)	34,596	8
⟪太湖流域⟫ (Taihu Lake Basin)	102,612	2
⟪择机⟫ (wait an opportunity)	126,044	31
⟦中华人民共和国劳动合同法⟧ (The People's Republic of China labor contract law)	387,235	1

Table 7: *Sample of extracted lexical units*

A sample of extracted lexical units is presented in Table 7. In this list, the lower number of occurrences is 1 and the longest unit length is 12 graphies. Most of the extracted lexical unit are terms, a significant number of people names, common words and larger named entities are extracted too. The most part of the very frequent lexical units are ranked at the top of the list but some low frequency LUCs are ranked over the high frequency candidates. The Figure 4 presents

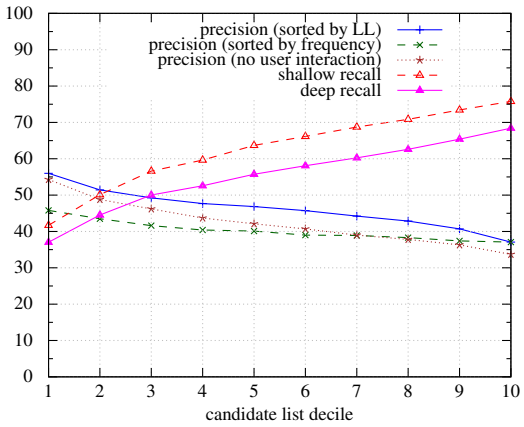

Figure 4: *ILex results using PMI-LL*

the results as a function of the LUC list deciles. The LL sorting is compared to frequency sorting for the precision at rank n. The LL sorting curve is above the frequency sorting curve, this fact shows that LL is more efficient at sorting valid LUCs. The majority of the missed candidates have a low number of occurrences ($\leq$3) and 57.8% of the longest lexical unit ($>$7) are also missed. Most of extraction errors have a low number of occurrences, 40.1% of the errors are caused by lexical unit composition errors (e.g. $*(\text{保险})\oplus|\overset{\text{study}}{\text{学}}|$ in $[(\text{保险})(\overset{\text{insurance institute}}{\text{学院}})]$ or $*(\overset{\text{reform}}{\text{改革}})|\overset{\text{commission}}{\text{委}}|$ in $[(\overset{\text{reform \& development commission}}{\text{发展}})(\text{改革})|\text{委}|]$) and 59.9% by association errors (e.g. $(\overset{\text{extend}}{\text{扩大}})\oplus[\overset{\text{agricultural Insurance}}{\text{农业保险}}]$ or $(\overset{\text{standard}}{\text{规范}})\oplus(\overset{\text{development}}{\text{发展}})$).

The AccessVar method (Feng et al., 2004), an unsupervised lexicon extraction method having the best performance, was reimplemented and used as a reference. This method uses the corpus substrings' number of distinct contexts, noted AV (*accessor variety*), to extract candidates. AccessVar is configured by an *accessors variety threshold* (AVT), which is the minimal AV required to hold a candidate, the number of occurrences of candidates is consequently greater or equal to the AVT. For the experiments, the candidate maximal length is set to 7 graphies[6] and AVT to 3. Similarly, ILex candidates appearing less than three times and having a length greater than 7 are discarded. The ILex user interaction is not applied for this comparison. In order unify the input data, AccessVar handles the segments detected by ILex

[6]Higher values cause space complexity issues.

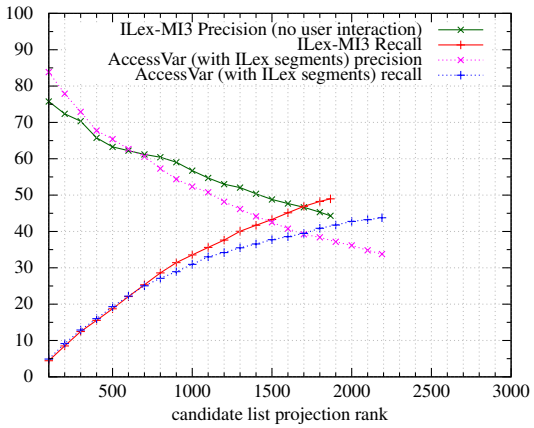

Figure 5: *ILex & AccessVar results*

instead of the corpus full text.

AccessVar and ILex extract respectively 125,467 and 116,412 LUCs and the candidate list projection contains 2,190 and 1,876 LUCs. The results are computed on the deep set (figure 5). AccessVar and ILex achieve respectively recall of 43.7% and 49.0%. A total of 667 of the lexical units extracted are common to both methods, 161 lexical units are extracted exclusively by ILex and 74 lexical units are extracted exclusively by AccessVar. This means that both methods have close covering capacities. From rank 100 to rank 700, the results are close but the curves begin to diverge after this rank, this trend means that the performance are similar for the 700 best candidates. However, ILex achieves 44.4% precision which is 10.6% higher than AccessVar (33.8%), this difference, in view of the close recall score, shows that ILex generates less invalid candidates. The errors specific to AccessVar are due to context adhesion errors (e.g. $*(\overset{\text{company}}{\text{保险}})\oplus|\overset{\text{specialty}}{\text{产}}|$ in $[(\overset{\text{insurance industry}}{\text{保险}})(\text{产业})]$, $[(\overset{\text{insurance product}}{\text{保险}})(\text{产品})]$, $[(\overset{\text{insurance produce}}{\text{保险}})(\text{产生})]$ etc.), or association errors (e.g. $*|\overset{\text{country}}{\text{国}}|\oplus|\overset{\text{East}}{\text{东}}|$, $*(\overset{\text{industry}}{\text{工业}})\oplus(\overset{\text{group}}{\text{集团}})$). ILex avoids these errors because of three mechanisms. First, the statistical likelihood between the couple components is tested (e.g. $*|\overset{\text{country}}{\text{国}}|\oplus|\overset{\text{East}}{\text{东}}|$ PMI score is negative). Second, the method checks association likelihood of the contexts before associating two morpho-syntactic units, (e.g. $(\overset{\text{aeronautic}}{\text{航空}})(\overset{\text{industry}}{\text{工业}})$ score is over $*(\overset{\text{industry}}{\text{工业}})\oplus(\overset{\text{group}}{\text{集团}})$ score in $[\overset{\text{Aviation Industries Corporation of China}}{\text{中国航空工业集团公司}}]$). Third, the incremental association process determine smaller unit before trying associating bigger couples (e.g. $(\overset{\text{insurance}}{\text{保险}})$ and $(\overset{\text{industry}}{\text{产业}})$ are associated before $[\overset{\text{insurance industry}}{\text{保险产业}}]$).

6 Conclusion and Further Works

The presented method features incremental lexical unit extraction with interactive candidate filtering capability. The maximal candidate length is not imposed directly, but instead is determined by the maximal number of associations. The lexical resources required are re-usable and non-domain specific, which significantly reduce their cost for long-term deployment. The method achieves decent performance and improves the reference method's precision for this task. Furthermore, the extracted results include low-frequency and long candidates which are known to be difficult to extract. Finally, the binary association process allows us to sort the candidates by association measure, which is more relevant than frequency.

This paper also introduced the beginning of a linguistically consistent lexical unit definition. This definition draws the outlines of a corpus annotation guide dedicated to the lexicon extraction task. The evaluation process is improved by the lexical unit trees annotations and a candidate list projection technique, which allows full-automatic estimation of extraction system performance.

The first upcoming objective is the development of a robust evaluation protocol for the lexical extraction task. This is crucial for further improvements and means that the variation between annotators of the evaluation corpus, and the stability of the method over different corpora need to be considered. Finally we will try to solve the not yet managed lexicon extraction issues, Latin characters tokens which cause the method miss some extractions (e.g. $(\!(\overset{\{\textit{product name}\}}{\text{新红A}})\!)$), and the discontinuous locutions (e.g. $[\![\overset{\text{reach on the phone}}{\text{打通电话}}]\!]$ in $(\overset{\text{call / through}}{\text{打通了}})\text{常总的}(\overset{\text{phone}}{\text{电话}})$ or $[\![\overset{\text{bear responsibility}}{\text{负责任}}]\!]$ in $\text{本公司}(\overset{\text{bear}}{\text{负}})\text{给付保险金}(\overset{\text{responsibility}}{\text{责任}})$).

Acknowledgements

Our sincere thanks to the anonymous reviewers. Special thanks to Pierre Zweigenbaum, to all my colleagues from Arisem and Ertim and to the corpus annotators without which this work would not be possible.

Improving Name Origin Recognition with Context Features and Unlabelled Data

Vladimir Pervouchine, Min Zhang, Ming Liu and Haizhou Li
Institute for Infocomm Research, A-STAR
vpervouchine@gmail.com,{mzhang,mliu,hli}@i2r.a-star.edu.sg

Abstract

We demonstrate the use of context features, namely, names of places, and unlabelled data for the detection of personal name language of origin.

While some early work used either rule-based methods or n-gram statistical models to determine the name language of origin, we use the discriminative classification maximum entropy model and view the task as a classification task. We perform bootstrapping of the learning using list of names out of context but with known origin and then using expectation-maximisation algorithm to further train the model on a large corpus of names of unknown origin but with context features. Using a relatively small unlabelled corpus we improve the accuracy of name origin recognition for names written in Chinese from 82.7% to 85.8%, a significant reduction in the error rate. The improvement in F-score for infrequent Japanese names is even greater: from 77.4% without context features to 82.8% with context features.

1 Introduction

Transliteration is a process of rewriting a word from a source language to a target language in a different writing system using the word's phonological equivalent. Many technical terms and proper nouns, such as personal names, names of places and organisations are transliterated during translation of a text from one language to another. A process reverse to the transliteration, which is recovering a word in its native language from its transliteration in a foreign language, is called back-transliteration (Knight and Graehl, 1998). In many natural language processing (NLP) tasks such as machine translation and cross-lingual information retrieval, transliteration is an important component.

Name origin refers to the language of origin of a name. For example, the origin of English name "Smith" and its Chinese transliteration "史密斯 (Shi-Mi-Si)" is English, while both "Tokyo" and "东京 (Dong-Jing)" are of Japanese origin.

For machine transliteration the name origins dictate the way we re-write a foreign name. For example, given a name written in Chinese for which we do not have a translation in an English-Chinese dictionary, we first have to decide whether the name is of Chinese, Japanese, Korean, English or another origin. Then we follow the transliteration rules implied by the origin of the name. Although all English personal names are rendered in 26 letters, they may come from different romanization systems. Each romanisation sys-

Coling 2008: Poster Volume, pages 972–978,
Beijing, August 2010

tem has its own rewriting rules. English name "Smith" could be directly transliterated into Chinese as "史密斯 (Shi-Mi-Si)" since it follows the English phonetic rules, while the Chinese translation of Japanese name "Koizumi" becomes "小泉 (Xiao-Quan)" following the Japanese phonetic rules. The name origins are equally important in back-transliteration. Li et al. (2007b) demonstrated that incorporating name origin recognition (NOR) into a transliteration system greatly improves the performance of personal name transliteration. Besides multilingual processing, the name origin also provides useful semantic information (regional and language information) for common NLP tasks, such as co-reference resolution and name entity recognition.

Unfortunately, not much attention has been given to name origin recognition (NOR) so far in the literature. In this paper, we are interested in recognition of the origins of names written in Chinese, which names can be of three origins: Chinese, Japanese or English, where "English" is a rather broad category that includes other West European and American names written natively in Latin script.

Unlike previous work (Qu and Grefenstette, 2004; Li et al., 2007a; Li et al., 2007b), where NOR was formulated with a generative model, we follow the approach of Zhang et al. (2008) and regard the NOR task as a classification problem, using a discriminative learning algorithm for classification. Furthermore, in the training data with names labelled with their origin is rather limited, whereas there is vast data from news articles that contains many personal names without any labels of their origins. In this research we propose a method to harness the power of the unlabelled noisy news data by bootstrapping the learning process with labelled data and then using the *personal name context* in the unlabelled data to improve the NOR model. We achieve that by using the maximum entropy model and the expectation-maximisation training, and demonstrate that our method can significantly improve the accuracy of NOR compared to the baseline model trained only from the labelled data.

The rest of the paper is organised as follows: in Section 2 we review the previous research. In Section 3 we present our approach, and in Section 4 we describe our experimental setup, the data used and the evaluation method. We conclude in Section 5.

2 Related research

Most the research up to date focuses primarily on recognition of origin of names written in Latin script, called English NOR (ENOR), although the same methods can be extended to names in Chinese script (CNOR). We notice that there are two informative clues that used in previous work in ENOR. One is the lexical structure of a romanisation system, for example, Hanyu Pinyin, Mandarin Wade-Giles, Japanese Hepbrun or Korean Yale, each has a finite set of syllable inventory (Li et al., 2007a). Another is the phonetic and phonotactic structure of a language, such as phonetic composition, syllable structure. For example, English has unique consonant clusters such as *"str"* and *"ks"* which Chinese, Japanese and Korean (CJK) do not have. Considering the NOR solutions by the use of these two clues, we can roughly group them into two categories: rule-based methods (for solutions based on lexical structures) and statistical methods (for solutions based on phonotactic structures).

Rule-based method Kuo et al. (2007) proposed using a rule-based method to recognise different romanisation system for Chinese only. The left-to-right longest match-based lexical segmentation was used to parse a test word. The romanisation system is confirmed

if it gives rise to a successful parse of the test word. This kind of approach (Qu and Grefenstette, 2004) is suitable for romanisation systems that have a finite set of discriminative syllable inventory, such as Pinyin for Chinese Mandarin. For the general tasks of identifying the language origin and romanisation system, rule based approach sounds less attractive because not all languages have a finite set of discriminative syllable inventory.

N-gram statistics methods

N-gram sum method Qu and Grefenstette (2004) proposed a NOR identifier using a trigram language model (Cavnar and Trenkle, 1994) to distinguish personal names of three language origins, namely Chinese, Japanese and English. In their work the training set includes 11,416 Chinese, 83,295 Japanese and 88,000 English name entries. However, the trigram is defined as the joint probability $p(c_i c_{i-1} c_{i-2})$ rather than the commonly used conditional probability $p(c_i|c_{i-1}c_{i-2})$. Therefore it is basically a substring unigram probability. For origin recognition of Japanese names, this method works well with an accuracy of 92%. However, for English and Chinese, the results are far behind with a reported accuracy of 87% and 70% respectively.

N-gram perplexity method Li et al. (2007a) proposed a method of NOR using n-gram character perplexity PP_c to identify the origin of names written in Latin script. Using bigrams, the perplexity is defined as

$$PP_c = 2^{\frac{-1}{N_c}\sum_{i=1}^{N_c} \log p(c_i|c_{i-1})}$$

where N_c is the total number of characters in a given name, c_i is the i-th character in the name and $p(c_i|c_{i-1})$ is the bigram probability learned from a list of names of the same origin. Therefore, PP_c can be used to measure how well a new name fits the model learned from the training set of names. The origin is assigned according to the model that gives the lowest perplexity value. Li et al. (2007a) demonstrated that using PP_c gives much better performance than with the substring unigram method.

Classification method Zhang et al. (2008) proposed using a discriminative classification approach and extract features from the names. They use Maximum Entropy (MaxEnt) model and a number of features based on n-grams, character positions, word length as well as some rule-based phonetic features. They performed both ENOR and CNOR and demonstrated that their method indeed leads to better performance in name origin recognition then the n-gram statistics method. They attribute that to the fact their model incorporates more robust features than the n-gram statistics based models.

In this paper we too follow the discriminating classification approach, but we add features based on the context of a personal name. These features require the original text with the names to be available. Our approach closely models the real-life situation when large corpora of articles with personal names is readily available in the Web, yet the origins of the names are unknown.

3 Model and training methods

3.1 Maximum entropy model for NOR

The principle of maximum entropy is that given a collection of facts we should choose a model that is consistent with all the facts but otherwise as uniform as possible (Berger et al., 1996). maximum entropy model (MaxEnt) is known to easily combine diverse features and

has been used widely in natural language processing research. Given an observation x the probability of outcome label c_i, $i = 1 \ldots N$ given x is given by

$$p(c_i|x) = \frac{1}{Z} \exp\left(\sum_{j=1}^{n} \lambda_j f_j\,(x, c_i)\right) \quad (1)$$

where N is the number of the outcome labels, which is the number of name origins in our case, n is the number of features, f_j are the feature functions and λ_j are the model parameters. Each parameter corresponds to exactly one feature and can be viewed as a "weight" for the corresponding feature. Z is the normalisation factor given by

$$Z = \sum_{i=1}^{N} p(c_i|x) \quad (2)$$

In the problem at hand x is a personal name and all the features are binary. The features, also known as contextual predicates, are in the form

$$f_i(x, c) = \begin{cases} 1 & \text{if } c = c_i \text{ and } cp(x) = true \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

where cp is the contextual predicate that maps a pair (c_i, x) to $\{true, false\}$.

In our experiments we use Zhang's maximum entropy library[1].

3.2 Initial training with labelled data and n-gram features

For the initial training of MaxEnt model we use labelled data: personal names of Chinese, Japanese or English origin written in Chinese. The origin of each name is known. Following paper by Zhang et al. (2008) and their findings regarding the contribution value of each feature that they studied, we extract unigram, positional unigram and word length features. For example, Chinese name "温家宝" has the following features:

温 家 宝 (温,0) (家,1) (宝,2) 3

We restrict the n-gram features to unigram only to avoid the data sparseness, because our data contains a number of Chinese surnames and given names, which have a length of one or two characters.

3.3 Further training with unlabelled data and context features

For further training of MaxEnt model we use unlabelled data collected from news articles. The name origin is not known but each personal name is in a context and is often surrounded by names of places that may give a hint about the personal name origin. For each personal name we extract all names of places in the same paragraph and use them as features. If a place name is repeated many times in the same paragraph we only include it once in the feature list.

For example, paragraph containing passage *"The U.S. President Barack Obama ..."* will result in two personal names "Barack" and "Obama" having "U.S." as their context feature. Due to the diversity of place names we also attempt to map the names of the places into the country names. In this case, features like "U.S.", "USA", "America" are manually substituted with "USA". In our experiments we also try to narrow the place name extraction to windows of different sizes surrounding the personal name. The rationale here is that the closer a place name is to the personal name, the more likely it has a connection to the origin of the personal name.

In summary, our algorithm includes two steps.

[1] http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit.html

First, we use the boostrap data and n-gram, positional n-gram and name length features to do the initial training (the 0-th iteration) of MaxEnt model with L-BFGS method (Byrd et al., 1995). After that we use the model to assign origin labels to names of the training set of the unlabelled data.

Next, we use both the bootstrap data and the training set of the unlabelled data, labelled in the previous step, and add the context features to the already used n-gram, positional n-gram and name length features. Since there is no context available for the bootstrap data, the context features for it are missing, which can be handled by the MaxEnt model. We perform the Expectation-Maximisation (EM) iterations by using the mixed data to train the i-th iteration of the MaxEnt model, then use the model to re-label the training set of the unlabelled data and repeat the training of the model for the $(i + 1)$-st iteration. We stop the iterations when the ratio of patterns that change the origin labels becomes less than 0.01%.

4 Experiments

4.1 Corpora

The corpora consists of two datasets. One dataset, called the "bootstrap data", is a set of Chinese, Japanese and English names written in Chinese following the respective transliteration rules according to the name origins. The names are a mixture of full names, first (given) names and surnames. Table 1 shows the number of names of each origin. This is the labelled data; the origin of each name is known. The data is used to start the MaxEnt model training.

The second dataset, called the "unlabelled data", is Chinese, Japanese and English personal names written in Chinese, which have been extracted from the news articles collected over 6 months from Xinhua news website. The articles have been processed by an automatic part-of-speech (POS) tagger, after which personal names and names of places have been manually identified (the latter for extracting the context features). Normally the first (given) name and surnames are identified as two separate personal names. The data is split into a training set of 27,882 names with unknown origin and a testing set of 1,476 names whose origin was manually assigned. We split data in such a way that there is no overlap between patterns in the training and testing sets, although there may be overlap between names. For example, if a name may be present in both training and testing sets but in a different context, making the two names two distinct patterns. The number of names of each origin in the testing set is shown in Table 2. As seen from the table, the number of Chinese names exceeds the number of English or Japanese names. This is an expected consequence of using articles from a Chinese news agency because many of the articles are reporting on local affairs. We have manually removed a number of Chinese name patterns from the testing set, since the original percentage of Chinese names in the articles is about 83%.

Origin	Number of names
Chinese	52,342
Japanese	26,171
English	26,171

Table 1: Number of names of each origin in the bootstrap dataset.

Origin	Number of names
Chinese	738
Japanese	369
English	422

Table 2: Number of names of each origin in the testing dataset.

4.2 Evaluation method

Following Zhang et al. (2008) to make our results comparable to theirs, we evaluate our system using precision P_o, recall R_o and F-score F_o for each origin $o \in \{\text{“}Chinese\text{”} \text{“}Japanese\text{”} \text{“}English\text{”}\}$. Let the number of correctly recognised names of a given origin o be k_o, and the total number of names recognised as being of origin o be m_o, while the actual number of names of origin o be n_o. Then the precision, recall and F-score are given as:

$$P_o = \frac{k_o}{m_o}$$

$$R_o = \frac{k_o}{n_o}$$

$$F_o = \frac{2 \times P_o \times R_o}{P_o + R_o}$$

We also report the overall accuracy of the system (or, rather the overall recall), which is the ratio of the total number of correctly recognised names to the number of all names:

$$Acc = \frac{k_{Chinese} + k_{Japanese} + k_{English}}{n_{Chinese} + n_{Japanese} + n_{English}}$$

4.3 Results

After each iteration of our MaxEnt-based EM algorithm, we record the number of patterns in the training set that changed their origin labels, as well as calculate the precision, recall and F-score for each origin as well as the overall accuracy. The results are reported in Tables 3 and 4, where for the sake of brevity the origin subscripts are “C”, “J” and “W” for Chinese, Japanese and English name origin respectively.

Compared to the 0-th iteration there is an significant improvement in accuracy, particularly in recognition of Japanese names, which are relatively infrequent compared to Chinese and English ones in the unlabelled training data. This clearly shows the effectiveness of our proposed method.

Iteration	P_C	P_J	P_W	R_C	R_J	R_W
0	0.887	0.724	0.857	0.823	0.911	0.761
1	0.914	0.736	0.875	0.823	0.968	0.775
2	0.910	0.736	0.874	0.823	0.968	0.767
3	0.914	0.737	0.874	0.824	0.973	0.767
4	0.913	0.742	0.875	0.825	0.968	0.778

Table 3: Results of running EM iterations, original names of the places are kept.

Iteration	Acc	F_C	F_J	F_W
0	0.829	0.854	0.807	0.806
1	0.847	0.866	0.836	0.822
2	0.845	0.864	0.836	0.817
3	0.847	0.867	0.839	0.817
4	0.849	0.867	0.840	0.824

Table 4: Results of running EM iterations, original names of the places are kept.

5 Conclusions

We propose extension of MaxEnt model for NOR task by using two types of data for training: origin-labelled names alone and origin-unlabelled names in their context surrounding. We show how to apply a simple EM method to make use of the contextual words as features, and improve the NOR accuracy from 82.9% to 84.9% overall, while for rare names such as Japanese the effect of using unlabelled data with context features is even greater.

The purpose of this research is to demonstrate how the unlabelled data can be used. In the future we hope to investigate the use of other context features, as well as to study the effect of data size on the NOR accuracy improvement.

The feature of names' places normally exhibit great variation: one country name may be spelled in many different ways, and often there are names of cities etc that surround personal names. We will explore to normalise names of places by substituting each name with name of the country where the place is in the future work.

Filling Knowledge Gaps in Text for Machine Reading

hovy@isi.edu

Abstract

Texts are replete with gaps, information omitted since authors assume a certain amount of background knowledge. We define the process of enrichment that fills these gaps. We describe how enrichment can be performed using a Background Knowledge Base built from a large corpus. We evaluate the effectiveness of various openly available background knowledge bases and we identify the kind of information necessary for enrichment.

1 Introduction: Knowledge Gaps

Automated understanding of connected text remains an unsolved challenge in NLP. In contrast to systems that harvest information from large collections of text, or that extract only certain pre-specified kinds of information from single texts, the task of extracting and integrating all information from a single text, and building a coherent and relatively complete representation of its content, is still beyond current capabilities.

A significant obstacle is the fact that text always omits information that is important, but that people recover effortlessly. Authors leave out information that they assume is known to their readers, since its inclusion (under the Gricean maxim of minimality) would carry an additional, often pragmatic, import. The problem is that systems cannot perform the recovery since they lack the requisite background knowledge and inferential machinery to use it.

In this research we address the problem of automatically recovering such omitted information to 'plug the gaps' in text. To do so, we describe the background knowledge required as well as a procedure of *enrichment*, which recognizes where gaps exist and fills them out using appropriate background knowledge as needed. We define *enrichment* as:

Def: Enrichment is the process of adding explicitly to a text's representation the information that is either implicit or missing in the text.

Central to enrichment is the source of the new knowledge. The use of Proposition Stores as Background Knowledge Bases (BKB) have been argued to be useful for improving parsing, coreference resolution, and word sense disambiguation (Clark and Harrison 2009). We argue here that Proposition Stores are also useful for Enrichment and show how in Section 4. However, we show in Section 5 that current BKB resources such as TextRunner (Banko et al. 2007) and DART (Clark and Harrison 2009) are not ideal for enrichment purposes. In some cases there is a lack in normalization. But the most important shortcoming is the lack in answering about instances, their possible classes, how they relate to propositions, and how different propositions are related through them. We propose easy to achieve extensions in this direction. We test this hypothesis building our own Proposition Store with the proposed extensions, and compare it with them for enrichment in the US football domain.

To perform enrichment, we begin with an initial simple text representation and a Proposition Stores as a background knowledge base. We execute a simple formalized procedure to select and attach appropriate elements from the BKB to the entities and implicit relations present in the initial text representation. Surprisingly, we find that some quite simple processing can be effective if we are able to contextualize the text under interpretation.

We describe in Section 2 our textual representations and in Section 3 the process of building the Proposition Store. Enrichment is described in Section 4, and an evaluation and comparison is performed in Section 5.

2 Text Representation

The initial, shallow, text representation must capture the first impression of what is going on in the text, possibly (unfortunately) losing some fragments. After the first impression, in accord with the purpose of the reading, we "contextual-

Coling 2008: Poster Volume, pages 979–987,
Beijing, August 2010

ize" each sentence, expanding its initial representation with the relevant related background knowledge in our base.

During this process of making explicit the implicit semantic relations it will become apparent whether we need to recover some of the missed elements, whether we need to expand some others, etc. So the process is identified with the growing of the context until deeper interpretation is possible. This approach resembles some well-known theories such as the Theory of Relevance (Sperber and Wilson, 1995). The particular method we envisage is related to Interpretation as Abduction (Hobbs et al. 1993).

How can the initial information be represented so as to enable the context to grow into an interpretation? We hypothesize that:

1. Behind certain syntactic dependencies there are semantic relations.
2. In the case of dependencies between nouns, this semantic relation can be made more explicit using verbs and/or prepositions. The knowledge base (our Proposition Store) must help us find them.

We look for a semantic representation close enough to the syntactic representation we can obtain from the dependency graph. The main syntactic dependencies we want to represent in order to enable enrichment are:

1. Dependencies between nouns such as noun-noun compounds (nn) or possessive (poss).
2. Dependencies between nouns and verbs, such as subject and object relations.
3. Prepositions having two nouns as arguments. Then the preposition becomes the label for the relation, being the object of the preposition the target of the relation.

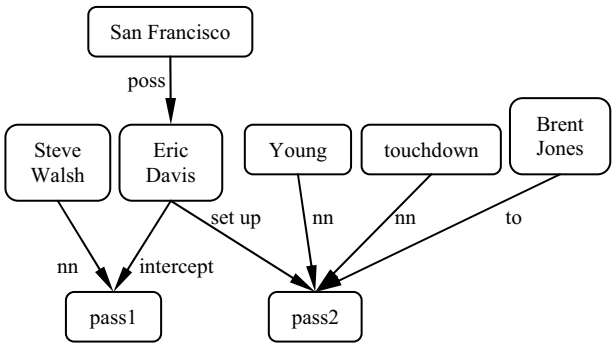

Figure 1. Initial text representation.

We collapse the syntactic dependencies between verb, subject, and object into a single semantic relation. Since we are assuming that the verb is the more explicit expression of a semantic relation, we fix this in the initial representation. The subject will be the source of the relation and the object will be the target of the relation. When the verb has more arguments we consider its expansion as a new node as referred in Section 4.4.

Figure 1 shows the initial minimal representation for the sentence we will use for our discussion: "*San Francisco's Eric Davis intercepted a Steve Walsh pass on the next series to set up a seven-yard Young touchdown pass to Brent Jones"*. Notice that some pieces of the text are missing in the initial representation of the text, as for example "*on the next series"* or *"seven-yard".*

3 Background Knowledge Base

We will use a Proposition Stores as a Background Knowledge Base (BKB). We built it from a collection of 30,826 New York Times articles about US football, similar to the kind of texts we want to interpret. We parsed the collection using a standard dependency parser (Marneffe and Manning, 2008; Klein and Maning, 2003) and, after collapsing some syntactic dependencies, obtained 3,022,305 raw elements in the BKB.

3.1 Types of elements in the BKB

We distinguish three kinds of elements in our Background Knowledge Base: Entities, Propositions, and Lexical relations. All three have associated their frequency in the reference collection.

Entities: We distinguish between entity classes and entity instances:

1. Entity classes: Entity classes are denoted by nouns. We don't restrict classes to any particular predefined set. In addition, we introduce two special classes: Person and Group. These two classes are related to the use of pronouns in text. Pronouns "I", "he" and "she" are linked to class Person. Pronouns "we" and "they" are linked to class Group. For example, the occurrence of the pronoun "he" in "He threw a pass" would produce an additional count of the proposition "person:throw:pass".

2. Entity Instances: Entity instances are indicated by proper nouns. Proper nouns are identified by the part of speech tagging. Some of these instances will participate in the "has-instance" relation (see below). When they participate in a proposition they produce proposition instances.

Propositions: Following Clark and Harrison (2009) we call *propositions* the tuples of words that have some determined pattern of syntactic relations among them. We focus on NVN, NVNPN and NPN proposition types. For example, a NVNPN proposition is a full instantiation of: *Subject:Verb:Object:Prep:Complement*.

The first three elements are the subject, the verb and the direct object. Fourth is the preposition that attaches the PP complement to the verb. For simplicity, indirect objects are considered as a Complement with the preposition "to".

The following are the most frequent NVN propositions in the BKB ordered by frequency.

NVN 2322 'NNP':'beat':'NNP'
NVN 2231 'NNP':'catch':'pass'
NVN 2093 'NNP':'throw':'pass'
NVN 1799 'NNP':'score':'touchdown'
NVN 1792 'NNP':'lead':'NNP'
NVN 1571 'NNP':'play':'NNP'
NVN 1534 'NNP':'win':'game'
NVN 1355 'NNP':'coach':'NNP'
NVN 1330 'NNP':'replace':'NNP'
NVN 1322 'NNP':'kick':'goal'

The 'NNP' tag replaces specific proper nouns (instances) found in the proposition.

When a sentence has more than one complement, a new occurrence is counted for each complement. For example, given the sentence *"Steve_Walsh threw a pass to Brent_Jones in the first quarter",* we would add a count to each of the following propositions:

Steve_Walsh:throw:pass
Steve_Walsh:throw:pass:to:Brent_Jones
Steve_Walsh:throw:pass:in:quarter

Notice that we include only the heads of the noun phrases in the propositions.

We call *proposition classes* the propositions that only involve instance classes (e.g., *"person:throw:pass"*), and *proposition instances* those that involve at least one entity instance (e.g., *"Steve_Walsh:throw:pass*").

Proposition instances are useful for the tracking of a entity instance. For example, *"'Steve_Walsh':'supplant':'John_Fourcade':'as':'quarterback'"*. When a proposition instance is found, it is stored also as a proposition class replacing the proper nouns by a special word (NNP) to indicate the presence of an entity instance. The enrichment of the text is based on the use of most frequent proposition classes.

Lexical Relations: We make use of very general patterns considering appositions and copula verbs (detected by the Stanford parser) in order to extract "is", and "has-instance" relations:

1. **Is**: between two entity classes. They denote a kind of identity between both entity classes, but not in any specific hierarchical relation such as hyponymy. Neither is a relation of synonymy. As a result, it is somehow a kind of underspecified relation that groups those more specific. For example, if we ask the BKB what a "receiver" is, the most frequent relations are:

   290 'person':is:'receiver'
   29 'player':is:'receiver'
   16 'pick':is:'receiver'
   15 'one':is:'receiver'
   14 'receiver':is:'target'
   8 'end':is:'receiver'
   7 'back':is:'receiver'
   6 'position':is:'receiver'

   The number indicates the frequency of the relation in the collection.
2. **Has-instance**: between an entity class and an entity instance. For example, if we ask for instances of team, the top instances with more support in the collection are:

   192 'team':has-instance:'Jets'
   189 'team':has-instance:'Giants'
   43 'team':has-instance:'Eagles'
   40 'team':has-instance:'Bills'
   36 'team':has-instance:'Colts'
   35 'team':has-instance:'Miami'

But we can ask also for the possible classes of an instance. For example, all the entity classes for "*Eric_Davis*" are:

12 'cornerback':has-instance:'Eric_Davis'
1 'hand':has-instance:'Eric_Davis'
1 'back':has-instance:'Eric_Davis'

We still work on other lexical relations such as "part-of" and "is-value-of". For example, the most frequent "is-value-of" relations are:

5178 '[0-9]-[0-9]':is-value-of:'lead'
3996 '[0-9]-[0-9]':is-value-of:'record'
2824 '[0-9]-[0-9]':is-value-of:'loss'
1225 '[0-9]-[0-9]':is-value-of:'season'

4 Enrichment operations

The goal of the following enrichment operations is to make explicit what kind of semantic relations and entity classes are involved in the text.

4.1 Fusion of nodes

Sometimes, the syntactic dependency ties two or more words that form a single concept. This is the case with multiword terms such as "*tight end*", "*field goal*", "*running back*", etc. In these cases, the meaning of the compound is beyond the syntactic dependency. Thus, we shouldn't look for its explicit meaning. Instead, we fuse the nodes into a single one.

The question is whether the fusion of the words into a single expression allows or not the consideration of possible paraphrases. For example, in the case of "*field:nn:goal*", we don't find other ways to express the concept in the BKB. However, in the case of "*touchdown:nn:pass*" we can find, for example, "*pass:for:touchdown*" a significant amount of times, and we want to identify them as equivalent expressions.

4.2 Building context for instances

Suppose we wish to determine what kind of entity "*Steve Walsh*" is in the context of the syntactic dependency "*Steve_Walsh:nn:pass*". First, we look into the BKB for the possible entity classes of *Steve_Walsh* previously found in the collection. In this particular case, the most frequent class is "*quarterback*":

40 'quarterback':has-instance:'Steve_Walsh'
2 'junior':has-instance:'Steve_Walsh'

But what happens if we see "*Steve_Walsh*" for the first time? Then we need to take into account the classes shared by other instances in the same syntactic context. The most frequent are "*Marino*", "*Kelly*", "*Elway*", etc. From them we are able to infer the most plausible class for the new entity. In our example, *quarterback*:

20 'quarterback':has-instance:'Marino'
6 'passer':has-instance:'Marino'
...
17 'quarterback':has-instance:'Kelly'
6 'passer':has-instance:'Kelly'
...
16 'quarterback':has-instance:'Elway'
9 'player':has-instance:'Elway'

4.3 Building context for dependencies

Now we want to determine the meaning behind such syntactic dependencies as:

"*Steve_Walsh:nn:pass*", "*touchdown:nn:pass*", "*Young:nn:pass*" or "*pass:to:Brent_Jones*".

We have two ways for adding more meaning to these syntactic dependencies: find the most appropriate prepositions to describe them, and find the most appropriate verbs. Whether one, the other, or both is useful has to be determined during the reasoning system development.

Finding the prepositions

Several types of propositions in the BKB involve prepositions. The most relevant are NPN and NVNPN. In the case of "*touchdown:nn:pass*", "*for*" is clearly the best interpretation:

NPN 712 'pass':'for':'touchdown'
NPN 24 'pass':'include':'touchdown'

In the case of "*Steve_Walsh:nn:pass*" and "*Young:nn:pass*", since we know they are quarterbacks, we can ask for all the prepositions between "*pass*" and "*quarterback*":

NPN 23 'pass':'from':'quarterback'
NPN 14 'pass':'by':'quarterback'

If we don't have any evidence on the instance class, and we know only that they are instances, the pertinent query to the BKB obtains:

NPN 1305 'pass':'to':'NNP'
NPN 1085 'pass':'from':'NNP'
NPN 147 'pass':'by':'NNP'

In the case of "*Young:nn:pass*" (in "*Young pass to Brent Jones*"), there exists already the preposition "*to*" ("*pass:to:Brent_Jones*"), so the most promising choice becomes the second, "*pass:from:Young*", which has one order of magnitude more occurrences than its successor.

In the case of "*Steve_Walsh:nn:pass*" (in "*Eric Davis intercepted a Steve Walsh pass*") we can use additional information: we know that "*Eric_Davis:intercept:pass"*. So, we can try to find the appropriate preposition using NVNPN propositions in the following way:

"Eric_Davis:intercept:pass:P:Steve_Walsh"

Asking the BKB about the propositions that involve two instances with "*intercept*" and "*pass*", we obtain:

NVNPN 48 'NNP':'intercept':'pass':'by':'NNP'

NVNPN 26 'NNP':'intercept':'pass':'at':'NNP'
NVNPN 12 'NNP':'intercept':'pass':'from':'NNP'

We could also query the BKB with the classes we have already found for "*Eric_Davis*" (*cornerback, player, person*):

NVNPN 11 'person':'intercept':'pass':'by':'NNP'
NVNPN 4 'person':'intercept':'pass':'at':'NNP'
NVNPN 2 'person':'intercept':'pass':'in':'NNP'
NVNPN 2 'person':'intercept':'pass':'against':'NNP'
NVNPN 1 'cornerback':'intercept':'pass':'by':'NNP'

All these queries accumulate evidence over the preposition "*by*" ("*pass:by:Steve_Walsh*").

Finding the verbs

The next exercise is to find a verb able to give meaning to syntactic dependencies such as "*Steve_Walsh:nn:pass*", "*touchdown:nn:pass*", "*Young:nn:pass*" or "*pass:to:Brent_Jones*".

We can ask the BKB what instances (NNP) do with *passes*. The most frequent propositions are:

NVN 2241 'NNP':'catch':'pass'
NVN 2106 'NNP':'throw':'pass'
NVN 844 'NNP':'complete':'pass'
NVN 434 'NNP':'intercept':'pass'
…
NVNPN 758 'NNP':'throw':'pass':'to':'NNP'
NVNPN 562 'NNP':'catch':'pass':'for':'yard'
NVNPN 338 'NNP':'complete':'pass':'to':'NNP'
NVNPN 255 'NNP':'catch':'pass':'from':'NNP'

Considering the evidence of "Brent_Jones" being instance of "*end*" (*tight end*), if we ask the BKB about the most frequent relations between "*end*" and "*pass*" we find:

NVN 28 'end':'catch':'pass'
NVN 6 'end':'drop':'pass'

So, in this case, the BKB suggests that the syntactic dependency "*pass:to:Brent_Jones*" means "*Brent Jones is an end catching a pass*". Or in other words, that "*Brent_Jones*" has a role of "*catch-ER*" with respect to "*pass*".

If we want to accumulate more evidence on this we can consider NVNPN propositions including "*touchdown*". We only find evidence for the most general classes (*NNP* and *person*):

NVNPN 189 NNP:'catch':'pass':'for':'touchdown'
NVNPN 26 NNP:'complete':'pass':'for':'touchdown'
NVNPN 84 person:catch:pass:for:touchdown
NVNPN 18 person:complete:pass:for:touchdown

This means that when we have "*touchdown*", we don't have counts for the second option "*Brent_Jones:drop:pass*", while "*catch*" becomes stronger.

In the case of "*Steve_Walsh:nn:pass*" we hypothesize that "*Steve_Walsh*" is a "*quarterback*". Asking the BKB about the most plausible relation between a *quarterback* and a *pass* we find:

NVN 98 'quarterback':'throw':'pass'
NVN 27 'quarterback':'complete':'pass'

Again, if we take into account that it is a "*touchdown:nn:pass*", then only the second option "*Steve_Walsh:complete:pass*" is consistent with the NVNPN propositions. So, in this case, the BKB suggests that the syntactic dependency "*Steve_Walsh:nn:pass*" means "*Steve_Walsh is a quarterback completing a pass*".

Finally, with respect to "*touchdown:nn:pass*", we can ask about the verbs that relate them:

NVN 14 'pass':'set_up':'touchdown'
NVN 6 'pass':'score':'touchdown'
NVN 5 'pass':'produce':'touchdown'

Figure 2 shows the resulting enrichment after the process described.

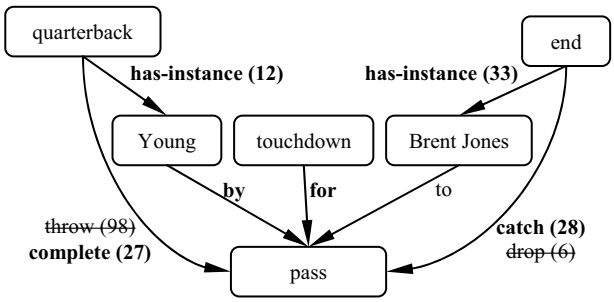

Figure 2. Enrichment of the noun phrase: "*Young touchdown pass to Brent Jones*"

4.4 Expansion of relations

Sometimes, the sentence shows a verb with more than two arguments. In our example, we have "*Eric_David:intercept:pass:on:series*". In these cases, relations can be expanded into new nodes.

Following our example, the new node is the eventuality of "*intercept*" ("*intercept-ION*"), "*Eric_Davis*" is the "*intercept-ER*" and "*pass*" is the "*intercept-ED*". Then, the missing information is attached to the new node (see Figure 3).

In addition, we can proceed with the expansion of the context considering this new node. For example, we are working with the hypothesis that "*Steve_Walsh*" is an instance of "*quarterback*" and thus, its most plausible relations with "*pass*" are "*throw*" and "*complete*". However, now we can ask about the most frequent relation between "quarterback" and a nominalization of

"intercept". The most frequent proposition is "*quarterback:throw:interception*", supported 35 times in the collection. In this way, we have inferred that the nominalization for the eventuality of intercept is interception (in our documents). Two further actions are possible: reinforce the hypothesis of "*throw:pass*" instead of "*complete:pass*" and add the hypothesis that "*Steve_Walsh:throw:interception*".

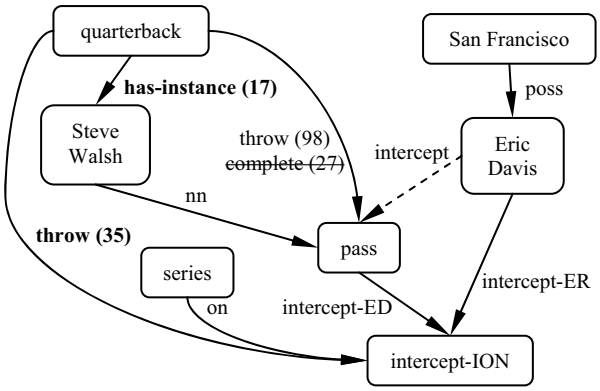

Figure 3. Expansion of "intercept" relation

Finally, notice that since "set_up" doesn't need to accommodate more arguments, we can maintain the collapsed edge.

4.5 Constraining the interpretations

Some of the inferences being performed are local in the sense that they involve only an entity and a relation. However, these local inferences must be coherent both with the sentence and the complete document. To ensure this coherence we can use additional information as a way to constrain different hypotheses. In section 4.3 we showed the use of NVNPN propositions to constrain NVN ones. Another example is the case of "*Eric_Davis:intercept:pass*". We can ask the BKB for the entity classes that participate in such kind of proposition:

NVN 75 'person':'intercept':'pass'
NVN 14 'cornerback':'intercept':'pass'
NVN 11 'defense':'intercept':'pass'
NVN 8 'safety':'intercept':'pass'
NVN 7 'group':'intercept':'pass'

So the local inference for the kind of entity "Eric_Davis" is (*cornerback*) must be coherent with the fact that it intercepted a pass. In this case "*cornerback*" and "*person*" are properly reinforced. In some sense, we are using these additional constrains as selectional preferences.

5 Evaluation

Properly evaluating the enrichment process is very difficult. Ideally, one would compare the output of an enrichment engine—a text graph fully fleshed out with additional knowledge—to a gold-standard graph containing all relevant information explicitly, and measure Recall and Precision of the links added by enrichment. But since we have no gold standard examples, and it is unclear how much knowledge should be included manually if one were to try to build some, two options remain: extrinsic evaluations and measuring the utility of the BKB in providing knowledge. We are in the process of performing an extrinsic evaluation, by measuring how much QA about the text read improves using the enriched representation. We report here the results of comparing the utility, for enrichment purposes, of two other publicly available background knowledge bases: DART (Clark and Harrison, 2009) and TextRunner (Banko et al. 2007).

5.1 Ability to answer about instances

As shown in our examples, BKBs need the ability to answer about instances and their classes. The BKBs don't need to be completely populated, but at least have enough instance-class attachments in order to allow analogy.

Neither DART nor TextRunner allow asking about possible classes for a particular instance. This is out of the scope of TextRunner. In DART, instances are replaced by one of three basic categories (person, place, organization). Although storing the original proper nouns attached to the assigned class would be straightforward, these three general classes are not enough to support inference. This leads us to the next ability.

5.2 Ability to discover new classes and relations

While *quarterbacks throw passes*, *ends* usually *catch or drop* them. As we have shown in our examples, classifying them as "*person"* or even "*player"* is not specific enough for enrichment.

Using a predefined set of entity classes doesn't seem a good approach for midterm goals. First, human abstraction is not correlated with the appropriate granularity level that enable recovering

of relevant background knowledge. Second, annotation will be needed for training.

In our Proposition Stores, we count simply what is explicitly said in the texts about our instances. This seems correlated to an appropriate level of granularity. Furthermore, an instance can be attached to several classes that can be compatible (quarterback, player, person, leader, veteran, etc.). Frequencies tell us the classes we have to consider in the first place in order to find a coherent interpretation of the text.

5.3 Ability to constrain interpretation and accumulate evidence

Enrichment must be guided by the coherence of the ensuing interpretation. For this reason BKBs must allow different types of queries over the same elements. The aim is to constrain as much as possible the relations we recover to the ones that give a coherent interpretation of the text.

As shown in our example, we require the ability to ask different syntactic contexts/structures (NN, NVNPN, etc.), not only NVN (subject-verb-object). Achieving this is very difficult for approaches that don't use parsing.

5.4 Ability to digest enough knowledge adapted to the domain

None of the abilities discussed above are relevant if the BKB doesn't contain enough knowledge about the domain in which we want to enrich documents. To evaluate, we ran three simple queries related to the US football domain in order to assess the suitability of the BKBs for enrichment: *What do quarterbacks do with passes? What do persons do with passes? Who intercepts passes?* Table 1 shows the results obtained with DART, TextRunner and our BKB.

Although DART is a general domain BKB built using parsing, its approach doesn't allow one to process enough information to answer the first question (first row in Table 1). A web scale resource such as TextRunner is better suited for this purpose. However, results show its lack of normalization. On the other hand, our BKB is able to return a clean and relevant answer.

The second question (second row) shows the ability of the three BKBs to deal with a basic abstraction needed for inference. Since TextRunner doesn't perform any kind of processing over entities or pronouns, it doesn't recover relevant knowledge for this question in the football domain. In addition, the table shows the need for domain adaptation: most of the TextRunner relations, such as "person:gets:pass" or "person:bought:pass", refer to different domains. DART shows the same effect: the first two entries ("person:make:pass", "person:take:pass") belong to different domains.

DART[1]	TextRunner[2]	BKB (Football)
(no results)	(~200) threw (~100) completed (36) to throw (26) has thrown (19) makes (19) has (18) fires	(99) throw (25) complete (7) have (5) attempt (5) not-throw (4) toss (3) release
(47) make (45) take (36) complete (30) throw (25) let (23) catch (1) make (1) expect	(22) gets (17) makes (10) has (10) receives (7) who has (7) must have (6) acting on (6) to catch (6) who buys (5) bought (5) admits (5) gives	(824) catch (546) throw (256) complete (136) have (59) intercept (56) drop (39) not-catch (37) not-throw (36) snare (27) toss (23) pick off (20) run
(13) person (6) person/ place/ organization (2) full-back (1) place	(30) Early (26) Two plays (24) fumble (20) game (20) ball (17) Defensively	(75) person (14) cornerback (11) defense (8) safety (7) group (5) linebacker

Table 1. Comparison of DART, TextRunner and our BKB for the following queries (rows): (1) *quarterback:X:pass*, (2) *person:X:pass*, (3) *X:intercept:pass*. Frequencies are in parentheses.

Finally, the third question is aimed at recovering possible agents (those that *intercept passes* in our case). Again, as shown in DART, the reduced set of classes given by the entity recognizer is not enough for the football domain. But having no classes (TextRunner) is even worse, showing its orientation to discovering relations rather than to generalizing and answering about their possible arguments. Our approach is able to discover plausible agent-classes for the query.

Other queries related to the football domain show the same behavior.

6 Related Work

Our approach lies between macro-reading and Open Information Extraction (OIE). Macro-reading (Mitchell et al. 2009) is a different task from ours; it seeks to populate ontologies. Here concepts and relations are predefined by the ontology.

OIE (Banko et al. 2007) does not use a predefined set of semantic classes and relations and is aimed at web scale. For this reason the framework does not include a complete NLP pipeline. The resulting lack of term normalization and absence of domain adaptation (e.g., the query *person:X:pass* return *throw* but also *buy*) makes the results less relevant to single-document reading.

When, as with DART, the complete NLP pipeline is applied over a general corpus, the amount of information to be processed has to be limited due to computational cost. Ultimately, too little knowledge remains for working in a specific domain. For example, asking DART about "*quarterback:X:pass*" produces no results.

Our approach takes advantage of both worlds, ensuring that enough amounts of documents related to the domain will be processed with a complete NLP pipeline. Doing so provides cleaner and canonical representations (our propositions) and even higher counts than TextRunner for our domain. This level of processing will be scalable in the midterm; various people including (Huang and Sagae, 2010) are working in linear time parsers with state-of-the-art performance.

Another intermediate point between a collection of domain documents and the general web, reached by restricting processing to the results of a web query, is explored in IE-on-demand (Sekine 2006; Shinyama and Sekine 2006). However, they use a predefined set of entity classes, preventing from discovering the appropriate granularity level that enables retrieval of relevant background knowledge. We do not predefine the concepts/classes and relations, but discover them from what it is explicitly said in the collection.

The process of building the BKB described here is closely related to DART (Clark and Harrison, 2009) which in turn is related to KNEXT (Van Durme and Schubert, 2008). Perhaps the most important extension we performed is the inclusion of lexical relations (like "*has-instance*") that activate more powerful uses of the Proposition Stores.

7 Conclusions and Future Work

In building a BKB, limiting oneself to a specific domain provides some powerful benefits. Ambiguity is reduced inside the domain, making counts in propositions more accurate. Also, frequency distributions of propositions differ from one domain to another. For example, the list of the most frequent NVN propositions in our BKB (see Section 3.1) is, by itself, an indication of the most salient and important events specifically in the US football domain. Furthermore, the amount of text required to build the BKB is reduced significantly allowing processing such as parsing.

The task of inferring omitted but necessary information is a significant part of automated text interpretation. In this paper we show that even simple kinds of information, gleaned relatively straightforwardly from a parsed corpus, can be quite useful. Though they are still lexical and not even starting to be semantic, propositions consisting of verbs as relations between nouns seem to provide a surprising amount of utility. It remains a research problem to determine what kinds and levels of knowledge are most useful in the long run.

In the paper, we discuss only the propositions that are grounded in instantial statements about players and events. But for true learning by reading, a system has to be able to recognize when the input expresses general rules, and to formulate such input as axioms or inferences. In addition is the significant challenge of generalizing certain kinds of instantial propositions to produce inferences. At which point, for example, should the system decide that "all football players have teams", and how should it do so? This remains a topic for future work.

A further topic of investigation is the time at which expansion should occur. Doing so at question time, in the manner of traditional task-oriented back-chaining inference, is the obvious choice, but some limited amount of forward chaining at reading time seems appropriate too, especially if it can significantly assist with text processing tasks, in the manner of expectation-driven understanding.

Finally, as discussed above, the evaluation of intrinsic evaluation procedures remains to be developed.

Acknowledgments

We are grateful to Hans Chalupsky and David Farwell for their comments and input for this work. We acknowledge the builders of TextRunner and DART for their willingness to make their resources openly available.

Dynamic Parameters for Cross Document Coreferece

Octavian Popescu
papsi@racai.ro
Racai, Romanina Academy

Abstract

In this paper we present a new algorithm for the Person Cross Document Coreference task. We show that accurate results require a way to adapt the parameters of the similarity function – metrics and threshold – to the ontological constraints obeyed by individuals. The technique we propose dynamically changes the initial weights computed when the context is analyzed. The weight recomputation is necessary in order to resolve clusters borders, which are inevitably blurred by a static approach. The results show a significant gain in accuracy.

1 Introduction

The Person Cross Document Coreference, CDC, task requires that all the personal name mentions, PNMs, in a corpus be clustered together according to the individuals they refer to (Grishman 1994). The coreference between two PNMs is decided on the basis of the local contexts. In this paper we consider a news corpus, and the local context is the piece of news to which a particular PNM belongs. We work on a seven year Italian local newspaper corpus, Adige 500K (Magnini et. al. 2006).

While there are certain similarities between a disambiguation task and the CDC task, we maintain that there is a significant difference which sets the CDC task apart. Unlike in other disambiguation tasks, in the CDC tasks the relevant coreference context depends on the corpus itself. In word sense disambiguation, for instance, the distribution of the relevant context is mainly regulated by strong syntactic and semantic rules. The existence of such rules allows for disambiguation decisions which are made by considering the local context only. On the other hand, the distribution of the PNMs in a corpus is rather random and the relevant coreference context is a dynamic variable which depends on the diversity of the corpus, that is, on how many different persons with the same name share a similar context. Unlike the word senses which are subject to strong linguistic constraints, the name distribution is more or less random. To exemplify, consider the name "John Smith" and an organization, say "U.N.". The extent to which "works for U.N." in "John Smith works for U.N." is a relevant coreference context depends on the diversity of the corpus itself. If in that corpus, among all the "John Smiths" there is only one person who works for "U.N." then "works for U.N." is a relevant coreference context, but if there are many "John Smiths" working for U.N., then "works for U.N." is not a relevant coreference system.

In this paper we present a method to exactly determine the relevance of a piece of context for the coreference. As above, the exactness is understood in relationship with the whole system of clusters. The relevance of a piece of context is computed by means of a weighting procedure. The classic weighting procedures are static, each piece of context receives an initial value that is also a final one and the clustering proceeds on the basis of these values. We demonstrate that this approach has serious drawbacks and we argue that in order to obtain accurate results, a dynamic weighting procedure is necessary, which outputs new values depending on the cluster configuration.

In Section 2 we review the relevant literature. In Section 3 we present the problems related to the classical approach to the CDC task and we present evidence that the data distribution in a news corpus requires a proper treatment of these

Coling 2008: Poster Volume, pages 988–996,
Beijing, August 2010

problems. In Section 4 we present the technique that permits to overcome the problems identified in Section 3. In Section 5 we present the context extraction technique that supports the method developed in Section 4. In Section 6 we present the results of an evaluation experiment. The paper ends with Conclusion and Further Work section.

2 Related Work

In a classical paper (Bagga and Baldwin 1998), a PCDC system based on the vector space model (VSM) is proposed. While there are many advantages in representing the context as vectors on which a similarity function is applied, it has been shown that there are inherent limitations associated with the vectorial model (Popescu 2008). These problems, related to the density in the vectorial space (superposition) and to the discriminative power of the similarity power (masking), become visible as more cases are considered.

Testing the system on many names, (Gooi and Allan, 2004), it has been noted empirically that the accuracy of the results varies significantly from name to name. Indeed, by considering just the sentence level context, which is a strong requirement for establishing coreference, a PCDC system obtains a good score for "John Smith". This happens because the prior probability of coreference of any two "John Smiths" mentions is low, as this is a very common name and none of the "John Smiths" has an overwhelming number of mentions. But for other types of names the same system is not accurate. If it considers, for instance, "Barack Obama", the same system obtains a very low recall, as the probability of any two "Barack Obama" mentions to corefer is very high and the relevant coreference context is very often found beyond the sentence level. Without further adjustments, a vectorial model cannot resolve the problem of considering too much or too little contextual evidence in order to obtain a good precision for "John Smith" and simultaneously a good recall for "Barack Obama". These types of name have different cluster systems

In an experiment using bigrams (Pederson et al. 2005) on a news corpus, it has been observed that the relationship between the amount of information given to a CDC system and the performances is not linear. If the system has received in input the correct number of persons with the same name, the accuracy of the system has dropped. A typical case for this situation is when there is a person that is very often mentioned, and few other persons that have few mentions. When the number of clusters is passed in the input, the clusters representing the persons who are rarely mentioned are wrongly enriched. However, this situation can be avoided if there is a measure of how big the threshold should be. The system of clusters is not developed unrealistically if we are able to handle the fact that individuals obey different constraints which are derived directly from the ontological properties. These constraints are determined directly from the context and adequate weights can be set.

Recently, there has been a major interest in the CDC systems, and, in the last two years, two important evaluation campaigns have been organized: Web People Search-1 (Artiles et al. 2007) and ACE 2008 (www.nist.gov/speech/tests/ace/). It has been noted that the data variance between training and test is very high (Lefever 2007). Rather than being a particularity of those corpora, the problem is general. The performances of a bag of words VSM depends to a very high extent on the corpus diversity (see Section 3.2). For reliable results, a CDC system must have access to global information regarding the coreference space.

Rich biographic facts have been shown to improve the accuracy of CDC (Mann and Yarowsky 2003). Indeed, when available, the birth date, the occupation etc. represent a relevant coreference context because the probability that two different persons have the same name, the same birth date and the same occupation is negligible. However, it is equally unlikely to find this information in a news corpus a sufficient number of times. Even for a web corpus, where the amount of this kind of information is higher than in a news corpus, the extended biographic facts, including e-mail address, phones, etc., contribute only with approximately 3% to the total number of coreferences (Elmacioglu et al. 2007). In order to improve the performances of the CDC systems based on VSM, the special importance of pieces of context has been exploited by implementing a cascade clustering technique (Wei 2006). Other authors have relied on advanced clustering techniques (among others Han et al. 2005, Chen 2006). However, these techniques rely on the precise analysis of the context, which is a time consuming process. It has been also noted that, in spite of deep analysis, the relevant coreference context is hard to find (Vu 2007).

3 Coreference Based on Association Sets

The coreference of two PNMs is realized on the basis of the context. In a news corpus, the context surrounding each PNM, which is relevant for coreference, is extracted into a set, called association set. In Table 1 we present an example of association sets related to the same name.

Name	Associated Sets
Paolo Rossi	TV, comedian, , satire research, conference politics, meeting

Table 1: Associated Sets

A weighting schema, a global metrics and threshold are set, and the distance between two association sets is computed. The decision of coreferencing two PNMs is made on comparing the distance to the threshold and clustering the PNMs representing the same individual into a unique cluster. The accuracy of a CDC system based on association sets depends on two factors: (1) the ability to extract the relevant elements for the association sets from the news context and (2) the adequacy of the similarity formula - metrics and threshold.

Regarding the first factor, the ability to extract the relevant pieces of context, the right heuristics must be found, because the exact syntax-semantics analysis of text is unfortunately very hard or impossible to implement. A strong limitation comes from the fact that even a shallow parsing requires too much time in order to be practical. However, it has been shown that accurate parings of PNMs and co-occurring special words can be found by employing relaxed extraction techniques (Buitelaar&Magnini 2005). The association sets built in this way are effective in solving the CDC task (Sekine 2008, Popescu 2008). We make use of these findings in order to build the association sets, which mainly include named entities and certain special words, which are bound to an ontology. The details of these particular association sets are given in Section 5.

As straightforward as the classical approach based on the distance between association sets may seem, there are actually a series of problems related to the second requirement, namely the adequacy of similarity formula. We make these problems explicit below.

3.1 Masking, Superposition and Border Proximity

In order to introduce the first problem we start with an intuitive example. Suppose that we want to individuate the persons with the name Michael Jackson in a news corpus. A simplistic solution is to cluster together all such PNMs and declare that than there is just one person mentioned in the whole corpus with this name. This solution has the advantage of being very simple and of obtaining a very high score in terms of precision and recall. This is because most of such PNMs refer to only one person indeed – the pop star. However, the above method fails short when it comes to presenting the evidence for its coreference decision. Actually, it turns out that this is a very hard task, because the number of PNMs, which do not refer to the pop star, is extremely small. Thus, the prior chances of correctly finding two PNMs which do not refer to this person are quite small. Unfortunately, the classical metrics are too coarse to capture the difference in such cases, even if the association sets are 100% correct. To support this statement, let us consider three classes under the same name, with each class corresponding to a different individual. Let us further suppose that two classes contain the great majority of the PNMs, and the third class only has a small number of PNMs. A linear decision is likely to confound the elements of the third class to the ones of the first two[1]. This happens because the elements of the third class are transparent to the hyper plane that separates the two well-represented classes. This situation is called masking, and is a direct effect of applying an inaccurate weighting schema and metrics (Hastie&Tibshirani 2001). The effects of masking on the CDC task have been empirically noticed in (Pederson 2005). The main obstacle in dealing with masking is the correct treatment of the border elements. δ_{ij}, the discrimant function between two classes, i and j respectively, must assign zero to all border elements. In Section 4, we directly address this problem.

The second problem that needs to be solved by the CDC systems based on associated sets may be regarded as the negative effect of counter balancing the sparseness problem. In general, the association sets are too sparse to permit pair to pair comparison. Rather, the information must be interpolated from a set of corefered association sets. For example, in Figure 1, any two association sets chosen from the three ones on the left, AS_1, AS_2 and AS_3 respectively, are similar

[1] In fact any decision functions that can be bijectively transformed into a linear function, like most exponential kernel functions for example, are similarly prone to masking.

enough to one another to corefer. However, none of these association sets is similar enough to the one on the right – AS_4. But accepting the coreference of any initial pair, in this particular case, we implicitly accept the coreference with the fourth one.

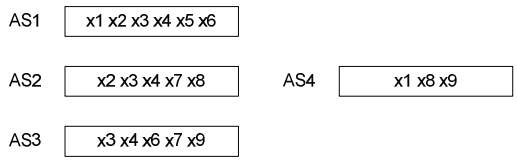

Figure 1. Interpolating

By interpolating the information in the set of the initial three association sets, the coreference becomes possible between all four association sets. In general, by interpolating from a set of the association sets, one wants to find the right coreferences and to avoid the false ones accurately. In a vector space, the interpolation is safe if the initial vectors are orthogonal to each other, because the sum of orthogonal vectors is also orthogonal to any other vector that is not part of the sum. Therefore the right coreferences have a big dot product with the sum, while the false ones have a dot product with the sum close to zero. This property of the sum of the orthogonal vectors is called superposition (Gallant 1993). By representing the association sets as vectors, where each set of vectors is associated exclusively with a certain individual, the sum of these vectors has the superposition property.

However, if the vectors representing the association sets are not orthogonal, then the interpolated vectors are prone to false coreferences. In this case, the accidental coincidences – which are responsible for the original vectors not being orthogonal – biases the dot product and introduces false coreferences. Consequently the superposition affects negatively the overall accuracy. The aggravating effect of superposition in conjunction with an agglomerative clustering procedure has been empirically noted in Gooi&Allan.

The third problem is directly related to the fact that in the most ambiguous cases the association sets lead to high-dimensional, very sparse vectors. The basic fact is that inside a cluster of correctly corefered PNMs that refer to the same individual, the distance from most of these PNMS to the center of the cluster is smaller than the distance from these PNMs to the border. Let us consider that all the *m* PNMs representing the same individual are points in an *n* dimensional vector space and their cluster is normalized to the unit sphere. The distance from the center of the sphere to the closest point is an exponentially growing formula both in *1/n* and *1/m*. Even for small values, the distance from the center to the closest point is larger than ½. The points representing the PNMs in the same cluster are closer to the border, and not to the center of the sphere. This is a secondary effect of the curse of dimensionality problem in the vector space[2].

3.2 Data Distribution

Let us consider the corpus, focusing on the distribution of PNMs. Many PNMs are the mentions of the same name, considered as a string. We are interested in the frequency with which a certain name appears. We have noticed that there is a strict relationship between the names, their frequencies and the number of mentions; see Table 2.

Freq	PNM	# PNM
1	317,245	317,245
2 – 5	166,029	467,560
6 – 20	61,570	634,309
21 – 100	25,651	1,090,836
101 – 1000	7,750	2,053,994
1001 – 2000	4,25	569,627
2001 – 4000	157	422,585
4001 – 5000	17	73,860
5001 – 31091	22	190,373

Table 2 Frequency of Names and PNMs in Adige500k

The names have a very unbalanced distribution. A name which has a frequency over 20 and is ambiguous represents a difficult case. The measure we use in order to evaluate the difficulty is the Gini's mean difference. Let X_1, X_2, …, X_n be the individuals that are named with the same name and let S be the set of the PNMs of this name PNMS, S_1, S_2, … S_n. The Gini's mean difference is a measure of the spread of the information in the set S:

$$\sum_{j=2}^{n} \sum_{i} \binom{n}{2} |Si - Sj| = G \qquad (1)$$

The uniform distribution makes Gini's factor null. A value of this factor close to 1 shows a skewed distribution. In the first case, $G \approx 0$, the superposition effect is likely to be responsible for false coreferences, while in the latter case, $G \approx 1$,

[2] The curse of dimensionality refers to the fact that the number of sample points required to state confident values for a statistics grows exponentially with the dimension of vector space.

the masking effect is predominant. However, there is a close relationship between all the three problems above. As the most ambiguous cases are near the border, it is likely that the vectors are not orthogonal and consequently the false coreferences are introduced in the system, which ultimately leads to masking.

4 Resolving the Border Condition

We are going to present a technique developed to deal with the problems identified in the previous section. The bottom line is that the weights and the threshold required by the similarity function of two association sets should be dynamically computed. In this way the border between any pair of clusters can be accurately set.

We present the procedure of adjusting the weights and the threshold for a given group of clusters in order to maximize the probability of the correct coreferences. The first step is to present the construction of the association sets, with initial weight values. The second step is to show how these initial weight values are recomputed for a set of given clusters.

Initialization

As mentioned in the first paragraph of Section 3, the association sets are built out of the surrounding context by considering the named entities, and special words. The named entities are clearly marked in the input, the corpus having being tagged by a Named Entities Recognition tool. The words considered special are identified using an ontology and the procedure is given in Section 5. The construction of the association set is a search procedure starting from the PNM. The first search space is the longest nominal group which is headed by a PNM:

uno dei falchi dell' amministrazione di Stati Uniti guidata dal presidente George W.Bush
one of the falcons of the U.S. administration lead by the president Georg W. Bush

All the special words that are present in this nominal group are included in the association set of this PNM. In this example, these special words are "president" and "administration" respectively. The named entity "U.S." is also included. These elements receive the highest weights. The search space is extended to the sentence level and new named entities/special words are included. However, unlike in the first phase, the weight of these words is determined on the basis of a second parameter, namely the number of different names interfering between the PNM and these words. We take into consideration three values 0, 1 and 2 or more. After the sentence, the next search domain is the whole news. Basically, the significance of an element decreases linearly with the distance and the number of other interfering PNMs. In Table 3 we present the linear kernel weighting schema described above. The series α_{ij} is decreasing linearly over both indexes.

	Interfering PNMs		
Domain	0	1	≥2
PNM Group	α_{11}	α_{12}	α_{13}
IN Sentence	α_{21}	α_{22}	α_{23}
Out Sentence	α_{31}	α_{32}	α_{33}

Table 3. Linear Kernel for Initial Weights

Recomputation

The association set is basically a pair of two vectors: $X = (x_1, \ldots, x_n)$ the set of words and $W = (w_1, \ldots, w_n)$ the set of the initial weights. Two PNMs corefer or not depending on whether the sum of their common part is bigger, respectively lesser than a threshold.

$$coref: \sum_{common\ xi} wi \geq T \quad (2)$$

$$non\ coref: \sum_{common\ xi} wi \leq T \quad (3)$$

Suppose now that we have an independent way to know the truth regarding the coreference. Then, we have to readjust the initial weights such that the real configuration of clusters is promoted also by Equations (2) and (3). For clarity, let us give an example: suppose that we know that in our corpus there is only one person named "Roberto Bizzo" and only one person named "Roberto Cuillo", and no other person is called "Roberto". Consequently the PNMs "Roberto" are clustered to the clusters "Robert Bizzo" xor "Roberto Cuillo". Suppose further that the named entity "Roma" is associated with some of the PNMs "Roberto". If only "Roberto Bizzo" is associated with "Roma", then the coreference between those "Roberto" associated with "Roma" and "Roberto Bizzo" can be made. However, it is often the

case that both "Roberto Bizzo" and "Roberto Cuillo" are associated with "Roma", which has its particular weight for each PNM. In this case this named entity, "Roma", may bear no relevance for the coreference of "Roberto" in either of the clusters. Consequently, whatever the initial value for "Roma" in certain association sets, it must be nullified. In order to find out which elements of the association sets are relevant, and what weights the relevant elements must have, we propose the following strategy: we replace the "Roberto Bizzo" with "Roberto X", and "Roberto Cuillo" with "Roberto X". We obtain a big set of association sets corresponding to the PNMs "Roberto X". We reweight the elements of their association sets and the threshold, such that, from this set of association sets, we obtain exactly two clusters, one that is identical with "Roberto Bizzo", and one that is identical with "Roberto Cuillo". Conceptually, this strategy is similar to the pseudo words technique used in building test corpora. After the reweighting of the elements associated with "Robert Bizzo" and "Roberto Cuillo" respectively, we can associate the simple PNMs "Roberto" to one of these two clusters.

In the above example we make use of the fact that if two persons have different last names then they are different persons. This is a prior ontological constraint. In fact, whenever we know the set of ontological constraints that correctly cluster a set of PNMs in two or more clusters, we can intentionally confound the PNMs, recompute the weights and the thresholds of their association sets, in order to obtain the initial cluster configuration. Now we use the new computed values to cluster new PNMs whose relationship with the ontological constraints could not have been determined from the corpus.

We show that we can use the Simplex method to recompute the initial weights. Indeed, by intentionally confounding a system of clusters, we determine the coefficients which, when multiplied with the initial weights, lead to the correct clustering. These coefficients are the solution to a set of inequalities like those presented in Equations (2), and (3). The objective function in Simplex is a max or a min depending on whether we know that the PNMs corefer or not: if they do not corefer then there is a max Simplex system, and the threshold is just higher than the value of the objective function. Let us give an example. Suppose we have the following configuration, where AS_i represents the association set of the PNM_i, where wi is the vector of the initial weights and T is the threshold: .

$AS_1 \cap AS_2 = \{x_1, x_2, x_3\}$	wi = (1, 2, 2)	T = 7	No Coreference	$x_1 + 2x_2 + 2x_3 \leq 7$
$AS_1 \cap AS_3 = \{x_1, x_3\}$	wi = (5,0,4)	T = 11	Coreference	$5x_1 + 4x_3 \geq 11$
$AS_2 \cap AS_4 = \{x_2, x_3\}$	wi = (0,3,4)	T = 9	Coreference	$3x_2 + 4x_3 \geq 9$
$AS_5 \cap AS_6 = \{x_1, x_2\}$	w i= (2,1,0)	T = ?	No Coreference	max $(2x_1 + x_2)$

The above cluster configuration leads to the following Simplex system:

$$\max 2x_1 + x_2$$

$$\begin{cases} x1 + 2x2 + 2x3 \leq 7 \\ 5x1 + 4x3 \geq 11 \\ 3x2 + 4x3 \geq 9 \end{cases}$$

which has the solution wr = (1.55, 1.91, 0.82) with max = 5. Therefore the initial weights for the elements x_1, x_2, x_3 must be multiplied with 1.55, 1.91, 0.82 respectively and the appropriate threshold for making a decision is 5.01.

5 Ontological Constrained Association Sets

In the preceding section we presented a strategy based on Simplex Algorithm developed for the border weight assignment. The similarity formula is recomputed such that a set of ontological restriction is satisfied. In this section we present the way the set of ontological restrictions is found. The set of special words is identified on the basis of an ontology. We have used SUMO (Niles 2003) because it has the advantage that its hierarchies are connected to the WordNet, which is a Multilanguage aligned resource. Below we present the main categories of the SUMO attributes used. Summing up, there are more than 7 000 special words taken into account.

Corporation
Organization
Occupational Role
Occupies Position
Social Interaction
Social Role
Unemployed

There are mainly three different ways to create the set of ontological restrictions: fixed, prior ontological constraints, local restrictions and exclusive ontological relationships.

The fixed, prior ontological constraints are those that tend to be expressed in a fixed pattern, making it easy to identify them in the context. Usually they express the date and place of birth,

contact information, but also the gender, the family relationship, the ethnic group etc.

The local restrictions are a very rich source of information. It has been argued that inside each piece of news the coreference of all the PNMs is a valid procedure, with more than 99% accuracy (Popescu et al. 2008). By comparing the structure of the largest nominal group headed by two locally corefered PNMs we can found ontological compatibilities. Table 4 shows a sample of the compatible pairs as extracted from corpus. These pairs can be used successfully for coreferencing purposes, but these do not form ontological hierarchies and cannot be used to build inference chains.

Pairs of compatible professions
albergatore comerciante
ala giocatore
agronomo professore
allenatore mister
alpinista guida alpina
architetto progettista
arcivescovo monsignore
monsignore teologo
monsignore sacerdote
assessore consigliere

Table 4. Compatible Occupational Role

The exclusive ontological relationships are given explicitly under the form of rules. These rules stipulate what is ontologically inacceptable. We have seen an example of such rules referring to the family names in Section 4. The Occupational Role and Social Role attributes are one of the most useful exclusive ontological ones, because they are frequently mentioned in a news corpus. In average, local information at the news level produces a special word from the above categories in approximately in 30% of cases (Magnini et al 2006.). An example of the realization of the exclusive rules for a sample of multi pairs of words as extracted from corpus is presented below:

Secretary≠Priest≠Judge
Architect≠Attorney
Waiter≠Manager
Actor≠Researcher

The system of clusters determined using the technique described in Section 4 obeys the set of these constraints. The set C of ontological constraints are used to generate active rules at the word level, which, by means of fixed text patterns, are compared against the association sets. This permits the realization of ontological motivated cluster systems, which in combination with the technique of reweighting presented, leads to accurate new coreferences outside the scope of C, while avoiding the border problems presented in Section 3 ..

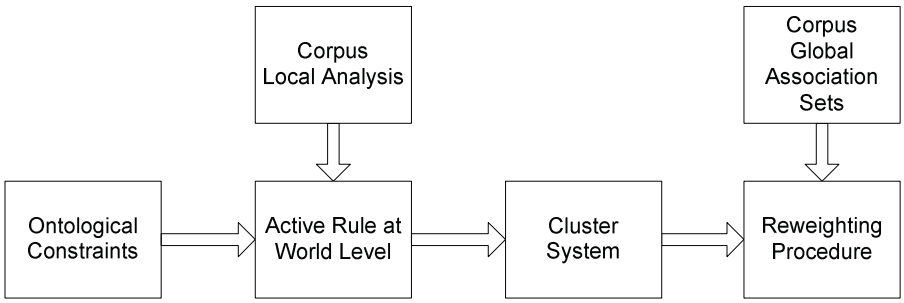

Figure 2. The dynamic reweighting schema flow

6 Evaluation

The technique we propose is designed for an accurate border detection between clusters of ambiguous names. We created a sample of the ambiguous names. For each name we computed the Gini's mean difference using the formula introduced in Section 3, which gives an indication of the spread of information relevant for coreference. We have noticed that there is a strong correlation between the Gini's mean difference and the difficulty of a coreference system. The names chosen for this experiment are such that the Gini's factor uniformly distributed in (0,1). However, the number of PNMs for each name is bigger than the number of individuals having that name. The choice is motivated by the fact that these are the most difficult cases for a CDC system, as they require strong and consistent evidence for accurate results. The opposite cases, when the number of the individuals is close to the number of PNMs or the Gini's coefficient is

close to 0 or 1, can be approached with a pure statistical approach (Popescu 2009).
The first column in Table 5 lists the names, the second column lists the number of the PNMs considered for each name, the third column lists the number of individuals having the respective name, the fourth column lists the number of PMNs for each individual, the fifth column lists the Gini's factor and the sixth column lists how many clusters have been found obeying ontological constraints/ and how many PNMs have been clustered in these clusters.

Name	#PNMs	#P	Distribution	Gini	Constraints
Angelo Elia	58	5	{20,24,7,2,2,3}	.428	2 / 18
Gifuni	89	3	{47,21,31}	.175	3/ 12
Giuseppe Rossi	185	12	{69,32,5,9,4,5,6,6,12,7,8,22}	.503	5 / 38
Paulo Rossi	137	9	{91,17,9,3,2,3,5,5,2}	.673	3 / 74
Schlesinger	62	4	{26,19,6,11}	.274	4 / 19
Tanzi	370	3	{315,49,16}	.524	3/129

Table 5. Name Test Set

We compare the technique proposed in Section 4 (DYN) against three different approaches: the first is a no weight coreference, requiring a fix number of similar elements in the association set (NOW), the second is Baga&Baldwin quadratic metric formula at sentence level (BB), and the third is an agglomerative vector space clustering algorithm as in Gooi&Allan(GA). All these three approaches use fixed similarity parameters.
The evaluation is done using the B-CUBED algorithm (Baga&Baldwin). The results, computed with F formula, are presented in Table 6.

Name	NW	BB	GA	DYN
Angelo Elia	.426	.639	.684	.672
Gifuni	.53	.635	.661	.726
Giuseppe Rossi	.481	.619	.589	.673
Paulo Rossi	.446	.623	.598	.691
Schlesinger	.528	.588	.723	.829
Tanzi	.572	.539	.699	.815
Average	**.417**	**.607**	**.659**	**.734**

Table 6. F-formula on B-CUBED

The BB and GA have been tested on the John Smith corpus, which contains the PNMs of just one name, John Smith. As John Smith is a very common name and no famous person carries it, this corpus is rather biased as the Gini's factor is small; that is why BB performs better than GA on "Giuseppe Rossi" and "Paulo Rossi". The DYN scores the best , gaining in average 7 points in F formula.

Conclusion and Further Work

In this paper we present a new technique for the CDC task which allows us to dynamically change the weights in the association sets in order to accurately account for border cases. As we showed in Section 3, the border cases are actually the most important ones due to the high dimensionality of the vector space which models the association sets.

The results we have obtained are superior to other approaches. We think that this is possible because the technique we used directly addresses the problem related to masking and superposition.

We plan to further study this technique by following mainly three directions. First, we want to study further the behavior of masking and superposition within a larger test corpus. Second, we want to extend the set of exclusive ontological relationships which can be determined from the context with shallow text analysis. Third, we want to understand better the ways in which the set of ontological constraints interact with the vector space in order to increase the overall accuracy of the coreference system.

A secondary effect of the proposed technique is that a stronger control of the inferences resulting from a cluster system can be obtained. In the future this seems to be a promising method to link the coreference tasks to the chain of inferences.

Abstract

We present an evaluation framework for plagiarism detection.[1] The framework provides performance measures that address the specifics of plagiarism detection, and the PAN-PC-10 corpus, which contains 64 558 *artificial* and 4 000 *simulated* plagiarism cases, the latter generated via Amazon's Mechanical Turk. We discuss the construction principles behind the measures and the corpus, and we compare the quality of our corpus to existing corpora. Our analysis gives empirical evidence that the construction of tailored training corpora for plagiarism detection can be automated, and hence be done on a large scale.

1 Introduction

The lack of an evaluation framework is a serious problem for every empirical research field. In the case of plagiarism detection this shortcoming has recently been addressed for the first time in the context of our benchmarking workshop PAN [15, 16]. This paper presents the evaluation framework developed in the course of the workshop. But before going into details, we survey the state of the art in evaluating plagiarism detection, which has not been studied systematically until now.

1.1 A Survey of Evaluation Methods

We have queried academic databases and search engines to get an overview of all kinds of contributions to automatic plagiarism detection. Altogether 275 papers were retrieved, from which 139 deal with plagiarism detection in text, 123 deal with plagiarism detection in code, and 13 deal with other media types. From the papers related to text and code we analyzed the 205 which present evaluations. Our analysis covers the following aspects: experiment tasks, performance measures, underlying corpora, and, whether comparisons to other plagiarism detection approaches were conducted. Table 1 summarizes our findings.

Table 1: Summary of the plagiarism detection evaluations in 205 papers, from which 104 deal with text and 101 deal with code.

Evaluation Aspect	Text	Code
Experiment Task		
local collection	80%	95%
Web retrieval	15%	0%
other	5%	5%
Performance Measure		
precision, recall	43%	18%
manual, similarity	35%	69%
runtime only	15%	1%
other	7%	12%
Comparison		
none	46%	51%
parameter settings	19%	9%
other algorithms	35%	40%

Evaluation Aspect	Text	Code
Corpus Acquisition		
existing corpus	20%	18%
homemade corpus	80%	82%
Corpus Size [# documents]		
$[1, 10)$	11%	10%
$[10, 10^2)$	19%	30%
$[10^2, 10^3)$	38%	33%
$[10^3, 10^4)$	8%	11%
$[10^4, 10^5)$	16%	4%
$[10^5, 10^6)$	8%	0%

With respect to the experiment tasks the majority of the approaches perform overlap detection by exhaustive comparison against some locally stored document collection—albeit a Web retrieval scenario is more realistic. We explain this shortcoming by the facts that the Web cannot be utilized easily as a corpus, and, that in the case of code plagiarism the focus is on collusion detection in student courseworks. With respect to performance measures the picture is less clear: a manual result evaluation based on similarity measures is used about the same number of times for text (35%), and even more often for code (69%), as an automatic computation of precision and recall. 21% and 13% of the evaluations on text and code use custom measures or examine only the de-

[1] The framework is available free of charge at `http://www.webis.de/research/corpora`.

Coling 2008: Poster Volume, pages 997–1005,
Beijing, August 2010

tection runtime. This indicates that precision and recall may not be well-defined in the context of plagiarism detection. Moreover, comparisons to existing research are conducted in less than half of the papers, a fact that underlines the lack of an evaluation framework.

The right-hand side of Table 1 overviews two corpus-related aspects: the use of existing corpora versus the use of handmade corpora, and the size distribution of the used corpora. In particular, we found that researchers follow two strategies to compile a corpus. Small corpora (<1 000 documents) are built from student courseworks or from arbitrary documents into which plagiarism-alike overlap is manually inserted. Large corpora (>1 000 documents) are collected from sources where overlap occurs more frequently, such as rewritten versions of news wire articles, or from consecutive versions of open source software. Altogether, we see a need for an open, commonly used plagiarism detection corpus.

1.2 Related Work

There are a few surveys about automatic plagiarism detection in text [7, 8, 14] and in code [12, 17, 19, 20]. These papers, as well as nearly all papers of our survey, omit a discussion of evaluation methodologies; the following 4 papers are an exception.

In [21] the authors introduce graph-based performance measures for code plagiarism detection that are intended for unsupervised evaluations. We argue that evaluations in this field should be done in a supervised manner. An aside: the proposed measures have not been adopted since their first publication. In [15] we introduce preliminary parts of our framework. However, the focus of that paper is less on methodology but on the comparison of the detection approaches that were submitted to the first PAN benchmarking workshop. In [9, 10] the authors report on an unnamed corpus that comprises 57 cases of simulated plagiarism. We refer to this corpus as the Clough09 corpus; a comparison to our approach is given later on. Finally, a kind of related corpus is the METER corpus, which has been the only alternative for the text domain up to now [11]. It comprises 445 cases of text reuse among 1 716 news articles. Although the corpus can be used to evaluate plagiarism detection its design does not support this task. This is maybe the reason why it has not been used more often. Furthermore, it is an open question whether or not cases of news reuse differ from plagiarism cases where the plagiarists strive to remain undetected.

1.3 Contributions

Besides the above survey, the contributions of our paper are threefold: Section 2 presents formal foundations for the evaluation of plagiarism detection and introduces three performance measures. Section 3 introduces methods to create artificial and simulated plagiarism cases on a large scale, and the PAN-PC-10 corpus in which these methods have been operationalized. Section 4 then compares our corpus with the Clough09 corpus and the METER corpus. The comparison reveals important insights for the different kinds of text reuse in these corpora.

2 Plagiarism Detection Performance

This section introduces measures to quantify the precision and recall performance of a plagiarism detection algorithm; we present a micro-averaged and a macro-averaged variant. Moreover, the so-called detection granularity is introduced, which quantifies whether the contiguity between plagiarized text passages is properly recognized. This concept is important: a low granularity simplifies both the human inspection of algorithmically detected passages as well as an algorithmic style analysis within a potential post-process. The three measures can be applied in isolation but also be combined into a single, overall performance score. A reference implementation of the performance measures is distributed with our corpus.

2.1 Precision, Recall, and Granularity

Let d_{plg} denote a document that contains plagiarism. A *plagiarism case* in d_{plg} is a 4-tuple $s = \langle s_{\text{plg}}, d_{\text{plg}}, s_{\text{src}}, d_{\text{src}} \rangle$, where s_{plg} is a plagiarized passage in d_{plg}, and s_{src} is its original counterpart in some source document d_{src}. Likewise, a *plagiarism detection* for document d_{plg} is denoted as $r = \langle r_{\text{plg}}, d_{\text{plg}}, r_{\text{src}}, d'_{\text{src}} \rangle$; r associates an allegedly plagiarized passage r_{plg} in d_{plg} with

a passage r_{src} in d'_{src}. We say that r *detects* s iff $r_{\text{plg}} \cap s_{\text{plg}} \neq \emptyset$, $r_{\text{src}} \cap s_{\text{src}} \neq \emptyset$, and $d'_{\text{src}} = d_{\text{src}}$. With regard to a plagiarized document d_{plg} it is assumed that different plagiarized passages of d_{plg} do not intersect; with regard to detections for d_{plg} no such restriction applies. Finally, S and R denote sets of plagiarism cases and detections.

While the above 4-tuples resemble an intuitive view of plagiarism detection we resort to an equivalent, more concise view to simplify the subsequent notations: a document d is represented as a set of references to its characters $\mathbf{d} = \{(1, d), \ldots, (|d|, d)\}$, where (i, d) refers to the i-th character in d. A plagiarism case s can then be represented as $\mathbf{s} = \mathbf{s}_{\text{plg}} \cup \mathbf{s}_{\text{src}}$, where $\mathbf{s}_{\text{plg}} \subseteq \mathbf{d}_{\text{plg}}$ and $\mathbf{s}_{\text{src}} \subseteq \mathbf{d}_{\text{src}}$. The characters referred to in $\mathbf{s}_{\text{plg}}$ and $\mathbf{s}_{\text{src}}$ form the passages s_{plg} and s_{src}. Likewise, a detection r can be represented as $\mathbf{r} = \mathbf{r}_{\text{plg}} \cup \mathbf{r}_{\text{src}}$. It follows that r detects s iff $\mathbf{r}_{\text{plg}} \cap \mathbf{s}_{\text{plg}} \neq \emptyset$ and $\mathbf{r}_{\text{src}} \cap \mathbf{s}_{\text{src}} \neq \emptyset$. Based on these representations, the micro-averaged precision and recall of R under S are defined as follows:

$$prec_{\text{micro}}(S, R) = \frac{|\bigcup_{(s,r) \in (S \times R)} (\mathbf{s} \sqcap \mathbf{r})|}{|\bigcup_{r \in R} \mathbf{r}|}, \quad (1)$$

$$rec_{\text{micro}}(S, R) = \frac{|\bigcup_{(s,r) \in (S \times R)} (\mathbf{s} \sqcap \mathbf{r})|}{|\bigcup_{s \in S} \mathbf{s}|}, \quad (2)$$

$$\text{where} \quad \mathbf{s} \sqcap \mathbf{r} = \begin{cases} \mathbf{s} \cap \mathbf{r} & \text{if } r \text{ detects } s, \\ \emptyset & \text{otherwise.} \end{cases}$$

The macro-averaged precision and recall are unaffected by the length of a plagiarism case; they are defined as follows:

$$prec_{\text{macro}}(S, R) = \frac{1}{|R|} \sum_{r \in R} \frac{|\bigcup_{s \in S} (\mathbf{s} \sqcap \mathbf{r})|}{|\mathbf{r}|}, \quad (3)$$

$$rec_{\text{macro}}(S, R) = \frac{1}{|S|} \sum_{s \in S} \frac{|\bigcup_{r \in R} (\mathbf{s} \sqcap \mathbf{r})|}{|\mathbf{s}|}, \quad (4)$$

Besides precision and recall there is another concept that characterizes the power of a detection algorithm, namely, whether a plagiarism case $s \in S$ is detected as a whole or in several pieces. The latter can be observed in today's commercial plagiarism detectors, and the user is left to combine these pieces to a consistent approximation of s. Ideally, an algorithm should report detections R in a one-to-one manner to the true cases S. To capture this characteristic we define the detection granularity of R under S:

$$gran(S, R) = \frac{1}{|S_R|} \sum_{s \in S_R} |R_s|, \quad (5)$$

where $S_R \subseteq S$ are cases detected by detections in R, and $R_s \subseteq R$ are the detections of a given s:

$$S_R = \{s \mid s \in S \wedge \exists r \in R : r \text{ detects } s\},$$
$$R_s = \{r \mid r \in R \wedge r \text{ detects } s\}.$$

The domain of $gran(S, R)$ is $[1, |R|]$, with 1 indicating the desired one-to-one correspondence and $|R|$ indicating the worst case, where a single $s \in S$ is detected over and over again.

Precision, recall, and granularity allow for a partial ordering among plagiarism detection algorithms. To obtain an absolute order they must be combined to an overall score:

$$plagdet(S, R) = \frac{F_\alpha}{\log_2(1 + gran(S, R))}, \quad (6)$$

where F_α denotes the F_α-Measure, i.e., the weighted harmonic mean of precision and recall. We suggest using $\alpha = 1$ (precision and recall equally weighted) since there is currently no indication that either of the two is more important. We take the logarithm of the granularity to decrease its impact on the overall score.

2.2 Discussion

Plagiarism detection is both a retrieval task and an extraction task. In light of this fact not only retrieval performance but also extraction accuracy becomes important, the latter of which being neglected in the literature. Our measures incorporate both. Another design objective of our measures is the minimization of restrictions imposed on plagiarism detectors. The overlap restriction for plagiarism cases within a document assumes that a certain plagiarized passage is unlikely to have more than one source. Imprecision or lack of evidence, however, may cause humans or algorithms to report overlapping detections, e.g., when being unsure about the true source of a plagiarized passage. The measures (1)-(4) provide for a sensible treatment of this fact since the set-based

passage representations eliminate duplicate detections of characters. The macro-averaged variants allot equal weight to each plagiarism case, regardless of its length. Conversely, the micro-averaged variants favor the detection of long plagiarism passages, which are generally easier to be detected. Which of both is to be preferred, however, is still an open question.

3 Plagiarism Corpus Construction

This section organizes and analyzes the practices that are employed—most of the time implicitly—for the construction of plagiarism corpora. We introduce three levels of *plagiarism authenticity*, namely, real plagiarism, simulated plagiarism, and artificial plagiarism. It turns out that simulated plagiarism and artificial plagiarism are the only viable alternatives for corpus construction. We propose a new approach to scale up the generation of simulated plagiarism based on crowdsourcing, and heuristics to generate artificial plagiarism. Moreover, based on these methods, we compile the PAN plagiarism corpus 2010 (PAN-PC-10) which is the first corpus of its kind that contains both a large number and a high diversity of artificial and simulated plagiarism cases.

3.1 Real, Simulated, and Artificial Plagiarism

Syntactically, a plagiarism case is the result of copying a passage s_{src} from a source document into another document d_{plg}. Since verbatim copies can be detected easily, plagiarists often rewrite s_{src} to obfuscate their illegitimate act. This behavior must be modeled when constructing a training corpus for plagiarism detection, which can be done at three levels of authenticity. Ideally, one would secretly observe a large number of plagiarists and use their *real plagiarism* cases; at least, one could resort to plagiarism cases which have been detected in the past. The following aspects object against this approach:

- The distribution of detected real plagiarism is skewed towards ease of detectability.
- The acquisition of real plagiarism is expensive since it is often concealed.
- Publishing real cases requires the consents from the plagiarist and the original author.
- A public corpus with real cases is questionable from an ethical and legal viewpoint.
- The anonymization of real plagiarism is difficult due to Web search engines and authorship attribution technology.

It is hence more practical to let people create plagiarism cases by "purposeful" modifications, or to tap resources that contain similar kinds of text reuse. We subsume these strategies under the term *simulated plagiarism*. The first strategy has often been applied in the past, though on a small scale and without a public release of the corpora; the second strategy comes in the form of the METER corpus [11]. Note that, from a psychological viewpoint, people who simulate plagiarism act under a different mental attitude than plagiarists. From a linguistic viewpoint, however, it is unclear whether real plagiarism differs from simulated plagiarism.

A third possibility is to generate plagiarism algorithmically [6, 15, 18], which we call *artificial plagiarism*. Generating artificial plagiarism cases is a non-trivial task if one requires semantic equivalence between a source passage s_{src} and the passage s_{plg} that is obtained by an automatic obfuscation of s_{src}. Such semantics-preserving algorithms are still in their infancy; however, the similarity computation between texts is usually done on the basis of document models like the bag of words model and not on the basis of the original text, which makes obfuscation amenable to simpler approaches.

3.2 Creating Simulated Plagiarism

Our approach to scale up the creation of simulated plagiarism is based on Amazon's Mechanical Turk, AMT, a commercial crowdsourcing service [3]. This service has gathered considerable interest, among others to recreate TREC assessments [1], but also to write and translate texts [2].

We offered the following task on the Mechanical Turk platform: *Rewrite the original text found below* [on the task Web page] *so that the rewritten version has the same meaning as the original, but with a different wording and phrasing. Imagine a scholar copying a friend's homework just before class, or imagine a plagiarist willing to use the*

Table 2: Summary of 4 000 Mechanical Turk tasks completed by 907 workers.

Worker Demographics			
Age		*Education*	
18, 19	10%	HS	11%
20–29	37%	College	30%
30–39	16%	BSc.	17%
40–49	7%	MSc.	11%
50–59	4%	Dr.	2%
60–69	1%		
n/a	25%	n/a	29%
Native Speaker		*Gender*	
yes	62%	male	37%
no	14%	female	39%
n/a	23%	n/a	24%
Prof. Writer		*Plagiarized*	
yes	10%	yes	16%
no	66%	no	60%
n/a	24%	n/a	25%

Task Statistics	
Tasks per Worker	
average	15
std. deviation	20
minimum	1
maximum	103
Work Time (minutes)	
average	14
std. deviation	21
minimum	1
maximum	180
Compensation	
pay per task	0.5 US$
rejected results	25%

original text without proper citation.

Workers were required to be fluent in English reading and writing, and they were informed that every result was to be reviewed. A questionnaire displayed alongside the task description asked about the worker's age, education, gender, and native speaking ability. Further we asked whether the worker is a professional writer, and whether he or she has ever plagiarized. Completing the questionnaire was optional in order to minimize false answers, but still, these numbers have to be taken with a grain of salt: the Mechanical Turk is not the best environment for such surveys. Table 2 overviews the worker demographics and task statistics. The average worker appears to be a well-educated male or female in the twenties, whose mother tongue is English. 16% of the workers claim to have plagiarized at least once, and if at least the order of magnitude of the latter number can be taken seriously this shows that plagiarism is a prevalent problem.

A number of pilot experiments were conducted to determine the pay per task, depending on the text length and the task completion time: for 50 US-cents about 500 words get rewritten in about half an hour. We observed that decreasing or increasing the pay per task has proportional effect on the task completion time, but not on the result quality. This observation is in concordance with earlier research [13]. Table 3 contrasts a source passage s_{src} and its rewritten, plagiarized passage s_{plg} obtained via the Mechanical Turk.

3.3 Creating Artificial Plagiarism

To create artificial plagiarism, we propose three obfuscation strategies. Given a source passage s_{src} a plagiarized passage s_{plg} can be created as follows (see Table 4):

- *Random Text Operations.* s_{plg} is created from s_{src} by shuffling, removing, inserting, or replacing words or short phrases at random. Insertions and replacements are taken from the document d_{plg} where s_{plg} is to be inserted.
- *Semantic Word Variation.* s_{plg} is created from s_{src} by replacing words by one of their synonyms, antonyms, hyponyms, or hypernyms, chosen at random. A word is kept if none of them is available.

Table 3: Example of a simulated plagiarism case s, generated with Mechanical Turk.

Source Passage s_{src}	**Plagiarized Passage** s_{plg}
The emigrants who sailed with Gilbert were better fitted for a crusade than a colony, and, disappointed at not at once finding mines of gold and silver, many deserted; and soon there were not enough sailors to man all the four ships. Accordingly, the Swallow was sent back to England with the sick; and with the remainder of the fleet, well supplied at St. John's with fish and other necessaries, Gilbert (August 20) sailed south as far as forty-four degrees north latitude. Off Sable Island a storm assailed them, and the largest of the vessels, called the Delight, carrying most of the provisions, was driven on a rock and went to pieces. [Excerpt from "*Abraham Lincoln: A History*" by John Nicolay and John Hay.]	The people who left their countries and sailed with Gilbert were more suited for fighting the crusades than for leading a settled life in the colonies. They were bitterly disappointed as it was not the America that they had expected. Since they did not immediately find gold and silver mines, many deserted. At one stage, there were not even enough man to help sail the four ships. So the Swallow was sent back to England carrying the sick. The other fleet was supplied with fish and the other necessities from St. John. On August 20, Gilbert had sailed as far as forty-four degrees to the north latitude. His ship known as the Delight, which bore all the required supplies, was attacked by a violent storm near Sable Island. The storm had driven it into a rock shattering it into pieces.

Table 4: Examples of the obfuscation strategies.

Obfuscation Examples
Original Text
The quick brown fox jumps over the lazy dog.
Manual Obfuscation (by a human)
Over the dog which is lazy jumps quickly the fox which is brown. Dogs are lazy which is why brown foxes quickly jump over them. A fast auburn vulpine hops over an idle canine.
Random Text Operations
over The. the quick lazy dog <*context word*> jumps brown fox over jumps quick brown fox The lazy. the brown jumps the. quick dog The lazy fox over
Semantic Word Variation
The quick brown dodger leaps over the lazy canine. The quick brown canine jumps over the lazy canine. The quick brown vixen leaps over the lazy puppy.
POS-preserving Word Shuffling
The brown lazy fox jumps over the quick dog. The lazy quick dog jumps over the brown fox. The brown lazy dog jumps over the quick fox.

- *POS-preserving Word Shuffling.* The sequence of parts of speech in s_{src} is determined and s_{plg} is created by shuffling words at random while retaining the original POS sequence.

To generate different degrees of obfuscation the strategies can be adjusted by varying the number of operations made on s_{src}, and by limiting the range of affected phrases within s_{src}. For our corpus, the strategies were combined and adjusted to match an intuitive understanding of a "low" and a "high" obfuscation. Of course other obfuscation strategies are conceivable, e.g., based on automatic paraphrasing methods [4], but for performance reasons simple strategies are preferred at the expense of readability of the obfuscated text.

3.4 Overview of the PAN-PC-10

To compile the PAN plagiarism corpus 2010, several other parameters besides the above plagiarism obfuscation methods have been varied. Table 5 gives an overview.

The documents used in the corpus are derived from books from the Project Gutenberg.[2] Every document in the corpus serves one of two purposes: it is either used as a source for plagiarism or as a document suspicious of plagiarism. The latter documents divide into documents that actually contain plagiarism and documents that don't.

[2] http://www.gutenberg.org

Table 5: Corpus statistics of the PAN-PC-10 for its 27 073 documents and 68 558 plagiarism cases.

Document Statistics	
Document Purpose	
source documents	50%
suspicious documents	
– with plagiarism	25%
– w/o plagiarism	25%
Intended Algorithms	
external detection	70%
intrinsic detection	30%
Plagiarism per Document	
hardly (5%-20%)	45%
medium (20%-50%)	15%
much (50%-80%)	25%
entirely (>80%)	15%
Document Length	
short (1-10 pp.)	50%
medium (10-100 pp.)	35%
long (100-1000 pp.)	15%

Plagiarism Case Statistics	
Topic Match	
intra-topic cases	50%
inter-topic cases	50%
Obfuscation	
none	40%
artificial	
– low obfuscation	20%
– high obfuscation	20%
simulated (AMT)	6%
translated ({de,es} to en)	14%
Case Length	
short (50-150 words)	34%
medium (300-500 words)	33%
long (3000-5000 words)	33%

The documents without plagiarism allow to determine whether or not a detector can distinguish plagiarism cases from overlaps that occur naturally between random documents.

The corpus is split into two parts, corresponding to the two paradigms of plagiarism detection, namely external plagiarism detection and intrinsic plagiarism detection. Note that in the case of intrinsic plagiarism detection the source documents used to generate the plagiarism cases are omitted: intrinsic detection algorithms are expected to detect plagiarism in a suspicious document by analyzing the document in isolation. Moreover, the intrinsic plagiarism cases are not obfuscated in order to preserve the writing style of the original author; the 40% of unobfuscated plagiarism cases in the corpus include the 30% of the cases belonging to the intrinsic part.

The fraction of plagiarism per document, the lengths of the documents and plagiarism cases, and the degree of obfuscation per case determine the difficulty of the cases: the corpus contains short documents with a short, unobfuscated plagiarism case, resulting in a 5% fraction of plagiarism, but it also contains large documents with several obfuscated plagiarism cases of varying lengths, drawn from different source documents and resulting in fractions of plagiarism up to 100%. Since the true distributions of these parameters in real plagiarism are unknown, sensible

estimations were made for the corpus. E.g., there are more simple plagiarism cases than complex ones, where "simple" refers to short cases, hardly plagiarism per document, and less obfuscation.

Finally, plagiarism cases were generated between topically related documents and between unrelated documents. To this end, the source documents and the suspicious documents were clustered into $k = 30$ clusters using bisecting k-means [22]. Then an equal share of plagiarism cases were generated for pairs of source documents and suspicious documents within as well as between clusters. Presuming the clusters correspond to (broad) topics, we thus obtained intra-topic plagiarism and inter-topic plagiarism.

4 Corpus Validation

This section reports on validation results about the "quality" of the plagiarism cases created for our corpus. We compare both artificial plagiarism cases and simulated plagiarism cases to cases of the two corpora Clough09 and METER. Presuming that the authors of these corpora put their best efforts into case construction and annotation, the comparison gives insights whether our scale-up strategies are reasonable in terms of case quality. To foreclose the results, we observe that simulated plagiarism and, in particular, artificial plagiarism behave similar to the two handmade corpora. In the light of the employed strategies to construct plagiarism this result may or may not be surprising—however, we argue that it is necessary to run such a comparison in order to provide a broadly accepted evaluation framework in this sensitive area.

The experimental setup is as follows: given a plagiarism case $s = \langle s_{\text{plg}}, d_{\text{plg}}, s_{\text{src}}, d_{\text{src}} \rangle$, the plagiarized passage s_{plg} is compared to the source passage s_{src} using 10 different retrieval models. Each model is an n-gram vector space model (VSM) where n ranges from 1 to 10 words, employing stemming, stop word removal, tf-weighting, and the cosine similarity. Similarity values are computed for all cases found in each corpus, but since the corpora are of different sizes, 100 similarities are sampled from each corpus to ensure comparability.

The rationale of this setup is as follows: a well-known fact from near-duplicate detection is that if two documents share only a few 8-grams—so-called shingles—it is highly probable that they are duplicates [5]. Another well-known fact is that two documents which are longer than a few sentences and which are exactly about the same topic will, with a high probability, share a considerable portion of their vocabulary. I.e., they have a high

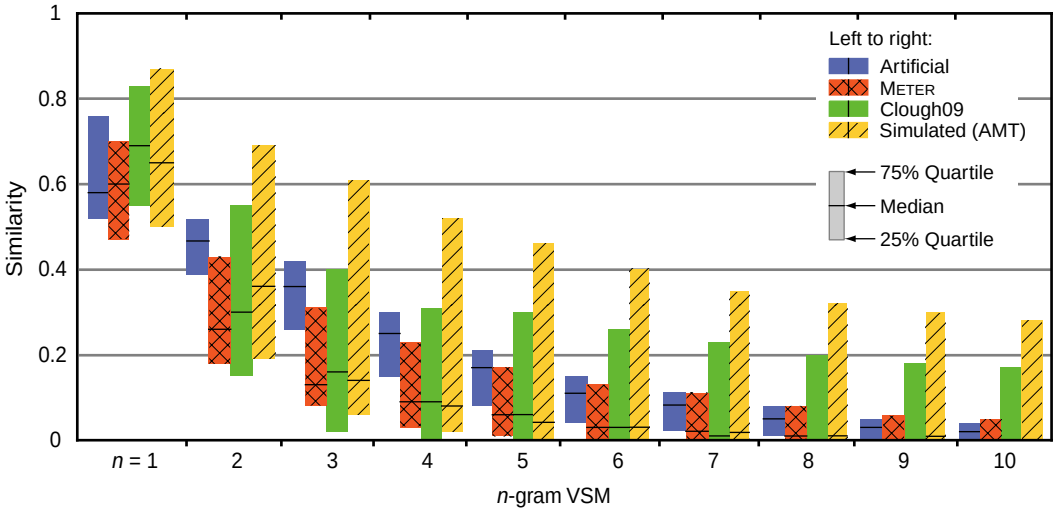

Figure 1: Comparison of four corpora of text reuse and plagiarism: each box plot shows the middle range of the measured similarities when comparing source passages to their rewritten versions. Basis is an n-gram VSM, where $n \in \{1, 2, \ldots, 10\}$ words.

similarity under a 1-gram VSM. It follows for plagiarism detection that a common shingle between s_{plg} and s_{src} pinpoints very accurately an unobfuscated portion of s_{plg}, while it is inevitable that even a highly obfuscated s_{plg} will share a portion of its vocabulary with s_{src}. The same holds for all other kinds of text reuse.

Figure 1 shows the obtained similarities, contrasting each n-gram VSM and each corpus. The box plots show the middle 50% of the respective similarity distributions as well as median similarities. The corpora divide into groups with comparable behavior: in terms of the similarity ranges covered, the artificial plagiarism compares to the METER corpus, except for $n \in \{2, 3\}$, while the simulated plagiarism from the Clough09 corpus behaves like that from our corpus, but with a different amplitude. In terms of median similarity, METER, Clough09, and our simulated plagiarism behave almost identical, while the artificial plagiarism differs. Also note that our simulated plagiarism as well as the Clough09 corpus contain some cases which are hardly obfuscated.

We interpret these results as follows: (1) Different kinds of plagiarism and text reuse do not differ very much under n-gram models. (2) Artificial plagiarism, if carefully generated, is a viable alternative to simulated plagiarism cases and real text reuse cases. (3) Our strategies to scale-up the construction of plagiarism corpora works well compared to existing, handmade corpora.

5 Summary

Current evaluation methodologies in the field of plagiarism detection research have conceptual shortcomings and allow only for a limited comparability. Our research contributes right here: we present tailored performance measures for plagiarism detection and the large-scale corpus PAN-PC-10 for the controlled evaluation of detection algorithms. The corpus features various kinds of plagiarism cases, including obfuscated cases that have been generated automatically and manually. An evaluation of the corpus in relation to previous corpora reveals a high degree of maturity. Until now, 31 plagiarism detectors have been compared using our evaluation framework. This high number of systems has been achieved based on two benchmarking workshops in which the framework was employed and developed, namely PAN'09 [15] and PAN'10 [16]. We hope that our framework will be beneficial as a challenging and yet realistic test bed for researchers in order to pinpoint the room for the development of better plagiarism detection systems.

Acknowledgements

We thank Andreas Eiselt for his devoted work on the corpus over the past two years. This work is partially funded by CONACYT-Mexico and the MICINN project TEXT-ENTERPRISE 2.0 TIN2009-13391-C04-03 (Plan I+D+i).

Expressing OWL axioms by English sentences: dubious in theory, feasible in practice

Abstract

With OWL (Web Ontology Language) established as a standard for encoding ontologies on the Semantic Web, interest has begun to focus on the task of verbalising OWL code in controlled English (or other natural language). Current approaches to this task assume that axioms in OWL can be mapped to sentences in English. We examine three potential problems with this approach (concerning logical sophistication, information structure, and size), and show that although these could in theory lead to insuperable difficulties, in practice they seldom arise, because ontology developers use OWL in ways that favour a transparent mapping. This result is evidenced by an analysis of patterns from a corpus of over 600,000 axioms in about 200 ontologies.

1 Introduction

Since the adoption of OWL (Web Ontology Language) as a standard in 2004, several research groups have explored ways of mapping between OWL and controlled English, with the aim of presenting ontologies (both for viewing and editing) in natural language (Schwitter and Tilbrook, 2004; Kaljurand and Fuchs, 2007; Funk et al., 2007; Hart et al., 2008); this task has been called ontology 'verbalisation' (Smart, 2008). To develop generic methods for ontology verbalisation, some kind of structural mapping is needed between the formal and natural languages, and the assumption generally adopted has been a three-tier model in which identifiers for atomic terms (e.g., individuals, classes, properties) map to lexical entries, single axioms map to sentences, and groups of related axioms map to higher textual units such as paragraphs and sections. The purpose of this paper is to look in detail at one level of this model, the realisation of axioms by sentences, and to check its feasibility through an analysis of a large corpus of ontologies.

The input to a verbaliser is a file in one of the standard formats such as OWL/RDF or OWL/XML, containing axioms along with supporting statements such as annotations. As examples of the nature of the input, table 1 shows three axioms in OWL/XML format; without any attempt at aggregation or pronominalisation, they could be realised by the following sentences[1]:

> Horatio Nelson is an admiral.
>
> Horatio Nelson is the victor of the Battle of Trafalgar.
>
> Every admiral is commander of a fleet.

Without attempting anything like a full description of OWL, it will be useful to look more closely at the structure of these expressions. Note first that they are essentially in functor-argument form[2]. In the first axiom, for example, there is a functor called *ClassAssertion* with two arguments, one a class and the other an individual; the meaning of the axiom is that the individual belongs to the class. The second functor (*ObjectPropertyAssertion*) requires instead three arguments,

[1] Note that one limitation of OWL is that at present it contains no treatment of time; we therefore have to fall back on the historical present.

[2] In fact, there is an alternative format called OWL Functional Syntax in which, for example, the first axiom would be represented by a predication of the form `ClassAssertion(X,Y)`.

Coling 2008: Poster Volume, pages 1006–1013,
Beijing, August 2010

```
<ClassAssertion>
  <Class IRI="http://www.example.org#admiral"/>
  <NamedIndividual IRI="www.example.org#HoratioNelson"/>
</ClassAssertion>

<ObjectPropertyAssertion>
  <ObjectProperty IRI="http://www.example.org#victorOf"/>
  <NamedIndividual IRI="http://www.example.org#HoratioNelson"/>
  <NamedIndividual IRI="http://www.example.org#BattleOfTrafalgar"/>
</ObjectPropertyAssertion>

<SubClassOf>
  <Class IRI="http://www.example.org#admiral"/>
  <ObjectSomeValuesFrom>
    <ObjectProperty IRI="http://www.example.org#commanderOf"/>
    <Class IRI="http://www.example.org#fleet"/>
  </ObjectSomeValuesFrom>
</SubClassOf>
```

Table 1: Examples of axioms in OWL/XML

and describes a relation (in OWL these are called 'properties') holding between two individuals; the third (*SubClassOf*) requires two arguments, both classes, and asserts that the first class is a subclass of the second.

Turning to the structure of the arguments, there are two possibilities: either the argument is *atomic*, in which case it will be represented by an identifier (or a literal if it is a data value), or it is *complex*, in which case it will be represented by an OWL functor with arguments of its own. Most of the arguments in table 1 are atomic, the sole exception being the second argument of *SubClassOf*, which denotes a complex class meaning 'someone that is commander of a fleet'[3]. In general, then, the OWL functors denote *logical* concepts such as class membership and class inclusion, while atomic terms denote domain-specific concepts such as *Nelson* and *admiral*. A fundamental design decision of the Semantic Web is that logical concepts are standardised, while domain concepts are left open: ontology developers are free to name the class *admiral* in any way they please, provided that the identifier takes the form of an IRI (Internationalized Resource Identifier).

Given this distinction, the obvious strategy to follow in developing a verbaliser is to divide linguistic resources into two parts: (a) a generic set of rules for realising logical expressions (based on standardised OWL functors); (b) a domain-specific lexicon for realising atomic individuals, classes and properties. This obviously raises the problem of how to acquire the specialised lexicons needed for each ontology. All else failing, these would have to be crafted by hand, but provided that we are not too concerned about text quality, a provisional lexicon can often be derived automatically from internal evidence within the ontology (i.e., either from identifier names or annotation labels)[4].

Assuming that a lexicon for atomic terms can be obtained (by fair means or foul), there remains a question of whether we can find sentence patterns which provide understandable realisations of the logical patterns determined by (possibly nested) OWL functors. In section 2 we show that this is not guaranteed, for three reasons. First, there may be OWL functors that represent *logically sophisticated* concepts which cannot be expressed in non-technical English. Secondly, an OWL axiom may be hard to verbalise because it lacks the right kind of *information structure* (i.e., because it fails to make a statement about a recognisable topic such as an individual or atomic class). Finally, since arguments can be nested indefinitely, an axiom might contain so much *se-*

[3]To be more precise we should say 'someone that is commander of one or more fleets'; this kind of trade-off between elegance and precision often arises in systems that verbalise formal languages.

[4]We have discussed elsewhere whether phrases derived in this way provide suitable lexicalisations (Power, 2010), but this topic lies outside the scope of the present paper.

mantic complexity that it cannot be compressed clearly into a single sentence. We then describe (section 3) an empirical analysis of axiom patterns from about 200 ontologies, which investigates whether these potential problems are common in practice. Section 4 discusses the results, and section 5 concludes.

2 Potential problems in verbalising axioms

2.1 Logical sophistication

We show in table 2 the 16 most commonly used OWL functors for expressing axioms, each accompanied by a simple English sentence illustrating what the functor means. As will be seen, the functors divide into two groups. For those in the upper segment, it is relatively easy to find English constructions that realise the logical content of the axiom — assuming we have suitable lexicalisations of the atomic terms. For those in the lower segment, finding a good English realisation is harder, since statements describing properties are normally found only in the rarified worlds of mathematics and logic, not in everyday discourse. Our attempts to verbalise these axioms are accordingly clumsy (e.g., through resorting to variables like X and Y), and not even entirely precise (e.g., the sentence for *FunctionalObjectProperty* should really specify 'For any X...'); perhaps the reader can do better.

Does this mean that our aim of realising OWL axioms in non-technical English is doomed? We would argue that this depends on how the axioms describing properties are used in practice. First, for any difficult axiom functor, it is important to consider its frequency. If it turns out that a functor accounts for (say) only one axiom in every thousand, then it will give rise only to the occasional clumsy sentence, not a text that is clumsy through and through. Second, it is important to take account of argument complexity. If a functor is used invariably with atomic terms as arguments, then the sentence expressing it will contain only one source of complexity — logical sophistication; if instead the functor has non-atomic arguments, this additional strain might push it over a threshold from difficult to incomprehensible. Fortunately, OWL syntax requires that all property arguments for the difficult functors are atomic — for *FunctionalObjectProperty*, for instance, the argument cannot be a complex property expression. For statements about domains and ranges, however, class arguments can be non-atomic, so here a complexity issue might arise.

2.2 Information structure

We learn at school that sentences have a subject (preferably simple) and predicate (relatively complex), the purpose of the predicate being to say something about the subject. This rather simplified idea is developed technically in work on information structure (Kruijff-Korbayová and Steedman, 2003) and centering theory (Walker et al., 1998). Is there any equivalent to this topic-comment distinction in OWL? Formally speaking, one would have to answer in the negative. The two-argument functor *SubClassOf*, for example, can have class expressions of any complexity in either argument position, and there is no logical reason to claim that it is 'about' one of these classes rather than the other. This is still clearer in the case of *EquivalentClasses*, where the functor is commutative (so that switching the arguments leaves the meaning unchanged). Again there seems to be a difficulty here — and again we argue that this difficulty might disappear, or at least diminish, if we consider how OWL is used in practice.

Suppose, for instance, that although OWL syntax allows indefinitely complex arguments in either position for the *SubClassOf* functor, in practice users invariably construct axioms in which the first argument is an atomic term, with complex expressions occurring (if at all) only in second-argument position. This would strongly suggest, in our view, that developers are assigning a topic-comment structure to the two arguments, with the first expressing the topic and the second expressing the comment. As we will show later in the paper, this pattern is found overwhelmingly — so much so that in a sample of nearly half a million *SubClassOf* axioms, fewer than 1000 instances (0.2%) were found of non-atomic first arguments.

Functor	Example
SubClassOf	Every admiral is a sailor
EquivalentClasses	An admiral is defined as a person that commands a fleet
DisjointClasses	No sailor is a landlubber
ClassAssertion	Nelson is an admiral
ObjectPropertyAssertion	Nelson is victor of the Battle of Trafalgar
DataPropertyAssertion	The Battle of Trafalgar is dated 1805
ObjectPropertyDomain	If X commands Y, X must be a person
ObjectPropertyRange	If X commands Y, Y must be a fleet
SubObjectPropertyOf	If X is a child of Y, X must be related to Y
InverseObjectProperties	If X is a child of Y, Y must be a parent of X
TransitiveObjectProperty	If X contains Y and Y contains Z, X must contain Z
FunctionalObjectProperty	There can be only one Y such that X has as father Y
DataPropertyDomain	If X is dated Y, X must be an event
DataPropertyRange	If X is dated Y, Y must be an integer
SubDataPropertyOf	If X occurs during Y, X must be dated Y
FunctionalDataProperty	There can be only one Y such that X is dated Y

Table 2: Meanings of OWL functors

2.3 Semantic complexity

When encoding knowledge in description logic, developers have considerable freedom in distributing content among axioms, so that axiom size is partly a matter of style — rather like sentence length in composing a text. Development tools like Protégé (Rector et al., 2004) support *refactoring* of axioms, so that for example any axiom of the form $C_A \sqsubseteq C_S \sqcap C_L$ (e.g., 'Every admiral is a sailor and a leader') can be split into two axioms $C_A \sqsubseteq C_S$ and $C_A \sqsubseteq C_L$ ('Every admiral is a sailor. Every admiral is a leader.'), or vice-versa[5]. Indeed, it can be shown that *any* set of *SubClassOf* axioms can be amalgamated into a single axiom (Horrocks, 1997) of the form $\top \sqsubseteq M$, where $\top$ is the class containing all individuals in the domain, and M is a class to which any individual respecting the axiom set must belong[6]. Applying this transformation to just two axioms already yields an amalgam that will perplex most readers:

> Every admiral is a sailor
> Every admiral commands a fleet.
>
> Everything is (a) either a non-admiral or a sailor, and (b) either a non-admiral or something that commands a fleet.

There is thus no guarantee that an axiom in OWL can be verbalised transparently by a single sentence; in theory it could contain as much knowledge as a textbook. As before, we have to appeal to practice. Do ontology developers distribute content among knowledge units (axioms) equivalent in size to sentences? If they (almost always) do, then our approach is worth pursuing; if not, we have to reconsider.

3 Method

To investigate the issues of usage just described, we have analysed axiom patterns in a large corpus of ontologies of varying subject-matter and provenance. The corpus was based on the TONES Ontology Repository (TONES, 2010), which is a searchable database of RDF/XML ontologies from a range of sources. The repository is intended to be useful to developers of tools to work with ontologies, and as such represents a wide range of ontology kinds and features. It also classifies ontologies by 'expressivity' — the weakest description logic necessary to express every axiom. While the TONES site itself acknowledges that the expressivity categorisation is only a guideline, it can serve as a rough guide for comparison with the pattern frequency analysis carried out here.

The whole repository was downloaded, comprising 214 files each containing between 0 and 100726 logical axioms[7]. (Note that an OWL

[5]The symbols $\sqsubseteq$ and $\sqcap$ in logical notation correspond to the OWL functors *SubClassOf* and *ObjectIntersectionOf*.

[6]This all-embracing axiom or 'meta-constraint' is computed by the standard description logic reasoning algorithms when determining the consistency of a knowledge base.

[7]A few of the ontologies in the TONES repository were excluded, either because of syntax errors in the original files (2-3 files), or because they exceeded our processing limits —

file may contain no logical axioms and still be non-empty.) To develop quickly a program that could cope with the larger ontologies without memory problems, we used the Java-based OWL API (Horridge and Bechhofer, 2010) as much as possible, in conjunction with standard Unix text-processing tools ('grep', 'sed' and 'awk' (Dougherty and Robbins, 1997)) for pattern recognition[8].

Each ontology was converted into OWL Functional Syntax (Motik et al., 2010) and lists were automatically generated of the identifiers it contains — classes, named individuals, properties, and so on. The Unix tools were scripted to replace every occurrence of such an identifier with a string representing its type. This process generated a new file in which every axiom of the original ontology had been replaced with a string representing its logical structure: thus *SubClassOf(Admiral, Sailor)* and *SubClassOf(Sailor, Person)* would each have been replaced with *SubClassOf(Class, Class)*. The number of occurrences of each unique pattern was then counted and the results converted into a set of Prolog facts for further analysis. Some manual tidying-up of the data was necessary in order to correct some complex cases such as quoted string literals which themselves contained (escaped) quoted strings; however, these cases were so rare that any remaining errors should not adversely affect output quality.

4 Results

To address the issue of *logical sophistication*, we first calculated frequencies for each axiom functor, using two measures: (a) the number of ontologies in which the functor was used at least once, and (b) the number of axioms using the functor overall. The former measure (which we will call 'ontology frequency') is a useful corrective since a simple axiom count can be misleading when a functor is used profusely in a few very large ontologies, but rarely elsewhere. The results are presented in table 3, ordered by ontology frequency rather than overall axiom frequency[9]. As can be seen, the ten functors classified as logically sophisticated in table 2 are relatively rare, by both measures, accounting overall for just 2.2% of the axioms in the corpus, with none of them having a frequency reaching even 5 in 1000.

Next, to address *information structure*, we looked at the argument patterns for each axiom functor, distinguishing three cases: (a) all arguments simple (i.e., atomic); (b) all arguments complex (non-atomic); (c) mixed arguments (some atomic, some non-atomic). This comparison is relevant only for the functors *SubClassOf*, *EquivalentClasses* and *DisjointClasses*, for which OWL syntax allows multiple non-atomic arguments. The results (table 4) show a clear preference for patterns in which at least one argument is simple. Thus for *SubClassOf*, given the overall frequencies of simple and complex arguments for this functor, the expected frequency for the combination Complex-Complex would be 12606 (2.7%), whereas the observed frequency was only 978 (0.2%) (χ^2 = 16296 with df=2, $p < 0.0001$)[10]. The corresponding result for *EquivalentClasses* is even clearer, with not a single instance of an axiom in which all arguments are complex, against an expected frequency of 973 (16.0%) (χ^2 = 2692 with df=2, $p < 0.0001$)[11]. For *DisjointClasses* no complex arguments were obtained, so the only possible combination was 'All Simple'. Overall, 99.8% of axioms for these three functors contained at least one atomic term, suggesting that the arguments were interpreted according to intuitions of information structure, with one atomic argument serving as the topic. This point is reinforced by our next analysis, which considers detailed argument patterns.

e.g., the Foundational Model of Anatomy (Rosse and Mejino, 2003).

[8] A pure Java solution was not practical in the time available since the OWL API was designed to support reasoning and evaluation of OWL ontologies rather than syntactic analysis of their axioms. We hope to produce an extension of the OWL API to support straightforward and portable analysis of ontologies in the future.

[9] Note that the total in the first column of table 3 is simple the number of ontologies in our sample; the sum of the frequencies in the column is of no interest at all.

[10] The data for this test, with expected values in brackets, are SS = 297293 (312138), CC = 978 (12606), and SC = 170541 (144068), where S means 'Simple' and C means 'Complex'.

[11] The data for this test, with expected values in brackets, are SS = 1222 (2190), CC = 0 (973), and SC = 4860 (2919), where again S means 'Simple' and C means 'Complex'.

Functor	Ontology Frequency	Percent	Axiom Frequency	Percent

Table 5: Frequencies for OWL Functor-Argument patterns

Finally, to address *semantic complexity* (i.e., axiom size), we counted the frequencies of detailed argument patterns, abstracting from atomic terms as explained in section 3. The results (ordered by pattern frequency) are presented in table 5, which reveals several clear trends:

- A small number of patterns covers most of the axioms in the corpus. Thus the top five patterns cover 91.9% of the axioms, the top 10 cover 95.8%, and the top 20 cover 97.2%.
- All of the frequent patterns (i.e., the top 20) can be expressed by a single sentence without problems of semantic complexity arising from size. The most complex is the *EquivalentClasses* pattern (number 10 in the list), but this can be realised comfortably by a sentence following the classical Aristotelian pattern for a definition — e.g., 'An admiral is defined as a person that commands a fleet'.
- None of the first ten patterns employs the axiom functors previously classified as logically sophisticated (bottom half of table 2).
- In the patterns where one argument is simple and the other is complex (i.e., *SubClassOf* and *EquivalentClasses*), the simple argument invariably comes first, supporting the intuition that developers conceptualise these statements in subject-predicate form, with (simple) topic preceding (possibly complex) comment.
- Among the frequent patterns, different functors have distinctive argument preferences. For instance, for *SubClassOf* most axioms have atomic arguments, presumably because it is through this functor that the class hierarchy is specified. For *EquivalentClasses*, instead, the Aristotelean definition pattern is by far the most frequent, although all-atomic arguments are occasionally employed (0.2% of axioms) to show that two class terms are synonymous.

5 Conclusion

Our analysis of over 600,000 axioms from 203 ontologies provides empirical support for the assumption that in practice OWL axioms can be transparently expressed by English sentences. In principle, as we have seen, OWL syntax grants users the freedom to construct axioms that would defeat this assumption entirely, either by concentrating too much semantic content into a single axiom, or by filling all argument positions by complex expressions that are unsuited to fulfilling the role of topic; it also allows logically sophisticated statements about properties, which would lead to impossibly clumsy texts if they occurred too often, or were exacerbated by complex arguments. In practice, if our sample is typical, none of these problems seems to arise, and we think it would be a fair summary of our results to say that ontology developers treat OWL axioms by analogy with sentences, by assigning a clear information structure (so that one atomic argument is identified with the topic) and including only an appropriate amount of content.

Having identified a relatively small set of common axiom patterns, it is obviously interesting to consider how each pattern can best be expressed in a given natural language. Considering the pattern *SubClassOf(Class,Class)* for instance (47% of all axioms), one could weigh the relative merits of 'Every admiral is a sailor', 'All admirals are sailors', 'Admirals are sailors', 'If X is an admiral, then X must be a sailor', and so forth. To address this issue we are planning a quite different kind of empirical study on how various sentence patterns are interpreted by human readers; by highlighting the logical patterns that occur most often in practice, the results reported here will help set the parameters for such an investigation.

Acknowledgments

The research described in this paper was undertaken as part of the SWAT project (Semantic Web Authoring Tool), which is supported by the UK Engineering and Physical Sciences Research Council (EPSRC) grants G033579/1 (Open University) and G032459/1 (University of Manchester). We thank the anonymous reviewers and our colleagues on the SWAT project for their comments.

Abstract

We go beyond simple propositional meaning extraction and present experiments in determining which propositions in text the author believes. We show that deep syntactic parsing helps for this task. Our best feature combination achieves an F-measure of 64%, a relative reduction in F-measure error of 21% over not using syntactic features.

1 Introduction

Recently, interest has grown in relating text to more abstract representations of its propositional meaning, as witnessed by work on semantic role labeling, word sense disambiguation, and textual entailment. However, there is more to "meaning" than just propositional content. Consider the following examples, and suppose we find these sentences in the *New York Times*:

(1) a. *GM will lay off workers.*

b. *A spokesman for GM said GM will lay off workers.*

c. *GM may lay off workers.*

d. *The politician claimed that GM will lay off workers.*

e. *Some wish GM would lay of workers.*

f. *Will GM lay off workers?*

g. *Many wonder if GM will lay off workers.*

If we are searching text to find out whether GM will lay off workers, all of the sentences above contain the proposition LAY-OFF(GM,WORKERS). However, they allow us very different inferences about whether GM will lay off workers or not. Supposing we consider the *Times* a trustworthy news source, we would be fairly certain if we read (1a) and (1b). (1c) suggests the *Times* is not certain about the layoffs, but considers them possible. When reading (1d), we know that someone else thinks that GM will lay off workers, but that the *Times* does not necessarily share this belief. (1e), (1f), and (1g) do not tell us anything about whether anyone believes whether GM will lay off workers.

In order to tease apart what is happening, we need to abandon a simple view of text as a repository of propositions about the world. We use two assumptions to aid us. The first assumption is that discourse participants model each other's cognitive state during discourse (we take the term to include the reading of monologic written text), and that language provides cues for the discourse participants to do the modeling. This assumption is commonly made, for example by Grice (1975) in his Maxim of Quantity. Following the literature in Artificial Intelligence (Bratman, 1999; Cohen and Levesque, 1990), we model cognitive state as beliefs, desires, and intentions. Crucially, these three dimensions are orthogonal; for example, we can desire something but not believe it.

(2) I know John won't be here, but I wouldn't mind if he were

However, we cannot both believe something and not believe it:

(3) #John won't be here, but nevertheless I think he may be here

Note that (2) requires *but* in order to be felicitous, but sentence (3) cannot be "saved" by any discourse markers – it is not interpretable. In this paper, we are interested in beliefs (and in distin-

Coling 2008: Poster Volume, pages 1014–1022,
Beijing, August 2010

guishing them from desires and intentions).

The second assumption is that communication is intention-driven, and understanding text actually means understanding the communicative intention of the writer. Furthermore, communicative intentions are intentions to affect the reader's cognitive state – his or her beliefs, desires, and/or intentions. This view has been adopted in the text generation and dialog community more than in the information extraction and text understanding communities (Mann and Thompson, 1987; Hovy, 1993; Moore, 1994; Bunt, 2000; Stone, 2004). In this paper we explore the following: we would like to recognize what the writer of the text intends the reader to believe about various people's beliefs about the world (including the writer's own). In this view, the result of text processing is not a list of facts about the world, but a list of facts about different people's cognitive states. In this paper, we limit ourselves to the writer's beliefs, but we specifically want to determine which propositions he or she intends us to believe he or she holds as beliefs, and with what strength. The result of such processing will be a much more fine-grained representation of the information contained in written text than has been available so far.

2 Belief Annotation and Data

We use a corpus of 10,000 words annotated for speaker belief of stated propositions (Diab et al., 2009). The corpus is very diverse in terms of genre, and it includes newswire text, email, instructions, and solicitations. The corpus annotates each verbal proposition (clause or small clause), by attaching one of the following tags to the head of the proposition (verbs and heads of nominal, adjectival, and prepositional predications).

• Committed belief (CB): the writer indicates in this utterance that he or she believes the proposition. For example, *GM has laid off workers*, or, even stronger, *We know that GM has laid off workers*. Committed belief can also include propositions about the future: people can have equally strong beliefs about the future as about the past, though in practice probably we have stronger beliefs about the past than about the future.

• Non-committed belief (NCB): the writer identifies the proposition as something which he or she could believe, but he or she happens not to have a strong belief in. There are two subcases. First, the writer makes clear that the belief is not strong, for example by using a modal auxiliary epistemically: *GM may lay off workers*. Second, in reported speech, the writer is not signaling to the reader what he or she believes about the reported speech: *The politician claimed that GM will lay off workers*. Again, the issue of tense is orthogonal.

• Not applicable (NA): for the writer, the proposition is not of the type in which he or she is expressing a belief, or could express a belief. Usually, this is because the proposition does not have a truth value in this world (be it in the past or in the future). This covers expressions of desire (*Some wish GM would lay of workers*), questions (*Will GM lay off workers?*), and expressions of requirements (*GM is required to lay off workers* or *Lay off workers!*).

All propositional heads are classified as one of the classes CB, NCB, or NA, and all other tokens are classified as O. Note that in this corpus, event nominals (such as *the lay-offs by GM were unexpected*) are, unfortunately, not annotated for belief and are always marked "O". Note also that the syntactic form does not determine the annotation, but the perceived writer's intention – a question will usually be an NA, but sometimes a question can be used to convey a belief (for example, a rhetorical question), in which case it would be labeled CB.

3 Automatic Belief Tagging

3.1 Approach

We applied a supervised learning framework to the problem of identifying committed belief in context. Our task consists of two conceptual subtasks: identifying the propositions, and classifying each proposition as CB, NCB, or NA. For the first subtask, we could use a system that cuts a sentence into propositions, but we are not aware of such a system that performs at an adequate level. Instead, we tag the heads of the proposition, which amounts to the same in the sense that there is a bijection between propositions and their heads. Practically, we have the choice between

No	Feature	Type	Description
Features that performed well			
1	isNumeric	L	Word is Alphabet or Numeric?
2	POS	L	Word's POS tag
3	verbType	L	Modal/Aux/Reg (= 'nil' if the word is not a verb)
4	whichModalAmI	L	If I am a modal, what am I? (= 'nil' if I am not a modal)
3	amVBwithDaughterTo	S	Am I a VB with a daughter *to*?
4	haveDaughterPerfect	S	Do I have a daughter which is one of *has, have, had*?
5	haveDaughterShould	S	Do I have a daughter *should*?
6	haveDaughterWh	S	Do I have a daughter who is one of *where, when, while, who, why*?
7	haveReportingAncestor	S	Am I a verb/predicate with an ancestor whose lemma is one of *tell, accuse, insist, seem, believe, say, find, conclude, claim, trust, think, suspect, doubt, suppose*?
8	parentPOS	S	What is my parent's POS tag?
9	whichAuxIsMyDaughter	S	If I have a daughter which is an auxiliary, what is it? (= 'nil' if I do not have an auxiliary daughter)
10	whichModalIsMyDaughter	S	If I have a daughter which is a modal, what is it? (= 'nil' if I do not have a modal daughter)
Features that were not useful			
1	Lemma	L	Word's Lemma
2	Stem	L	Word stem (Using Porter Stemmer)
3	Drole	S	Deep role (drole in MICA features)
4	isRoot	S	Is the word the root of the MICA Parse tree?
5	parentLemma	S	Parent word's Lemma
6	parentStem	S	Parent word stem (Using Porter Stemmer)
7	parentSupertag	S	Parent word's super tag (from Penn Treebank)
8	Pred	S	Is the word a predicate? (pred in MICA features)
9	wordSupertag	S	Word's Super Tag (from Penn Treebank)

Table 1: All Features Used

a joint model, in which the heads are chosen and classified simultaneously, and a pipeline model, in which heads are chosen first and then classified. In this paper, we consider the joint model in detail and in Section 3.5.3, we present results of the pipeline model; they support our choice.

In the joint model, we define a four-way classification task where each token is tagged as one of four classes – CB, NCB, NA, or O (nothing) – as defined in Section 2. For tagging, we experimented with Support Vector Machines (SVM) and Conditional Random Fields (CRF). For SVM, we used the YAMCHA(Kudo and Matsumoto, 2000) sequence labeling system,[1] which uses the TinySVM package for classification.[2] For CRF, we used the linear chain CRF implementation of the MALLET(McCallum, 2002) toolkit.[3]

3.2 Features

We divided our features into two types - Lexical and Syntactic. Lexical features are at the token level and can be extracted without any parsing with relatively high accuracy. We expect these features to be useful for our task. For example, isNumeric, which denotes whether the word is a number or alphabetic, is a lexical feature. Syntactic features of a token access its syntactic context in the dependency tree. For example, parentPOS, the POS tag of the parent word in the dependency parse tree, is a syntactic feature. We used the MICA deep dependency parser (Bangalore et al., 2009) for parsing in order to derive the syntactic features. We use MICA because we assume that the relevant information is the

[1] http://chasen.org/ taku/software/YAMCHA/

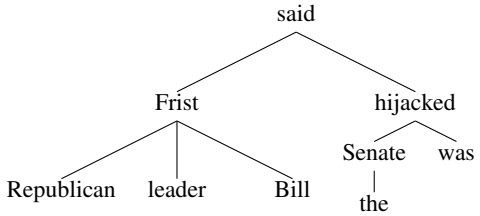
[2] http://chasen.org/ taku/software/TinySVM/

[3] http://MALLET.cs.umass.edu/

predicate-argument structure of the verbs, which is explicit in the MICA output. While it is clear that having a perfect parse would yield useful features, current parsers perform at levels of accuracy lower than that of part-of-speech taggers, so that it is not a foregone conclusion that using automatic parser output helps in our task.

The list of features we used in our experiments are summarized in Table 1. The column 'Type' denotes the type of the feature. 'L' stands for lexical features and 'S' stands for syntactic features.

The tree below shows the dependency parse tree output by MICA for the sentence *Republican leader Bill Frist said the Senate was hijacked*.



In the above sentence, *said* and *hijacked* are the propositions that should be tagged. Let's look at *hijacked* in detail. The feature haveReportingAncestor of *hijacked* is 'Y' because it is a verb with a parent verb *said*. Similarly, the feature haveDaughterAux would also be 'Y' because of daughter *was*, whereas whichAuxIsMyDaughter would get the value *was*.

We also considered several other features which did not yield good results. For example, the token's supertag (Bangalore and Joshi, 1999), the parent token's supertag, a binary feature isRoot (Is the word the root of the parse tree?) were deemed not useful. We list the features we experimented with and decided to discard in Table 1.

For finding the best performing features, we did an exhaustive search on the feature space, incrementally pruning away features that are not useful.

3.3 Experiments

This section describes different experiments we conducted in detail. It explains the experimental setup for both learning frameworks we used - YAMCHA and MALLET. We also explain the pipeline model in detail.

Class	Description
L_C	Lexical features with Context
$L_N S_N$	Lexical and Syntactic features with No-context
$L_C S_N$	Lexical features with Context and Syntactic features with No-context
$L_C S_C$	Lexical and Syntactic features with Context

Table 2: YAMCHA Experiment Sets

3.3.1 YAMCHA Experiments

We categorized our YAMCHA experiments into different experimental conditions as shown in Table 2. For each class, we did experiments with different feature sets and (linear) context widths. Here, context width denotes the window of tokens whose features are considered. For example, a context width of 2 means that the feature vector of any given token includes, in addition to its own features, those of 2 tokens before and after it as well as the tag prediction for 2 tokens before it. For $L_N S_N$, the context width of all features was set to 0. For $L_C S_N$, the context width of syntactic features alone was set to 0. A context width of 0 for a feature means that the feature vector includes that feature of the current token only. When context width was non-zero, we varied it from 1 to 5, and we report the results for the optimal context width.

We tuned the SVM parameters, and the best results were obtained using the *One versus All* method for multiclass classification on a quadratic kernel with a c value of 0.5. All results presented for YAMCHA here use this setting.

3.3.2 MALLET Experiments

Class	Description
L	Lexical features only
LS	Lexical and Syntactic features

Table 3: MALLET Experiment Sets

We categorized our MALLET experiments into two classes as shown in Table 3. We computed the features described in Section 3.2 at the token level and converted them to binary in order to use them for CRF. We experimented with varying orders and the best results were obtained for or-

Class	Feature Set	Parm	P	R	F
YAMCHA - Joint Model					
L_C	POS, whichModalAmI, verbType, isNumeric	CW=3	61.9	52.7	56.9
$L_N S_N$	POS, whichModalAmI, parentPOS, haveReportingAncestor, whichModalIsMyDaughter, haveDaughterPerfect, whichAuxIsMyDaughter, amVBwithDaughterTo, haveDaughterWh, haveDaughterShould	CW=0	62.5	57.5	59.9
$L_C S_N$	POS, whichModalAmI, parentPOS, haveReportingAncestor, whichModalIsMyDaughter, whichAuxIsMyDaughter, haveDaughterShould	CW=2	67.4	58.1	62.4
$L_C S_C$	POS, whichModalAmI, parentPOS, haveReportingAncestor, whichModalIsMyDaughter, haveDaughterPerfect, whichAuxIsMyDaughter, haveDaughterWh, haveDaughterShould	CW=2	68.5	60.0	64.0
MALLET - Joint Model					
L	POS, whichModalAmI, verbType	GV=1	55.1	45.0	49.6
LS	POS, whichModalAmI, parentPOS, haveReportingAncestor, whichModalIsMyDaughter, haveDaughterPerfect, whichAuxIsMyDaughter, haveDaughterWh, haveDaughterShould	GV=1	64.5	54.4	59.0
Pipeline Model					
$L_C S_C$	POS, whichModalAmI, parentPOS, haveReportingAncestor, whichModalIsMyDaughter, haveDaughterPerfect, whichAuxIsMyDaughter, haveDaughterWh, haveDaughterShould	CW=2	49.8	42.9	46.1

Table 4: Overall Results. CW = Context Width, GV = Gaussian Variance, P = Precision, R = Recall, F = F-Measure

der= "0,1", which makes the CRF similar to Hidden Markov Model. All results reported here use the order= "0,1". We also conducted experiments varying the Gaussian variance parameter from 1.0 to 10.0 using the same experimental setup (i.e. we did not have a distinct tuning corpus) and observed that best results were obtained with a low value of 1 to 3, instead of MALLET's default value of 10.0.

3.3.3 Pipeline Model

We also did experiments to support our choice of the joint model over the pipeline model. We chose the best performing feature configuration of the $L_C S_C$ class (which is the overall best performer as we present in Section 3.5), and set up the pipeline model. We trained a sequence classifier using YAMCHA to identify the head tokens, where tokens are tagged as just propositional heads without distinguishing between CB/NA/NCB. The predicted head tokens were then classified using a 3-Way SVM classifier trained on gold data.

3.4 Evaluation

For evaluation, we used 4-fold cross validation on the training data. The data was divided into 4 folds of which 3 folds were used to train a model which was tested on the 4th fold. We did this with all four configurations and all the reported results in this paper are averaged results across 4 folds. We report Recall and Precision on word tokens in our corpus for each of the three tags. It is worth noting that the majority of the words in our data will not be tagged with any of the three classes. (Recall that most words have neither of the three tags). We also report $F_{\beta=1}$ (F)-measure as the harmonic mean between (P)recision and (R)ecall.

3.5 Results

This section summarizes the results of various experiments we conducted. The best performing feature configuration and corresponding Precision, Recall and F-measure for each experimental setup discussed in previous section is presented in Table 4. The best F-measure for each category under various experimental setups is presented in Table 5.

We obtained the best performance using YAM-

Setup	Class	CB	NCB	NA
Joint-YAMCHA	L_C	61.5	15.2	63.2
Joint-YAMCHA	$L_N S_N$	67.0	28.3	59.9
Joint-YAMCHA	$L_C S_N$	67.6	33.2	64.5
Joint-YAMCHA	$L_C S_C$	69.6	34.1	64.5
Joint-MALLET	L	53.9	7.5	54.1
Joint-MALLET	LS	65.8	40.6	59.1
Pipeline	$L_C S_C$	55.2	16.5	51.3

Table 5: Results per Category (F-Measure)

CHA in a joint model. So, we first analyze this configuration in great detail in Section 3.5.1. We discuss results obtained using MALLET in Section 3.5.2 and the pipeline model in Section-3.5.3.

3.5.1 YAMCHA - Results

As described in Section 3.3.1, we divide our experiments into 4 classes - L_C, $L_N S_N$, $L_C S_N$ and $L_C S_C$. Table 4 presents the best performing feature sets and context width configuration for each class. For all experiments with context, the best result was obtained with a context width of 2, except for L_C, where a context width of 3 gave the best results. The results show that syntactic features improve the classifier performance considerably. The best model obtained for L_C has an F-measure of 56.9%. In $L_N S_N$ it improves marginally to 59.9%. Adding back context to lexical features improves it to 62.4% in $L_C S_N$ whereas addition of context to syntactic features further improves this to 64.0%. We observed that the feature parentPOS has the most impact on increased context widths, among syntactic features.

The improvement pattern of Precision and Recall across the classes is also interesting. Syntactic features with no context improve Recall by 4.8 percentage points over only lexical features with context, whereas Precision improves only by 0.6 points. However, adding back context to lexical features further improves Precision by 4.9 points while Recall just improves by 0.6 points. Finally, adding context of syntactic features improves both Precision and Recall moderately. We infer that syntactic features (without context) help identify more annotatable patterns thereby improving Recall, whereas linear context helps removing the wrong ones, thereby improving Precision.

The per-category F-measure results presented in Table 5 are also interesting. The CB F-measure improves by 8.1 points and NCB improves 18.9 points from L_C to $L_C S_C$. But, the improvement in NA F-measure is only a marginal 1.3 points between L_C and $L_C S_C$. Furthermore, the F-measure decreases by 3.3 points when syntactic and lexical features with no context are used. On analysis, we found that NAs often occur in syntactic structures like *want to find* or *should go* (deontic *should*), in which the relevant words occur in a small linear window. In contrast, NCBs are often signaled by deeper syntactic structures. For example, in *He said that his visit to the US will mainly focus on the humanitarian issues*, a simplified sentence from our training set, the verb *focus* is an NCB because it is in the scope of the reporting verb *said* (specifically, it is its daughter). This could not be captured using the context because *said* and *focus* are far apart in the sentence. But a correct parse tree gives *focus* as the daughter of *said*. So, a feature like haveReportingAncestor could easily capture this. It is also the case that the root of a dependency parse tree would mostly be a CB. This is captured by the feature parentPOS having value 'nil'. This property also cannot be captured by lexical features alone.

However, NCB performs much worse than the other two categories. NCB is a class which occurs rarely compared to CB and NA in our corpus. Out of the $1,357$ propositions tagged, only 176 were NCB. We assume that this could be a main factor of its poor performance.

We analyzed the performance across the folds. Fold-2 contains only 0.03% NCBs compared to 1.89% on the rest of the folds. Similarly, it contains 6.43% NAs compared to 3.82% across other folds. However, our best performing model gives a Recall of 59.1% with a Precision of 69.7% (F-measure 64.0%) for Fold-2, which is as good as other folds. Hence, we observe that our learned model is robust under distributional variations.

3.5.2 MALLET Results

As explained in Section 3.3.2, we explored MALLET-CRF using two experimental conditions L and LS. Table 4 presents the best performing feature sets for both classes. These re-

sults again show that syntactic features improve the classifier performance considerably. The best model obtained for L class has an F-measure of 49.6%, whereas addition of syntactic features improves this to 59.0%. Both Precision and Recall are improved by 9.4 percentage points as well.

However, MALLET-CRF's performance was comparatively worse than YAMCHA's SVM. The best model for MALLET (LS) obtained an F-measure of 59.0% which is 5.0 percentage points less than that of the best model for YAMCHA ($L_C S_C$).

It is interesting to note that MALLET performed well on predicting NCB. The highest NCB F-measure of MALLET - 40.6% is 6.5 percentage points higher than the highest NCB F-measure for YAMCHA. However, corresponding CB and NA F-measures were 61.2% and 56.1% which are much lower than YAMCHA's performance for these categories.

Also, MALLET was more time efficient than YAMCHA. On an average, for our corpus size and feature sets, MALLET ran 3 times as fast as YAMCHA in a cross validation setup (i.e. training and testing together).

3.5.3 Joint Model vs Pipeline Model

As discussed in Section 3.3.3, we set up a pipeline model for the best performing configuration of $L_C S_C$ class of YAMCHA experiments. The head prediction step of the pipeline obtained an F-measure of 83.9% with Precision and Recall of 86.7% and 81.2%, respectively, across all 4 folds. The 3-way classification step to classify the belief of the identified head obtained an accuracy of 72.7% across all folds. In the pipeline model, false positives and false negatives adds up from step 1 and step 2, where as only the true positives of step 2 is considered as the true positives overall. In this way, the overall Precision was only 49.8% and Recall was 42.9% with an F-measure of 46.1% as shown in Table 4. The results for CB/NCB/NA separately are given in Table 5. The per-category best F-measure was decreased by 14.4, 17.6 and 13.2 percentage points from the YAMCHA joint model for CB, NCB and NA, respectively. The performance gap is big enough to conclude that our choice of joint model was right.

4 Related Work

Our work falls in the rich tradition of modeling agents in terms of their cognitive states (for example, (Rao and Georgeff, 1991)) and relating this modeling to language use through extensions to speech act theory (for example, (Perrault and Allen, 1980; Clark, 1996; Bunt, 2000)). These notions have been particularly fruitful in the dialog community, where dialog act tagging is a major topic of research; to cite just one prominent example: (Stolcke et al., 2000). A dialog act represents the communicative intention of the speaker, and its recognition is crucial for the building of dialog systems. The specific contribution of this paper is to investigate exactly how discourse participants signal their beliefs using language, and the strength of their beliefs; this latter point is not usually included in dialog act tagging.

This paper is not concerned with issues relating to logics for belief representation or inferencing that can be done on beliefs (for an overview, see (McArthur, 1988)), nor theories of automatic belief ascription (Wilks and Ballim, 1987). For example, this paper is not concerned with determining whether a belief in the requirement of p entails the belief in p; instead, we are only interested in whether the writer wants the reader to understand whether the writer holds a belief in the requirement that p or in p directly. This paper is also not concerned with subjectivity (Wiebe et al., 2004), the nature of the proposition p (statement about interior world or external world) is not of interest, only whether the writer wants the reader to believe the writer believes p. This paper is also not concerned with opinion and determining the polarity (or strength) of opinion (for example: (Somasundaran et al., 2008)), which corresponds to the desire dimension. Thus, this work is orthogonal to the extensive literature on opinion classification.

The work of (Saurí and Pustejovsky, 2007; Saurí and Pustejovsky, 2008) is, in many respects, very similar to ours. They propose Factbank, which represents the factual interpretation as modality-polarity pairs, extracted from the basic structural elements denoting factuality encoded by Timebank. Also, they attribute the factuality to specific sources within the text. Our work

is more limited in several ways: we currently only model the writer's beliefs; we do not express polarity (we believe we can derive it from the syntax and lexicon); Saurí and Pustejovsky (2008) ask their annotators to perform extensive linguistic transformations on the text to obtain a "normalized" representation of propositional content (we simply ask the annotators to make a judgment about the writer's strength of belief with respect to a given proposition, and expect to be able to extract representations of pure propositional meaning independently); and finally, Saurí and Pustejovsky (2008) have a more fine-grained representation of non-committed belief. While it is plausible to distinguish between more or less firm non-committed belief, we believe the crucial distinction is between committed belief and non-committed belief. Furthermore, Saurí and Pustejovsky (2008) group reported speech with non-belief statements (our NA), while we group them with weak belief (our NCB). The reason for our decision is that we wanted to keep NA as a category which contains no-one's beliefs, as we assumed this is semantically more coherent. The category NCB thus covers beliefs which the writer does not hold firmly or has expressed no opinion on — which is different from propositions which the writer has clearly attributed to other cognitive states (such as desire). In principle, we believe a 4-way distinction is the right approach, but our NCB category is already the least frequent, and splitting it would have resulted in two very rare classes. Another difference include the use of the word "fact" in the FactBank manual, which we avoid because we are interested in cognitive modeling; however, this is merely a terminological issue.

Other related works explored belief systems in an inference scenario as opposed to an intentionality scenario. In work by (Krestel et al., 2008), the authors explore belief in the context of reported speech in news media: they track newspaper text looking for elements indicating evidentiality. This is different from our work, since we seek to make explicit the intention of the author or the speaker.

5 Future Work

We are exploring ways to utilize the FactBank annotated corpus for our purpose, with the goal of automatically converting it to our annotation format. With the added data from FactBank, we hope to be able to split the NCB category into WB (weak belief) and RS (reported speech). We will also explore learning embedded belief attributions, as annotated in FactBank.

We found that the per-sentence F-measure has a small positive correlation with the length-normalized probability of the MICA derivation (a measure of parse confidence). In case of a bad parse, syntax features add noise which in turn reduces classifier performance. We are planning to exploit this correlation in order to choose sentences for selective self-training. Another direction we are looking to extend this work is to employ active learning to overcome the shortcomings of a small training set. Also, we found frequent use of epistemic and deontic modals in our data. Both types of modals have identical syntactic structure, but they receive very different annotations. This is not easily captured in our system. We are exploring ways to handle this.

We will release our Committed Belief Tagging tool as a standalone black-box tool. We also intend to release the annotated corpus.

Realization of Discourse Relations by Other Means: Alternative Lexicalizations

Abstract

Studies of discourse relations have not, in the past, attempted to characterize what serves as evidence for them, beyond lists of frozen expressions, or markers, drawn from a few well-defined syntactic classes. In this paper, we describe how the lexicalized discourse relation annotations of the Penn Discourse Treebank (PDTB) led to the discovery of a wide range of additional expressions, annotated as *AltLex* (*alternative lexicalizations*) in the PDTB 2.0. Further analysis of AltLex annotation suggests that the set of markers is open-ended, and drawn from a wider variety of syntactic types than currently assumed. As a first attempt towards automatically identifying discourse relation markers, we propose the use of syntactic paraphrase methods.

1 Introduction

Discourse relations that hold between the content of clauses and of sentences – including relations of cause, contrast, elaboration, and temporal ordering – are important for natural language processing tasks that require sensitivity to more than just a single sentence, such as summarization, information extraction, and generation. In written text, discourse relations have usually been considered to be signaled either explicitly, as lexicalized with some word or phrase, or implicitly due to adjacency. Thus, while the causal relation between the situations described in the two clauses in Ex. (1) is signalled explicitly by the connective *As a result*, the same relation is conveyed implicitly in Ex. (2).

(1) John was tired. As a result he left early.

(2) John was tired. He left early.

This paper focusses on the problem of how to characterize and identify explicit signals of discourse relations, exemplified in Ex. (1). To refer to all such signals, we use the term "discourse relation markers" (DRMs). Past research (e.g., (Halliday and Hasan, 1976; Martin, 1992; Knott, 1996), among others) has assumed that DRMs are frozen or fixed expressions from a few well-defined syntactic classes, such as conjunctions, adverbs, and prepositional phrases. Thus the literature presents *lists* of DRMs, which researchers try to make as complete as possible for their chosen language. In annotating lexicalized discourse relations of the Penn Discourse Treebank (Prasad et al., 2008), this same assumption drove the initial phase of annotation. A list of "explicit connectives" was collected from various sources and provided to annotators, who then searched for these expressions in the text and annotated them, along with their arguments and senses. The same assumption underlies methods for automatically identifying DRMs (Pitler and Nenkova, 2009). Since expressions functioning as DRMs can also have non-DRM functions, the task is framed as one of classifying given individual tokens as DRM or not DRM.

In this paper, we argue that placing such syntactic and lexical restrictions on DRMs limits a proper understanding of discourse relations, which can be realized in other ways as well. For example, one should recognize that the instantiation (or exemplification) relation between the two sentences in Ex. (3) is explicitly signalled in the second sentence by the phrase *Probably the most egregious example is*, which is sufficient to express the instantiation relation.

(3) Typically, these laws seek to prevent executive branch officials from inquiring into whether certain federal programs make any economic sense or proposing more market-oriented alternatives to regulations. Probably the most egregious example is a

Coling 2008: Poster Volume, pages 1023–1031,
Beijing, August 2010

proviso in the appropriations bill for the executive office that prevents the president's Office of Management and Budget from subjecting agricultural marketing orders to any cost-benefit scrutiny.

Cases such as Ex. (3) show that identifying DRMs cannot simply be a matter of preparing a list of fixed expressions and searching for them in the text. We describe in Section 2 how we identified other ways of expressing discourse relations in the PDTB. In the current version of the corpus (PDTB 2.0.), they are labelled as *AltLex* (*alternative lexicalizations*), and are "discovered" as a result of our lexically driven annotation of discourse relations, including explicit as well as implicit relations. Further analysis of AltLex annotations (Section 3) leads to the thesis that *DRMs are a lexically open-ended class of elements which may or may not belong to well-defined syntactic classes*. The open-ended nature of DRMs is a challenge for their automated identification, and in Section 4, we point to some lessons we have already learned from this annotation. Finally, we suggest that methods used for automatically generating candidate paraphrases may help to expand the set of recognized DRMs for English and for other languages as well (Section 5).

2 AltLex in the PDTB

The Penn Discourse Treebank (Prasad et al., 2008) constitutes the largest available resource of lexically grounded annotations of discourse relations, including both explicit and implicit relations.[1] Discourse relations are assumed to have two and only two arguments, called Arg1 and Arg2. By convention, Arg2 is the argument syntactically associated with the relation, while Arg1 is the other argument. Each discourse relation is also annotated with one of the several senses in the PDTB hierarchical sense classification, as well as the attribution of the relation and its arguments. In this section, we describe how the annotation methodology of the PDTB led to the identification of the AltLex relations.

Since one of the major goals of the annotation was to lexically ground each relation, a first step in the annotation was to identify the explicit markers of discourse relations. Following standard practice, a list of such markers – called "explicit connectives" in the PDTB – was collected from various sources (Halliday and Hasan, 1976; Martin, 1992; Knott, 1996; Forbes-Riley et al., 2006).[2] These were provided to annotators, who then searched for these expressions in the corpus and marked their arguments, senses, and attribution.[3] In the pilot phase of the annotation, we also went through several iterations of updating the list, as and when annotators reported seeing connectives that were not in the current list. Importantly, however, connectives were constrained to come from a few well-defined syntactic classes:

- *Subordinating conjunctions:* e.g., because, although, when, while, since, if, as.
- *Coordinating conjunctions:* e.g., and, but, so, either..or, neither..nor.
- *Prepositional phrases:* e.g., as a result, on the one hand..on the other hand, insofar as, in comparison.
- *adverbs:* e.g., then, however, instead, yet, likewise, subsequently

Ex. (4) illustrates the annotation of an explicit connective. (In all PDTB examples in the paper, Arg2 is indicated in boldface, Arg1 is in italics, the DRM is underlined, and the sense is provided in parentheses at the end of the example.)

(4) *U.S. Trust, a 136-year-old institution that is one of the earliest high-net worth banks in the U.S., has faced intensifying competition from other firms that have established, and heavily promoted, private-banking businesses of their own.* As a result, **U.S. Trust's earnings have been hurt.** (Contingency:Cause:Result)

After all explicit connectives in the list were annotated, the next step was to identify implicit discourse relations. We assumed that such relations are triggered by adjacency, and (because of resource limitations) considered only those that held between sentences within the same paragraph. Annotators were thus instructed to supply a connective – called "implicit connective" – for

[1] http://www.seas.upenn.edu/~pdtb

[2] All explicit connectives annotated in the PDTB are listed in the PDTB manual (PDTB-Group, 2008).

[3] These guidelines are recorded in the PDTB manual.

each pair of adjacent sentences, *as long as the relation was not already expressed with one of the explicit connectives provided to them*. This procedure led to the annotation of implicit connectives such as *because* in Ex. (5), where a causal relation is inferred but no explicit connective is present in the text to express the relation.

(5) *To compare temperatures over the past 10,000 years, researchers analyzed the changes in concentrations of two forms of oxygen.* (Implicit=because) **These measurements can indicate temperature changes**, . . . (Contingency:Cause:reason)

Annotators soon noticed that in many cases, they were not able to supply an implicit connective. Reasons supplied included (a) "there is a relation between these sentences but I cannot think of a connective to insert between them", (b) "there is a relation between the sentences for which I can think of a connective, but it doesn't sound good", and (c) "there is no relation between the sentences". For all such cases, annotators were instructed to supply "NONE" as the implicit connective. Later, we sub-divided these "NONE" implicits into "EntRel", for the (a) type above (an entity-based coherence relation, since the second sentence seemed to continue the description of some entity mentioned in the first); "NoRel" (no relation) for the (c) type; and "AltLex", for the (b) type, which we turn to next.

Closer investigation of the (b) cases revealed that the awkwardness perceived by annotators when inserting an implicit connective was due to *redundancy in the expression of the relation*: Although no explicit connective was present to relate the two sentences, some other expression appeared to be doing the job. This is indeed what we found. Subsequently, instances of AltLex were annotated if:

1. A discourse relation can be inferred between adjacent sentences.

2. There is no explicit connective present to relate them.

3. The annotator is not able to insert an implicit connective to express the inferred relation (having used "NONE" instead), because inserting it leads to an awkward redundancy in expressing the relation.

Under these conditions, annotators were instructed to look for and mark as *Altlex*, whatever *alternative expression* appeared to denote the relation. Thus, for example, Ex. (6) was annotated as AltLex because although a causal relation is inferred between the sentences, inserting a connective like *because* makes expression of the relation redundant. Here the phrase *One reason is* is taken to denote the relation and is marked as *AltLex*.

(6) *Now, GM appears to be stepping up the pace of its factory consolidation to get in shape for the 1990s.* **One reason is mounting competition from new Japanese car plants in the U.S. that are pouring out more than one million vehicles a year at costs lower than GM can match**. (Contingency:Cause:reason)

The result of this procedure led to the annotation of 624 tokens of AltLex in the PDTB. We turn to our analysis of these expressions in the next section.

3 What is found in AltLex?

Several questions arise when considering the AltLex annotations. What kind of expressions are they? What can we learn from their syntax? Do they project discourse relations of a different sort than connectives? How can they be identified, both during manual annotation and automatically? To address these questions, we examined the AltLex annotation for annotated senses, and for common lexico-syntactic patterns extracted using alignment with the Penn Treebank (Marcus et al., 1993).[4]

3.1 Lexico-syntactic Characterization

We found that we could partition AltLex annotation into three groups by (a) whether or not they belonged to one of the syntactic classes admitted as explicit connectives in the PDTB, and (b) whether the expression was frozen (ie, blocking free substitution, modification or deletion of any of its parts) or open-ended. The three groups are shown in Table 1 and discussed below.

[4]The source texts of the PDTB come from the Penn Treebank (PTB) portion of the Wall Street Journal corpus. The PDTB corpus provides PTB tree alignments of all its text span annotations, including connectives, AltLex's, arguments of relations, and attribution spans.

AltLex Group	No (%)	Examples
Syntactically admitted, lexically frozen	92 (14.7%)	quite the contrary (ADVP), for one thing (PP), as well (ADVP), too (ADVP), soon (ADVP-TMP), eventually (ADVP-TMP), thereafter (RB), even (ADVP), especially (ADVP), actually (ADVP), still (ADVP), only (ADVP), in response (PP)
Syntactically free, lexically frozen	54 (8.7%)	What's more (SBAR-ADV), Never mind that (ADVP-TMP;VB;DT), To begin with (VP), So (ADVP-PRD-TPC), Another (DT), further (JJ), As in (IN;IN), So what if (ADVP;IN), Best of all (NP)
Syntactically and lexically free	478 (76.6%)	That compares with (NP-SBJ;VBD;IN), After these payments (PP-TMP), That would follow (NP-SBJ;MD;VB), The plunge followed (NP-SBJ;VBD), Until then (PP-TMP), The increase was due mainly to (NP-SBJ;VBD;JJ;RB;TO), That is why (NP-SBJ;VBZ;WHADVP), Once triggered (SBAR-TMP)
TOTAL	624	–

Table 1: Breakdown of AltLex by Syntactic and Lexical Flexibility. Examples in the third column are accompanied (in parentheses) with their PTB POS tags and constituent phrase labels obtained from the PDTB-PTB alignment.

Syntactically admitted and lexically frozen: The first row shows that 14.7% of the strings annotated as AltLex belong to syntactic classes admitted as connectives and are similarly frozen. (Syntactic class was obtained from the PDTB-PTB alignment.) So, despite the effort in preparing a list of connectives (cf. Section 1), additional ones were still found in the corpus through AltLex annotation. This suggests that any pre-defined list of connectives should only be used to guide annotators in a strategy for "discovering" connectives.

Syntactically free and lexically frozen: AltLex expressions that were frozen but belonged to syntactic classes other than those admitted for the PDTB explicit connectives accounted for 8.7% (54/624) of the total (Table 1, row 2). For example, the AltLex *What's more* (Ex. 7) is parsed as a clause (SBAR) functioning as an adverb (ADV). It is also frozen, in not undergoing any change (eg, *What's less*, *What's bigger*, etc.[5]

(7) Marketers themselves are partly to blame: *They've increased spending for coupons and other short-term promotions at the expense of image-building advertising.* **What's more, a flood of new products has given consumers a dizzying choice of brands, many of which are virtually carbon copies of one other**. (Expansion:Conjunction)

[5]Apparently similar headless relative clauses such as *What's more exciting* differ from *What's more* in not functioning as adverbials, just as NPs.

Many of these AltLex annotations do not constitute a single constituent in the PTB, as with *Never mind that*. These cases suggest that either the restrictions on connectives as frozen expressions should be relaxed to admit all syntactic classes, or the syntactic analyses of these *multi-word expressions* is irrelevant to their function.

Both syntactically and lexically free: This third group (Table 1, row 3) constitutes the majority of AltLex annotations – 76.6% (478/624). Additional examples are shown in Table 2. Common syntactic patterns here include subjects followed by verbs (Table 2a-c), verb phrases with complements (d), adverbial clauses (e), and main clauses with a subordinating conjunction (f).

All these AltLex annotations are freely modifiable, with their fixed and modifiable parts shown in the regular expressions defined for them in Table 2. Each has a fixed "core" phrase shown as lexical tokens in the regular expression, e.g, *consequence of*, *attributed to*, plus obligatory and optional elements shown as syntactic labels. Optional elements are shown in parentheses. <NX> indicates any noun phrase, <PPX>, any prepositional phrase, <VX>, any verb phrase, and

AltLex String	AltLex Pattern
(a) A consequence of their departure could be ...	<DTX> consequence (<PPX>) <VX>
(b) A major reason is ...	<DTX> (<JJX>) reason (<PPX>) <VX>
(c) Mayhap this metaphorical connection made ...	(<ADVX>) <NX> made
(d) ... attributed the increase to ...	attributed <NX> to
(e) Adding to that speculation ...	Adding to <NX>
(f) That may be because ...	<NX> <VX> because

Table 2: Complex AltLex strings and their patterns

<JJX>, any adjectival phrase

These patterns show, for example, that other variants of the identified AltLex *A major reason is* include *The reason is*, *A possible reason for the increase is*, *A reason for why we should consider DRMs as an open class is*, etc. This is robust support for our claim that DRMs should be regarded as an open class: The task of identifying them cannot simply be a matter of checking an *a priori* list.

Note that the optional modification seen here is clearly also possible with many explicit connectives such as *if* (eg, *even if just if*, *only if*), as shown in Appendix C of the PDTB manual (PDTB-Group, 2008). This further supports the thesis that DRMs should be treated as an open class that includes explicit connectives.

3.2 Semantic Characterization

AltLex strings were annotated as denoting the discourse relation that held between otherwise unmarked adjacent utterances (Section 2). We found them to convey this relation in much the same way as anaphoric discourse adverbials. According to (Forbes-Riley et al., 2006), discourse adverbials convey both the discourse relation and an anaphoric reference to its Arg1. The latter may be either explicit (e.g., through the use of a demonstrative like "this" or "that"), or implicit. Thus, both *as a result of that* and *as a result* are discourse adverbials in the same way: the latter refers explicitly to Arg1 via the pronoun "that", while former does so via an implicit internal argument. (A *result* must be a result of something.)

The examples in Table 2 make this same two–part semantic contribution, albeit with more complex expressions referring to Arg1 and more complex modification of the expression denoting the relation. For example, in the AltLex shown in (Table 2c), *Mayhap this metaphorical connection made* (annotated in Ex. (8)), the relation is denoted by the causal verb *made*, while Arg1 is referenced through the definite description *this metaphorical connection*. In addition, the adverb *Mayhap* further modifies the relational verb.

(8) *Ms. Bartlett's previous work, which earned her an international reputation in the non-horticultural art world, often took gardens as its nominal subject.* **Mayhap this metaphorical connection made the BPC Fine Arts Committee think she had a literal green thumb**. (Contingency:Cause:Result)

These complex AltLex's also raise the question of why we find them at all in language. One part of the answer is that these complex AltLex's are used to convey more than just the meaning of the relation. In most cases, we found that substituting the AltLex with an adverbial connective led to some aspect of the meaning being lost, as in Ex. (9-10). Substituting *For example* for the AltLex with an (necessary) accompanying paraphrase of Arg2 loses the information that the example provided as Arg2 is possibly the most egregious one. The connective *for example* does not allow similar modification. This means that one must use a different strategy such as an AltLex expression.

(9) *Typically, these laws seek to prevent executive branch officials from inquiring into whether certain federal programs make any economic sense or proposing more market-oriented alternatives to regulations.* **Probably the most egregious example is a proviso in the appropriations bill for the executive office that prevents the president's Office of Management and Budget from subjecting agricultural marketing orders to any cost-benefit scrutiny**. (Expansion:Instantiation)

(10) For example, a proviso in the appropriations bill for the executive office prevents the president's Of-

fice of Management and Budget from subjecting agricultural marketing orders to any cost-benefit scrutiny.

Another part of the answer to *Why AltLex?* is that it can serve to convey a relation for which the lexicon lacks an adverbial connective. For example, while English has several adverbial connectives that express a "Cause:Consequence" relation (eg, *as a result, consequently*, etc.), it lacks an adverbial connective expressing "Cause:Reason" (or explanation) albeit having at least two subordinating conjunctions that do so (*because* and *since*). Thus, we find an AltLex whenever this relation needs to be expressed between sentences, as shown in Ex. (11).

(11) *But a strong level of investor withdrawals is much more unlikely this time around,* fund managers said. **A major reason is that investors already have sharply scaled back their purchases of stock funds since Black Monday.** (Contingency:Cause:reason)

Note, however, that even for such relations such as Cause:Reason, it is still not the case that a list of canned expressions will be sufficient to generate the Altlex or to identify them, since this relation can itself be further modified. In Ex. (12), for example, the writer intends to convey that there are multiple reasons for the walkout, although only one of them is eventually specified in detail.

(12) *In Chile, workers at two copper mines, Los Bronces and El Soldado,* which belong to the Exxon-owned Minera Disputada, *yesterday voted to begin a full strike tomorrow,* an analyst said. **Reasons for the walkout**, the analyst said, **included a number of procedural issues, such as a right to strike**. (Contingency:Cause:reason)

4 Lessons learned from AltLex

Like all lexical phenomena, DRMs appear to have a power-law distribution, with some very few high-frequency instances like (*and, but*), a block of mid-frequency instances (eg, *after, because, however*), and many many low-frequency instances in the "long tail" (eg, *much as, on the contrary, in short,* etc.). Given the importance of DRMs for recognizing and classifying discourse relations and their arguments, what have we learned from the annotation of AltLex?

First, the number of expressions found through AltLex annotation, that belong to syntactic classes admitted as connectives and also similarly frozen (Table 1, row 1) shows that even in the PDTB, there are additional instances of what we have taken to be explicit connectives. By recognizing them and unambiguously labelling their senses, we will start to reduce the number of "hard cases" of implicit connectives whose sense has to be recognized (Marcu and Echihabi, 2002; Sporleder and Lascarides, 2008; Pitler et al., 2009; Lin et al., 2009). Secondly, the number of tokens of expressions from other syntactic classes that have been annotated as AltLex (Table 1, rows 2 and 3) may actually be higher than was caught via our AltLex annotation, thus making them even more important for discourse processing. To assess this, we selected five of them and looked for all their tokens in the WSJ raw files underlying both the PTB and the PDTB. After eliminating those tokens that had already been annotated, we judged whether the remaining ones were functioning as connectives. Table 3 shows the expressions we used in the first column, with the second and third columns reporting the number of tokens annotated in PDTB, and the number of additional tokens in the WSJ corpus functioning as connectives. (The asterisk next to the expressions is a wild card to allow for variations along the lines discussed for Table 2.) These results show that these DRMs occur two to three times more frequently than already annotated.

Increased frequencies of AltLex occurrence are also observed in discourse annotation projects undertaken subsequent to the PDTB, since they were able to be more sensitive to the presence of AltLex. The Hindi Discourse Relation Bank (HDRB) (Oza et al., 2009), for example, reports that 6.5% of all discourse relations in the HDRB have been annotated as AltLex, compared to 1.5% in the PDTB. This also provides cross-linguistic evidence of the importance of recognizing the full range of DRMs in a language.

5 Identifying DRMs outside the PDTB

As the set of DRMs appears to be both open-ended and distributed like much else in language, with a very long tail, it is likely that many are missing from the one-million word WSJ corpus annotated in the PDTB 2.0. Indeed, in annotating En-

AltLex	Annotated	Unannotated

That means	11	17
TOTAL	47	82

Table 3: Annotated and Unannotated instances of AltLex

glish biomedical articles with discourse relations, Yu et al (2008) report finding many DRMs that don't appear in the WSJ (e.g., *as a consequence*). If one is to fully exploit DRMs in classifying discourse relations, one must be able to identify them all, or at least many more of them than we have to date. One method that seems promising is Callison-Burch's paraphrase generation through back-translation on pairs of word-aligned corpora (Callison-Birch, 2007). This method exploits the frequency with which a word or phrase is back translated (from texts in language A to texts in language B, and then back from texts in language B to texts in language A) across a range of pivot languages, into other words or phrases.

While there are many factors that introduce low-frequency noise into the process, including lexical ambiguity and errors in word alignment, Callison-Burch's method benefits from being able to use the many existing word-aligned translation pairs developed for creating translation models for SMT. Recently, Callison-Burch showed that paraphrase errors could be reduced by syntactically constraining the phrases identified through back-translation to ones with the same syntactic category as assigned to the source (Callison-Birch, 2008), using a large set of syntactic categories similar to those used in CCG (Steedman, 2000).

For DRMs, the idea is to identify through back-translation, instances of DRMs that were neither included in our original set of explicit connective nor subsequently found through AltLex annotation. To allow us to carry out a quick pilot study, Callison-Burch provided us with back-translations of 147 DRMs (primarily explicit connectives annotated in the PDTB 2.0, but also including a few from other syntactic classes found through AltLex annotation). Preliminary analysis of the results reveals many DRMs that don't appear anywhere in the WSJ Corpus (eg, *as a consequence*, *as an example*, *by the same token*), as well as additional DRMs that appear in the corpus but were not annotated as AltLex (e.g., *above all*, *after all*, *despite that*). Many of these latter instances appear in the initial sentence of a paragraph, but the annotation of implicit connectives — which is what led to AltLex annotation in the first place (Section 2) — was not carried out on these sentences.

There are two further things to note before closing this discussion. First, there is an additional source of noise in using back-translation paraphrase to expand the set of identified DRMs. This arises from the fact that discourse relations can be conveyed either explicitly or implicitly, and a translated text may not have made the same choices vis-a-vis explicitation as its source, causing additional word alignment errors (some of which are interesting, but most of which are not). Secondly, this same method should prove useful for languages other English, although there will be an additional problem to overcome for languages (such as Turkish) in which DRMs are conveyed through morphology as well as through distinct words and phrases.

6 Related work

We are not the first to recognize that discourse relations can realized by more than just one or two syntactic classes. Halliday and Hasan (1976) document prepositional phrases like *After that* being used to express conjunctive relations. More importantly, they note that any definite description can be substituted for the demonstrative pronoun.

Similarly, Taboada (2006), in looking at how often RST-based rhetorical relations are realized by discourse markers, starts by considering only adverbials, prepositional phrases, and conjunctions, but then notes the occurrence of a single instance of a nominal fragment *The result* in her corpus. Challenging the RST assumption that the basic unit of a discourse is a clause, with discourse relations holding between adjacent clausal units, Kibble (1999) provides evidence that *informational* discourse relations (as opposed to *intentional* discourse relations) can hold intra-clausally as well, with the relation "verbalized" and its arguments realized as nominalizations, as in *Early treatment with Brand X can prevent a cold sore developing*. Since his focus is intra-clausal, he does not observe that verbalized discourse relations can hold across sentences as well, where a verb and one of its arguments function similarly to a discourse adverbial, and in the end, he does not provide a proposal for how to systematically identify these alternative realizations. Le Huong et al. (2003), in developing an algorithm for recognizing discourse relations, consider non-verbal realizations (called NP cues) in addition to verbal realizations (called VP cues). However, they provide only one example of such a cue ("the result"). Like Kibble (1999), Danlos (2006) and Power (2007) also focus only on identifying verbalizations of discourse relations, although they do consider cases where such relations hold across sentences.

What has not been investigated in prior work is the basis for the alternation between connectives and AltLex's, although there are several accounts of why a language may provide more than one connective that conveys the same relation. For example, the alternation in Dutch between *dus* ("so"), *daardoor* ("as a result"), and *daarom* ("that's why") is explained by Pander Maat and Sanders (2000) as having its basis in "subjectivity".

7 Conclusion and Future Work

Categorizing and identifying the range of ways in which discourse relations are realized is important for both discourse understanding and generation. In this paper, we showed that existing practices of cataloguing these ways as lists of closed class expressions is problematic. We drew on our experience in creating the lexically grounded annotations of the Penn Discourse Treebank, and showed that markers of discourse relations should instead be treated as open-class items, with unconstrained syntactic possibilities. Manual annotation and automatic identification practices should develop methods in line with this finding if they aim to exhaustively identify all discourse relation markers.

Acknowledgments

We want to thank Chris Callison-Burch, who graciously provided us with EuroParl back-translation paraphrases for the list of connectives we sent him. This work was partially supported by NSF grant IIS-07-05671.

Designing Agreement Features for Realization Ranking

Rajakrishnan Rajkumar and **Michael White**

{raja,mwhite}@ling.osu.edu

Abstract

This paper shows that incorporating linguistically motivated features to ensure correct animacy and number agreement in an averaged perceptron ranking model for CCG realization helps improve a state-of-the-art baseline even further. Traditionally, these features have been modelled using hard constraints in the grammar. However, given the graded nature of grammaticality judgements in the case of animacy we argue a case for the use of a statistical model to rank competing preferences. Though subject-verb agreement is generally viewed to be syntactic in nature, a perusal of relevant examples discussed in the theoretical linguistics literature (Kathol, 1999; Pollard and Sag, 1994) points toward the heterogeneous nature of English agreement. Compared to writing grammar rules, our method is more robust and allows incorporating information from diverse sources in realization. We also show that the perceptron model can reduce balanced punctuation errors that would otherwise require a post-filter. The full model yields significant improvements in BLEU scores on Section 23 of the CCGbank and makes many fewer agreement errors.

1 Introduction

In recent years a variety of statistical models for realization ranking that take syntax into account have been proposed, including generative models (Bangalore and Rambow, 2000; Cahill and van Genabith, 2006; Hogan et al., 2007; Guo et al., 2008), maximum entropy models (Velldal and Oepen, 2005; Nakanishi et al., 2005) and averaged perceptron models (White and Rajkumar, 2009). To our knowledge, however, none of these models have included features specifically designed to handle grammatical agreement, an important task in surface realization. In this paper, we show that incorporating linguistically motivated features to ensure correct animacy and verbal agreement in an averaged perceptron ranking model for CCG realization helps improve a state-of-the-art baseline even further. We also demonstrate the utility of such an approach in ensuring the correct presentation of balanced punctuation marks.

Traditionally, grammatical agreement phenomena have been modelled using hard constraints in the grammar. Taking into consideration the range of acceptable variation in the case of animacy agreement and facts about the variety of factors contributing to number agreement, the question arises: tackle agreement through grammar engineering, or via a ranking model? In our experience, trying to add number and animacy agreement constraints to a grammar induced from the CCGbank (Hockenmaier and Steedman, 2007) turned out to be surprisingly difficult, as hard constraints often ended up breaking examples that were working without such constraints, due to exceptions, sub-regularities and acceptable variation in the data. With sufficient effort, it is conceivable that an approach incorporating hard agreement constraints could be refined to underspecify cases where variation is acceptable, but even so, one would want a ranking model to capture preferences in these cases, which might vary depending on genre, dialect or domain. Given that

Coling 2008: Poster Volume, pages 1032–1040,
Beijing, August 2010

a ranking model is desirable in any event, we investigate here the extent to which agreement phenomena can be more robustly and simply handled using a ranking model alone, with no hard constraints in the grammar.

We also show here that the perceptron model can reduce balanced punctuation errors that would otherwise require a post-filter. As White and Rajkumar (2008) discuss, in CCG it is not feasible to use features in the grammar to ensure that balanced punctuation (e.g. paired commas for NP appositives) is used in all and only the appropriate places, given the word-order flexibility that crossing composition allows. While a post-filter is a reasonably effective solution, it can be prone to search errors and does not allow balanced punctuation choices to interact with other choices made by the ranking model.

The starting point for our work is a CCG realization ranking model that incorporates Clark & Curran's (2007) normal-form syntactic model, developed for parsing, along with a variety of n-gram models. Although this syntactic model plays an important role in achieving top BLEU scores for a reversible, corpus-engineered grammar, an error analysis nevertheless revealed that many errors in relative pronoun animacy agreement and subject-verb number agreement remain with this model. In this paper, we show that features specifically designed to better handle these agreement phenomena can be incorporated into a realization ranking model that makes many fewer agreement errors, while also yielding significant improvements in BLEU scores on Section 23 of the CCGbank. These features make use of existing corpus annotations — specifically, PTB function tags and BBN named entity classes (Weischedel and Brunstein, 2005) — and thus they are relatively easy to implement.

1.1 The Graded Nature of Animacy Agreement

To illustrate the variation that can be found with animacy agreement phenomena, consider first animacy agreement with relative pronouns. In English, an inanimate noun can be modified by a relative clause introduced by *that* or *which*, while an animate noun combines with *who(m)*. With some nouns though — such as *team*, *group*, *squad*, etc. — animacy status is uncertain, and these can be found with all the three relative pronouns (*who, which* and *that*). Google counts suggest that all three choices are almost equally acceptable, as the examples below illustrate:

(1) The groups who protested against plans to remove asbestos from the nuclear submarine base at Faslane claimed victory when it was announced the government intends to dispose of the waste on site. (The Glasgow Herald; Jun 25, 2010)

(2) Mr. Dorsch says the HIAA is working on a proposal to establish a privately funded reinsurance mechanism to help cover small groups that ca n't get insurance without excluding certain employees . (WSJ0518.35)

1.2 The Heterogeneous Nature of Number Agreement

Subject-verb agreement can be described as a constraint where the verb agrees with the subject in terms of agreement features (number and person). Agreement has often been considered to be a syntactic phenomenon and grammar implementations generally use syntactic features to enforce agreement constraints (e.g. Velldal and Oepen, 2005). However a closer look at our data and a survey of the theoretical linguistics literature points toward a more heterogeneous conception of English agreement. Purely syntactic accounts are problematic when the following examples are considered:

(3) Five miles is a long distance to walk. (Kim, 2004)

(4) King prawns cooked in chili salt and pepper was very much better, a simple dish succulently executed. (Kim, 2004)

(5) " I think it will shake confidence one more time , and a lot of this business is based on client confidence . " (WSJ1866.10)

(6) It 's interesting to find that a lot of the expensive wines are n't always walking out the door . (WSJ0071.53)

In Example (3) above, the subject and determiner are plural while the verb is singular. In (4), the singular verb agrees with the dish, rather than with individual prawns. Measure nouns such as *lot*, *ton*, etc. exhibit singular agreement with the determiner *a*, but varying agreement with the verb depending on the head noun of the measure noun's *of*-complement. As is also well known, British and American English differ in subject-verb agreement with collective nouns. Kathol (1999) proposes an explanation where agreement is determined by the semantic properties of the noun rather than by its morphological properties. This accounts for all the cases above. In the light of this explanation, specifying agreement features in the logical form for realization could perhaps solve the problem. However, the semantic view of agreement is not completely convincing due to counterexamples like the following discussed in the literature (reported in Kim (2004)):

(7) Suppose you meet someone and they are totally full of themselves

(8) Those scissors are missing.

In Example (7), the pronoun *they* used in a generic sense is linked to the singular antecedent *someone*, but its plural feature triggers plural agreement with the verb. Example (8) illustrates a situation where the subject *scissors* is arguably semantically singular, but exhibits plural morphology and plural syntactic agreement with both the determiner as well as the verb. Thus this suggests that English has a set of heterogeneous agreement patterns rather than purely syntactic or semantic ones. This is also reflected in the proposal for a hybrid agreement system for English (Kim, 2004), where the morphology tightly interacts with the system of syntax, semantics, or even pragmatics to account for agreement phenomena. Our machine learning-based approach approximates the insights discussed in the theoretical linguistics literature. Writing grammar rules to get these facts right proved to be surprisingly difficult (e.g. discerning the actual nominal head contributing agreement feature in cases like *areas of the factory were/*was* vs. *a lot of wines are/*is*) and required a list of measure nouns and partitive quantifiers. We investigate here the extent to which a machine learning–based approach is a simpler, practical alternative for acquiring the relevant generalizations from the data by combining information from various information sources.

The paper is structured as follows. Section 2 provides CCG background. Section 3 describes the features we have designed for animacy and number agreement as well as for balanced punctuation. Section 4 presents our evaluation of the impact of these features in averaged perceptron realization ranking models, tabulating specific kinds of errors in the CCGbank development section as well as overall automatic metric scores on Section 23. Section 5 compares our results to those obtained with related systems. Finally, Section 6 concludes with a summary of the paper's contributions.

2 Background

2.1 Surface Realization with Combinatory Categorial Grammar (CCG)

CCG (Steedman, 2000) is a unification-based categorial grammar formalism which is defined almost entirely in terms of lexical entries that encode sub-categorization information as well as syntactic feature information (e.g. number and agreement). Complementing function application as the standard means of combining a head with its argument, type-raising and composition support transparent analyses for a wide range of phenomena, including right-node raising and long distance dependencies. An example syntactic derivation appears in Figure 1, with a long-distance dependency between *point* and *make*. Semantic composition happens in parallel with syntactic composition, which makes it attractive for generation.

OpenCCG is a parsing/generation library which works by combining lexical categories for words using CCG rules and multi-modal extensions on rules (Baldridge, 2002) to produce derivations. Conceptually these extensions are on lexical categories. Surface realization is the process by which logical forms are transduced to strings. OpenCCG uses a hybrid symbolic-statistical chart realizer (White, 2006) which takes logical forms as input and produces sentences by using CCG com-

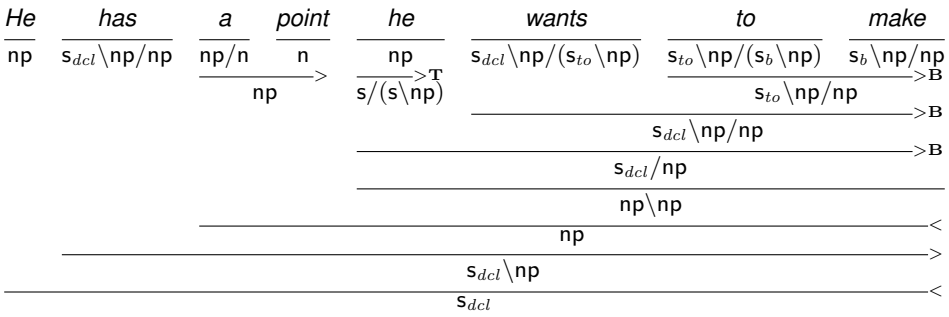

Figure 1: Syntactic derivation from the CCGbank for *He has a point he wants to make [. . .]*

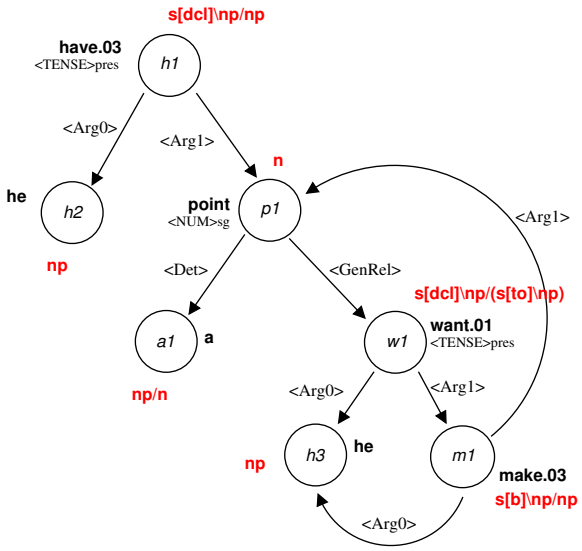

Figure 2: Semantic dependency graph from the CCGbank for *He has a point he wants to make [. . .]*, along with gold-standard supertags (category labels)

binators to combine signs. Edges are grouped into equivalence classes when they have the same syntactic category and cover the same parts of the input logical form. Alternative realizations are ranked using integrated n-gram or perceptron scoring, and pruning takes place within equivalence classes of edges. To more robustly support broad coverage surface realization, OpenCCG greedily assembles fragments in the event that the realizer fails to find a complete realization.

To illustrate the input to OpenCCG, consider the semantic dependency graph in Figure 2. In the graph, each node has a lexical predication (e.g. **make.03**) and a set of semantic features (e.g. ⟨NUM⟩sg); nodes are connected via dependency relations (e.g. ⟨ARG0⟩). (Gold-standard supertags, or category labels, are also shown; see Section 2.2 for their role in hypertagging.) Internally, such graphs are represented using Hybrid Logic Dependency Semantics (HLDS), a dependency-based approach to representing linguistic meaning (Baldridge and Kruijff, 2002). In HLDS, each semantic head (corresponding to a node in the graph) is associated with a nominal that identifies its discourse referent, and relations between heads and their dependents are modeled as modal relations.

For our experiments, we use an enhanced version of the CCGbank (Hockenmaier and Steedman, 2007)—a corpus of CCG derivations derived from the Penn Treebank—with Propbank (Palmer et al., 2005) roles projected onto it (Boxwell and White, 2008). Additionally, certain multi-word NEs were collapsed using underscores so that they are treated as atomic entities in the input to the realizer. To engineer a grammar from this corpus suitable for realization with OpenCCG, the derivations are first revised to reflect the lexicalized treatment of coordination and punctuation assumed by the multi-modal version of CCG that is implemented in OpenCCG (White and Rajkumar, 2008). Further changes are necessary to support semantic dependencies rather than surface syntactic ones; in particular, the features and unification constraints in the categories related to semantically empty function words such complementizers, infinitival-*to*, expletive subjects, and case-marking prepositions are adjusted to reflect their purely syntactic status.

2.2 Hypertagging

A crucial component of the OpenCCG realizer is the *hypertagger* (Espinosa et al., 2008), or supertagger for surface realization, which uses a maximum entropy model to assign the most likely lexical categories to the predicates in the input logical form, thereby greatly constraining the realizer's search space.[1] Category label prediction is done at run-time and is based on contexts within the directed graph structure as shown in Figure 2, instead of basing category assignment on linear word and POS context as in the parsing case.

3 Feature Design

The features we employ in our baseline perceptron ranking model are of three kinds. First, as in the log-linear models of Velldal & Oepen and Nakanishi et al., we incorporate the log probability of the candidate realization's word sequence according to our linearly interpolated language models as a single feature in the perceptron model. Since our language model linearly interpolates three component models, we also include the log prob from each component language model as a feature so that the combination of these components can be optimized. Second, we include syntactic features in our model by implementing Clark & Curran's (2007) normal form model in OpenCCG. The features of this model are listed in Table 1; they are integer-valued, representing counts of occurrences in a derivation. Third, we include discriminative n-gram features (Roark et al., 2004), which count the occurrences of each n-gram that is scored by our factored language model, rather than a feature whose value is the log probability determined by the language model. Table 2 depicts the new animacy, agreement and punctuation features being introduced as part of this work. The next two sections describe these features in more detail.

3.1 Animacy and Number Agreement

Underspecification as to the choice of pronoun in the input leads to competing realizations involving the relative pronouns *who*, *that*, *which* etc. The existing ranking models (n-gram models as well as perceptron) often allow the top-ranked output to have the relative pronoun *that* associated with animate nouns. The existing normal form model uses the word forms as well as part-of-speech tag based features. Though this is useful for associating proper nouns (tagged NNP or NNPS) with *who*, for other nouns (as in *consumers who* vs. *consumers that/which*), the model often prefers the infelicitous pronoun. So here we designed features which also took into account the named entity class of the head noun as well as the stem of the head noun. These features aid the discriminative n-gram features (*PERSON, which* has high negative weight). As the results section discusses,

[1] The approach has been dubbed *hypertagging* since it operates at a level "above" the syntax, moving from semantic representations to syntactic categories.

Feature Type	Example
LexCat + Word	$s/s/np$ + before
LexCat + POS	$s/s/np$ + IN
Rule	$s_{dcl} \rightarrow np\ s_{dcl}\backslash np$
Rule + Word	$s_{dcl} \rightarrow np\ s_{dcl}\backslash np$ + bought
Rule + POS	$s_{dcl} \rightarrow np\ s_{dcl}\backslash np$ + VBD
Word-Word	$\langle$company, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np$, bought$\rangle$
Word-POS	$\langle$company, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np$, VBD$\rangle$
POS-Word	$\langle$NN, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np$, bought$\rangle$
Word + Δ_w	$\langle$bought, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np\rangle + d_w$
POS + Δ_w	$\langle$VBD, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np\rangle + d_w$
Word + Δ_p	$\langle$bought, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np\rangle + d_p$
POS + Δ_p	$\langle$VBD, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np\rangle + d_p$
Word + Δ_v	$\langle$bought, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np\rangle + d_v$
POS + Δ_v	$\langle$VBD, $s_{dcl} \rightarrow np\ s_{dcl}\backslash np\rangle + d_v$

Table 1: Baseline features: Basic and dependency features from Clark & Curran's (2007) normal form model; distances are in intervening words, punctuation marks and verbs, and are capped at 3, 3 and 2, respectively

Feature	Example
Animacy features	
Noun Stem + Wh-pronoun	researcher + who
Noun Class + Wh-pronoun	PER_DESC + who

Punctuation feature	
Balanced Punctuation Indicator	$unbalPunct=1

Table 2: New features introduced

NE classes like PER_DESC contribute substantially towards animacy preferences.

For number agreement, we designed three classes of features (c.f. *Number Agr* row in Table 2). Each of these classes results in 4 features. During feature extraction, subjects of the verbs tagged VBZ and VBP and verbs *was, were* were identified using the PTB NP-SBJ function tag annotation projected on to the appropriate arguments of lexical categories of verbs. The first class of features encoded all possible combinations of subject-verb word forms and parts of speech tags. In the case of NPs involving *of*-complements like *a lot of ...* (Examples 5 and 6), feature classes 2 and 3 were extracted (class 1 was excluded). Class 2 features encode the fact that the syntactic head has an associated *of*-complement, while class 3 features also include the part of speech tag of the complement. In the case of conjunct/disjunct VPs and subject NPs, the feature specifically looked at the parts of speech of both the NPs/VPs forming the conjunct/disjunct. The motivation behind such a design was to glean syntactic and semantic generalizations from the data. During feature extraction, from each derivation, counts of animacy and agreement features were obtained.

3.2 Balanced Punctuation

A complex issue that arises in the design of bidirectional grammars is ensuring the proper presentation of punctuation. Among other things, this involves the task of ensuring the correct realization of commas introducing noun phrase appositives.

(9) John, CEO of ABC, loves Mary.
(10) * John, CEO of ABC loves Mary.
(11) Mary loves John, CEO of ABC.
(12) * Mary loves John, CEO of ABC,.
(13) Mary loves John, CEO of ABC, madly.
(14) * Mary loves John, CEO of ABC madly.

As of now, n-gram models rule out examples like 12 above. All the other unacceptable examples are ruled out using a post-filter on realized derivations. As described in White and Rajkumar (2008), the need for the filter arises because a feature-based approach appears to be inadequate for dealing with the class of examples presented above in CCG. This approach involves the incorporation of syntactic features for punctuation into atomic categories so that certain combinations are blocked. To ensure proper appositive balancing sentence finally, the rightmost element in the sentence should transmit a relevant feature to the clause level, which the sentence-final period can then check for the presence of right-edge punctuation. However, the feature schema does not constrain cases of balanced punctuation in cases involving crossing composition and extraction. However, in this paper we explore a statistical approach to ensure proper balancing of NP apposition commas. The first step in this solution is the introduction of a feature in the grammar which indicates balanced vs. unbalanced marks. We modified the result categories of unbalanced appositive commas and dashes to include a feature marking unbalanced punctuation, as follows:

(15) $, \vdash \mathsf{np}_{\langle 1 \rangle unbal=comma} \backslash_\star \mathsf{np}_{\langle 1 \rangle} /_\star \mathsf{np}_{\langle 2 \rangle}$

Then, during feature extraction, derivations were examined to detect categories such as $\mathsf{np}_{unbal=comma}$, and checked to make sure this NP is followed by another punctuation mark in the string such as a full stop. The feature indicates the presence or absence of unbalanced punctuation in the derivation.

4 Evaluation

4.1 Experimental Conditions

For the experiments reported below, we used a lexico-grammar extracted from Sections 02–21 of our enhanced CCGbank with collapsed NEs, a hypertagging model incorporating named entity class features, and a trigram factored language model over words, named entity classes, part-of-speech tags and supertags. Perceptron training events were generated for each training section separately. The hypertagger and POS/supertag language model were trained on all the training sections, while separate word-based models were trained excluding each of the training sections in turn. Event files for 26530 training sentences with complete realizations were generated, with an average n-best list size of 18.2. The complete set of models is listed in Table 3.

Model	Description
full-model	All the feats from models below
agr-punct	Baseline Feats + Punct + Num-Agr
wh-punct	Baseline Feats + Punct + Animacy-Agr
baseline-punct	Baseline Feats + Punct
baseline	Log prob + n-gram +Syntactic features

Table 3: Legend for experimental conditions

4.2 Results

Realization results on the development and test sections are given in Table 4. For the development section, in terms of both exact matches and BLEU scores, the model with all the three features discussed above (agreement, animacy and punctuation) performs better than the baseline which does not have any of these features. However, using these criteria, the best performing model is actually the model which has agreement and punctuation features. The model containing all the features does better than the punctuation-feature only model, but performs slightly worse than the agreement-punctuation model. Section 23, the test section, confirms that the model with all the features performs better than the baseline model. We calculated statistical significance for the main results using bootstrap random sampling.[2] After re-sampling 1000 times, significance was calculated using a paired t-test (999 d.f.). The results indicated that the model with all the features in it (full-model) exceeded the baseline with $p < 0.0001$. However, exact matches and BLEU scores do not necessarily reflect the extent to which important grammatical flaws have been reduced. So to judge the effectiveness of the new features, we computed the percentage of errors of each type that were present in the best Section 00 realization selected by each of these models. Also note that our baseline results differ slightly from the corresponding results reported in White and Rajkumar (2009) in spite of using the same feature set because quotes were introduced into the corpus on which these experiments were conducted. Previous results were based on the original CCGbank text where quotation marks are absent.

Table 6 reports results of the error analysis. It

Model	METEOR	TERP
baseline	0.9819	0.0939
baseline-punct	0.9819	0.0939
wh-punct	0.9827	0.0923
agr-punct	0.9821	0.0902
full-model	0.9826	0.0909

Table 5: Section 00 METEOR and TERP scores

can be seen that the punctuation-feature is effective in reducing the number of sentences with unbalanced punctuation marks. Similarly, the full model has fewer animacy mismatches and just about the same number of errors of the other two types, though it performs slightly worse than the agreement-only model in terms of BLEU scores and exact matches. We also manually examined the remaining cases of animacy agreement errors in the output of the full model here. Of the remaining 18 errors, 14 were acceptable paraphrases involving object relative clauses (eg. wsj_0083.40 ... *the business that*/∅ *a company can generate*). We also provide METEOR and TERP scores for these models (Table 5). In recently completed work on the creation of a human-rated paraphrase corpus to evaluate NLG systems, our analyses showed that BLEU, METEOR and TERP scores correlate moderately with human judgments of adequacy and fluency, and that the most reliable system-level comparisons can be made only by looking at all three metrics.

4.3 Examples

Table 7 presents four examples where the full model differs from the baseline. Example wsj_0003.8 illustrates an example where the NE tag PER_DESC for *researchers* helps the perceptron model enforce the correct animacy agreement, while the two baseline models prefer the

that realization. Example wsj_0003.18 illustrates an instance of simple subject-verb agreement being enforced by the models containing the agreement features. Example wsj_0070.4 presents a more complex situation where a single subject has to agree with both verbs in a conjoined verb phrase. The last example in Table 7 shows the case of a NP subject which is a disjunction of two individual NPs. In both these cases, while the baseline models do not enforce the correct choice, the models with the agreement features do get this right. This is because our agreement features are sensitive to the properties of both NP and VP conjuncts/disjuncts. In addition, most of the realizations involving *of*-complements are also ranked correctly. In the final example sentence provided (i.e. wsj_0018.6), the models with the agreement features are able to enforce the correct the agreement constraints in the phrase *many of the risks were* in contrast to the baseline models.

5 Conclusion

In this paper, we have shown for the first time that incorporating linguistically motivated features to ensure correct animacy and number agreement in a statistical realization ranking model yields significant improvements over a state-of-the-art baseline. While agreement has traditionally been modelled using hard constraints in the grammar, we have argued that using a statistical ranking model is a simpler and more robust approach that is capable of learning competing preferences and cases of acceptable variation. Our approach also approximates insights about agreement which have been discussed in the theoretical linguistics literature. We have also shown how a targeted error analysis can reveal substantial reductions in agreement errors, whose impact on quality no doubt exceeds what is suggested by the small BLEU score increases. As future work, we also plan to learn such patterns from large amounts of unlabelled data and use models learned thus to rank paraphrases.

Abstract

This paper looks at the *web* as a corpus and at the effects of using *web* counts to model language, particularly when we consider them as a domain-specific versus a general-purpose resource. We first compare three vocabularies that were ranked according to frequencies drawn from general-purpose, specialised and *web* corpora. Then, we look at methods to combine heterogeneous corpora and evaluate the individual and combined counts in the automatic extraction of noun compounds from English general-purpose and specialised texts. Better *n*-gram counts can help improve the performance of empirical NLP systems that rely on *n*-gram language models.

1 Introduction

Corpora have been extensively employed in several NLP tasks as the basis for automatically learning models for language analysis and generation. In theory, *data-driven* (*empirical* or *statistical*) approaches are well suited to take intrinsic characteristics of human language into account. In practice, external factors also determine to what extent they will be popular and/or effective for a given task, so that they have shown different performances according to the availability of corpora, to the linguistic complexity of the task, etc.

An essential component of most empirical systems is the *language model* (LM) and, in particular, *n-gram language models*. It is the LM that tells the system how likely a word or *n*-gram is in that language, based on the counts obtained from corpora. However, corpora represent a sample of a language and will be sparse, i.e. certain words or expressions will not occur. One alternative to minimise the negative effects of data sparseness and account for the probability of out-of-vocabulary words is to use discounting techniques, where a constant probability mass is discounted from each *n*-gram and assigned to unseen *n*-grams. Another strategy is to estimate the probability of an unseen *n*-gram by backing off to the probability of the smaller *n*-grams that compose it.

In recent years, there has also been some effort in using the *web* to overcome data sparseness, given that the *web* is several orders of magnitude larger than any available corpus. However, it is not straightforward to decide whether (a) it is better to use the *web* than a standard corpus for a given task or not, and (b) whether corpus and *web* counts should be combined and how this should be done (e.g. using interpolation or back-off techniques). As a consequence there is a strong need for better understanding of the impacts of *web* frequencies in NLP systems and tasks.

More reliable ways of combining word counts could improve the quality of empirical NLP systems. Thus, in this paper we discuss *web*-based word frequency distributions (§ 2) and investigate to what extent "*web*-as-a-corpus" approaches can be employed in NLP tasks compared to standard corpora (§ 3). Then, we present the results of two experiments. First, we compare word counts drawn from general-purpose corpora, from specialised corpora and from the *web* (§ 4). Second, we propose several methods to combine data from heterogeneous corpora (§ 5), and evaluate their effectiveness in the context of a specific multiword

expression task: automatic noun compound identification. We close this paper with some conclusions and future work (§ 6).

2 The *web* as a corpus

Conventional and, in particular, domain-specific corpora, are valuable resources which provide a closed-world environment where precise *n*-gram counts can be obtained. As they tend to be smaller than general purpose corpora, data sparseness can considerably hinder the results of statistical methods. For instance, in the biomedical Genia corpus (Ohta et al., 2002), 45% of the words occur only once (so-called *hapax legomena*), and this is a very poor basis for a statistical method to decide whether this is a significant event or just random noise.

One possible solution is to see the *web* as a very large corpus containing pages written in several languages and being representative of a large fraction of human knowledge. However, there are some differences between using regular corpora and the *web* as a corpus, as discussed by Kilgarriff (2003). One assumption, in particular, is that page counts can approximate word counts, so that the total number of pages is used as an estimator of the *n*-gram count, regardless of how many occurrences of the *n*-gram they contain.

This simple underlying assumption has been employed for several tasks. For example, Grefenstette (1999), in the context of example-based machine translation, uses *web* counts to decide which of a set of possible translations is the most natural one for a given sequence of words (e.g. *groupe de travail* as *work group* vs *labour collective*). Likewise, Keller and Lapata (2003) use the *web* to estimate the frequencies of unseen nominal bigrams, while Nicholson and Baldwin (2006) look at the interpretation of noun compounds based on the individual counts of the nouns and on the global count of the compound estimated from the *web* as a large corpus.

Villavicencio et al. (2007) show that the *web* and the British National Corpus (BNC) could be used interchangeably to identify general-purpose and type-independent multiword expressions. Lapata and Keller (2005) perform a careful and systematic evaluation of the *web* as a corpus in other general-purpose tasks both for analysis and generation, comparing it with a standard corpus (the BNC) and using two different techniques to combine them: linear interpolation and back-off. Their results show that, while *web* counts are not as effective for some tasks as standard counts, the combined counts can generate results, for most tasks, that are as good as the results produced by the best individual corpus between the BNC and the *web*. Nakov (2007) further investigates these tasks and finds that, for many of them, effective attribute selection can produce results that are at least comparable to those from the BNC using counts obtained from the *web*.

On the one hand, the *web* can minimise the problem of sparse data, helping distinguish rare from invalid cases. Moreover, a search engine allows access to ever increasing quantities of data, even for rare constructions and words, which counts are usually equated to the number of pages in which they occur. On the other hand, *n*-grams in the highest frequency ranges, such as the words *the*, *up* and *down*, are often assigned the estimated size of the *web*, uniformly. While this still gives an idea of their massive occurrence, it does not provide a finer grained distinction among them (e.g. in the BNC, *the*, *down* and *up* occur 6,187,267, 84,446 and 195,426 times, respectively, while in Yahoo! they all occur in 2,147,483,647 pages).

3 Standard vs *web* corpora
