Preface

You will find in this volume papers from the 23rd International Conference on Computational Linguistics (COLING 2010) held in Beijing, China on August 23-27, 2010 under the auspices of the International Committee on Computational Linguistics (ICCL), and organized by the Chinese Information Processing Society (CIPS) of China. For this prestigious natural language processing conference to be held in China is a significant event for computational linguistics and for colleagues in China, demonstrating both the maturity of our field and the development of academic areas in China.

COLING started as a friendly gathering in New York in 1965, and has grown steadily since. Yet COLINGs aspiration to be a different conference remains the same. COLING strives to maintain its key qualities of embracing different theories and encouraging young scholars in spite of its growing size. A new component introduced at COLING 2010 underlines this quality. A RefreshINGenious (RING) session, organized by Aravind Joshi, our General Chair, allows new and un-orthodox ideas to be presented before they are fully developed in order to generate more discussion and stimulate other new ideas. We hope that this can become an important feature of COLING in the future.

The 155 oral papers included in the hardcopy proceedings published by Tsinghua University Press, as well as the 334 papers included in the electronic proceedings (the same 155 oral papers plus 179 poster papers) are selected from among 815 effective submissions among the more than 840 submissions received. The very selective acceptance rate of 19.02% for oral presentations (155/815 submissions) indicates the extremely high quality of the papers. An additional 21.96% (179/815) are selected for poster presentations to bring the overall acceptance rate to 40.98% (334/815).

We would like to thank the program committee area chairs for their dedicated and efficient review work, and our 738 reviewers for giving us very high quality reviews with a very short turnaround time, allowing us to maintain both the review quality and schedule even given the extraordinary number of submissions. Of course we thank the authors of the 840 papers for submitting their labor of love to COLING. Although we were only able to accept a minority of the submitted papers, we do hope that all authors and reviewers benefit from this process of indirect dialogue. We are especially grateful to the incredibly hard-working team of Stanford volunteers Jenny Finkel, Adam Vogel, and Mengqiu Wang, and HIT volunteers Sam Liang and Lemon Liu, who provided timely and efficient support for the two program chairs at every step of the review and publication processes.

Last but not least, we would like to thank the people who made COLING 2010 and this volume possible. We thank local arrangement committee co-chairs Professor Chengqing Zong and Professor Le Sun for their tireless work which will make COLING-2010 a sure success. Our special appreciation goes to the Chinese Information Processing Society (CIPS) and Professor Youqi Cao for their generous support as the COLING 2010 organizer. Lastly, Professor Qin Lu and Professor Tiejun Zhao should be recognized for their meticulous preparation for editing and publication, which brought this volume to reality.

Chu-Ren Huang and Dan Jurafsky,
COLING 2010 Program Committee Co-chairs

July 8, 2010

COLING 2010 is organized by the Chinese Information Processing Society of China (**CIPS**) and under the auspices of the International Committee on Computational Linguistics (**ICCL**).

General Chair:

Aravind K .Joshi (University of Pennsylvania)

Program Chairs:

Chu-Ren Huang (The Hong Kong Polytechnic University)
Dan Jurafsky (Stanford University)

Advisors to Organizing Committee:

Youqi Cao (The Chinese Information Processing Society of China)
Zhendong Dong (The Chinese Information Processing Society of China)
Changning Huang (Microsoft Research Asia)
Sheng Li (Harbin Institute of Technology)
TianshunYao (Northeastern University)
Shiwen Yu (Peking University)
Zhiwei Feng (Institute of Applied Linguistics, Ministry of Education)
Kaiying Liu (Shanxi University)

OrganizationChairs:

Chengqing Zong (Institute of Automation, Chinese Academy of Sciences)
Le Sun (Institute of Software, Chinese Academy of Sciences)

Publication Chairs:

Qin Lu (The Hong Kong Polytechnic University)
Tiejun Zhao (Harbin Institute of Technology)

Tutorial Chairs:

Dan Gildea (University of Rochester)
Xuanjing Huang (Fudan University)

Workshop Chairs:

Noah Smith (Carnegie Mellon University)
Takenobu Tokunaga (Tokyo Institute of Technology)
Haifeng Wang (BaiDu)

Publicity Chairs:

Hal Daumé III (University of Utah)
Bin Wang (Institute of Computing Technology, Chinese Academy of Sciences)
Minghui Dong (Institute for Infocomm Research)
Monica Monachini (Institute for Computational Linguistics)

Aline Villavicencio (Federal University of Rio Grande do Sul)

Sponsorship Chairs:

Tingting He (Huazhong Normal University)
Hinrich Schütze (University of Stuttgart)
Key-Sun Choi (Korea Advanced Institute of Science and Technology)
Rion Snow (Stanford University)
Takehito Utsuro (University of Tsukuba)
Renata Vieira (Pontifical Catholic University of Rio Grande do Sul)
Hao Yu (Fujitsu(China) R&D Center)

Demo Chairs:

Ting Liu (Harbin Institute of Technology)
Yang Liu (The University of Texas at Dallas)

Program Committee Members/AreaChairs:

Nianwen Xue (Brandeis University)
Rajeev Sangal (India Institute of Information Technology)
Roger Levy (University of California, San Diego)
Justine Cassell (Northwestern University)
Caroline Sporleder (Saarland University)
Gary Geunbae Lee (Pohang University of Science and Technology)
Rosie Jones (Yahoo! Research)
Nicoletta Calzolari (Istituto di Linguistica Computazionale)
Chris Callison-Burch (Johns Hopkins University)
Qun Liu (Institute of Computing Technology)
Pierre Isabelle (National Research Council of Canada)
Sadao Kurohashi (Kyoto University)
Sebastian Padó (Universität Stuttgart)
Takenobu Tokunaga (Tokyo Institute of Technology)
Bo Pang (Yahoo! Research)
Haizhou Li (Institute for Infocomm Research)
David A Smith (University of Massachusetts, Amherst)
Donia Scott (University of Sussex)
Emily Bender (University of Washington)
Ming Zhou (Microsoft Research Asia)

Organization Committee Members:

Juanzi Li (Tsinghua University)
KWONG Olivia (Hong Kong City University)
Bin Sun (Peking University)
Houfeng Wang (Peking University)
Xiaojie Wang (Beijing University of Posts and Telecommunications)
Endong Xun (Beijing Language and Culture University)
Erhong Yang (Beijing Language and Culture University)
Jun Zhao (Institute of Automation, Chinese Academy of Sciences)
Jingbo Zhu (Northeastern University)

Abstract

There exists a well-established and almost unanimously adopted measure of tagger performance, namely, accuracy. Although it is perfectly adequate for small tagsets and typical approaches to disambiguation, we show that it is deficient when applied to rich morphological tagsets and propose various extensions designed to better correlate with the real usefulness of the tagger.

1 Introduction

Part-of-Speech (PoS) tagging is probably the most common and best researched NLP task, the first step in many higher level processing solutions such as parsing, but also information retrieval, speech recognition and machine translation. There are also well established evaluation measures, the foremost of which is accuracy, i.e., the percent of words for which the tagger assigns the correct — in the sense of some gold standard — interpretation.

Accuracy works well for the original PoS tagging task, where each word is assumed to have exactly one correct tag, and where the information carried by a tag is limited roughly to the PoS of the word and only very little morphosyntactic information, as in typical tagsets for English. However, there are two cases where accuracy becomes less than adequate: the situation where the gold standard and / or the tagging results contain multiple tags marked as correct for a single word, and the use of a rich morphosyntactic (or morphological) tagset.

The first possibility is discussed in detail in (Karwańska and Przepiórkowski, 2009), but the need for an evaluation measure for taggers which do not necessarily fully disambiguate PoS was already noted in (van Halteren, 1999), where the use of standard information retrieval measures precision and recall (as well as their harmonic mean, the F-measure) is proposed. Other natural generalisations of the accuracy measure, able to deal with non-unique tags either in the gold standard[1] or in the tagging results, are proposed in (Karwańska and Przepiórkowski, 2009).

Standard accuracy is less than adequate also in case of rich morphosyntactic tagsets, where the full tag carries information not only about PoS, but also about case, number, gender, etc. Such tagsets are common for Slavic languages, but also for Hungarian, Arabic and other languages. For example, according to one commonly used Polish tagset (Przepiórkowski and Woliński, 2003), the form *uda* has the following interpretations: `fin:sg:ter:perf` (a finite singular 3rd person perfective form of the verb UDAĆ 'pretend'), `subst:pl:nom:n` and

[1] There are cases were it makes sense to manually assign a number of tags as correct to a given word, as any decision would be fully arbitrary, regardless of the amount of context and world knowledge available. For example, in some Slavic languages, incl. Polish, there are verbs which optionally subcategorise for an accusative or a genitive complement, without any variation in meaning, and there are nouns which are syncretic between these two cases, so for such "verb + $\text{noun}_{\text{acc/gen}}$" sequences it is impossible to fully disambiguate case; see also (Oliva, 2001).

Coling 2008: Poster Volume, pages 1–8,
Beijing, August 2010

subst:pl:acc:n (nominative or accusative plural form of the neuter noun UDO 'thigh'). Now, assuming that the right interpretation in a given context is subst:pl:acc:n, accuracy will equally harshly penalise the other nominal interpretation (subst:pl:nom:n), which shares with the correct interpretation not only PoS, but also the values of gender and number, and the completely irrelevant verbal interpretation. A more accurate tagger evaluation measure should distinguish these two non-optimal assignments and treat subst:pl:nom:n as partially correct.

Similarly, the Polish tagset mentioned above distinguishes between nouns and gerunds, with some forms actually ambiguous between these two interpretations. For example, *zadanie* may be interpreted as a nominative or accusative form of the noun ZADANIE 'task', or a nominative or accusative form of the gerund derived from the verb ZADAĆ 'assign'. Since gerunds and nouns have very similar distributions, any error in the assignment of part of speech, noun vs. gerund, will most probably not matter for a parser of Polish — it will still be able to construct the right tree, provided the case is correctly disambiguated. However, the "all-or-nothing" nature of the accuracy measure regards the tag differing from the correct one only in part of speech or in case as harshly, as it would regard an utterly wrong interpretation, say, as an adverb.

In what follows we propose various evaluation measures which differentiate between better and worse incorrect interpretations, cf. § 2. The implementation of two such measures is described in § 3. Finally, § 4 concludes the paper.

2 Proposed Measures

2.1 Full Interpretations and PoS

The first step towards a better accuracy measure might consist in calculating two accuracy measures: one for full tags, and the other only for fragments of tags representing parts of speech. Two taggers wrongly assigning either fin:sg:ter:perf (T1) or subst:pl:nom:n (T2) instead of the correct subst:pl:acc:n would fare equally well with respect to the tag-level accuracy, but T2 would be — rightly — evaluated as better with respect to the PoS-level accuracy.

The second example given in § 1 shows, however, that the problem is more general and that a tagger which gets the PoS wrong (say, gerund instead of noun) but all the relevant categories (case, number, gender) right may actually be more useful in practice than the one that gets the PoS right at the cost of confusing cases (say, accusative instead of nominative).

2.2 Positional Accuracy

A generalisation of the idea of looking separately at parts of speech is to split tags into their components (or positions) and measure the correctness of the tag by calculating the F-measure. For example, if the (perfective, affirmative) gerundial interpretation ger:sg:nom:n:perf:aff is assigned instead of the correct nominal interpretation subst:sg:nom:n, the tags agree on 3 positions (sg, nom, n), so the precision is $\frac{3}{6}$, the recall — $\frac{3}{4}$, which gives the F-measure of 0.6. Obviously, the assignment of the correct interpretation results in F-measure equal 1.0, and the completely wrong interpretation gives F-measure 0.0. Taking these values instead of the "all-or-nothing" 0 or 1, accuracy is reinterpreted as the average F-measure over all tag assignments.

Note that while this measure, let us call it *positional accuracy* (PA), is more fine-grained than the standard accuracy, it wrongly treats all components of tags as of equal importance and difficulty. For example, there are many case syncretisms in Polish, but practically no ambiguities concerning the category of negation (see the value aff above), so case is inherently much more difficult than negation, and also much more important for syntactic parsing, and as such it should carry more weight when evaluating tagging results.

2.3 Weighted Positional Accuracy

In the current section we make a simplifying assumption that weights of positions are absolute, rather than conditional, i.e., that the weight of, say, case does not depend on part of speech, word or context. Once the weights are attained, weighted precision and recall may be used as in the following example.

Assume that PoS, case, number and gender have the same weight, say 2.0, which is 4 times larger than that of any other category. Then, in case `ger:sg:nom:n:perf:aff` is assigned instead of the correct `subst:sg:nom:n`, precision and recall are given by:

$$P = \frac{3 \times 2.0}{4 \times 2.0 + 2 \times 0.5} = \frac{2}{3},$$
$$R = \frac{3 \times 2.0}{4 \times 2.0} = \frac{3}{4}.$$

This results in a higher F-measure than in case of non-weighted positional accuracy.

The following subsections propose various ways in which the importance of particular grammatical categories and of the part of speech may be estimated.

2.3.1 Average Ambiguity

The average number of morphosyntactic interpretations per word is sometimes given as a rough measure of the difficulty of tagging. For example, tagging English texts with the Penn Treebank tagset is easier than tagging Czech or Polish, as the average number of possible tags per word is 2.32 in English (Hajič, 2004, p. 171), while it is 3.65 (Hajič and Hladká, 1997, p. 113) and 3.32 (Przepiórkowski, 2008, p. 44) for common tagsets for Czech and Polish, respectively.

By analogy, one measure of the difficulty of assigning the right value of a given category or part of speech is the average number of different values of the category per word.

2.3.2 Importance for Parsing

All measures mentioned so far are *intrinsic* (*in vitro*) evaluation measures, independent — but hopefully correlated with — the usefulness of the results in particular applications. On the other hand, *extrinsic* (*in vivo*) evaluation estimates the usefulness of tagging in larger systems, e.g., in parsers. Full-scale extrinsic evaluation is rarely used, as it is much more costly and often requires user evaluation of the end system.

In this and the next subsections we propose evaluation measures which combine the advantages of both approaches. They are variants of the weighted positional accuracy (WPA) measure, where weights correspond to the usefulness of a given category (or PoS) for a particular task.

Probably the most common task taking advantage of morphosyntactic tagging is syntactic parsing. Here, weights should indicate to what extent the parser relies on PoS and particular categories to arrive at the correct parse. Such weights may be estimated from an automatically parsed corpus in the following way:

for each category (including PoS) c **do**
  $\mathrm{count}(c) = 0$ {Initialise counts.}
end for
for each sentence s **do**
  for each rule r used in s **do**
    for each terminal symbol (word) t in the RHS of r **do**
      for each category c referred to by r in t **do**
        increase $\mathrm{count}(c)$
      end for
    end for
  end for
end for
{Use $\mathrm{count}(c)$'s as weights.}

In prose: whenever a syntactic rule is used, increase counts of all morphosyntactic categories (incl. PoS) mentioned in the terminal symbols occurring in this rule. These counts may be normalised or used directly as weights.

We assume here that either the parser produces a single parse for any sentence (assumption realistic only in case of shallow parsers), or that the best or at least most probable parse may be selected automatically, as in case of probabilistic grammars, or that parses are disambiguated manually. In case only a non-probabilistic deep parser is available, and parses are not disambiguated manually, the Expectation-Maximisation method may be used to select a probable parse (Dębowski, 2009) or all parses might be taken into account.

Note that, once a parser is available, such weights may be calculated automatically and used repeatedly for tagger evaluation, so the cost of using this measure is not significantly higher than the cost of intrinsic measures, while at the same time the correlation of the evaluation results with the extrinsic application is much higher.

2.3.3 Importance for Corpus Search

The final variant (many more are imaginable) of WPA that we would like to describe here concerns another application of tagging, namely, for the annotation of corpora. Various corpus search engines, including the IMS Open Corpus Workbench (`http://cwb.sourceforge.net/`) and Poliqarp (`http://poliqarp.sourceforge.net/`) allow the user to search for particular parts of speech and grammatical categories. Obviously, the tagger should maximise the quality of the disambiguation of those categories which occur frequently in corpus queries, i.e., the weights should correspond to the frequencies of particular categories (and PoS) in user queries. Note that the only resource needed to calculate weights are the logs of a corpus search engine.

An experiment involving an implementation of this measure is described in detail in § 3.

2.4 Conditional Weighted Positional Accuracy

The importance and difficulty of a category may depend on the part of speech. For example, after case syncretisms, gender ambiguity is one of the main problems for the current taggers of Polish. But this problem concerns mainly pronouns and adjectives, where the systematic gender syncretism is high. On the other hand, nouns do not inflect for gender, so only some nominal forms are ambiguous with respect to gender. Moreover, gerunds, which also bear gender, are uniformly neuter, so here part of speech alone uniquely determines the value of this category.

A straightforward extension of WPA capitalising on these observations is what we call *conditional weighted positional accuracy* (CWPA), where weights of morphosyntactic categories are conditioned on PoS.

Note that not all variants of WPA may be easily generalised to CWPA; although such an extension is obvious for the average ambiguity (§ 2.3.1), it is less clear for the other two variants. For parsing-related WPA, we assume that, even if a given rule does not mention the PoS of a terminal symbol,[2] that PoS may be read off the parse tree, so the conditional weights may still be calculated. On the other hand, logs of a corpus search engine are typically not sufficient to calculate such conditional weights; e.g., a query for a sequence of 5 genitive words occurring in logs would have to be rerun on the corpus again in order to find out parts of speech of the returned 5-word sequences. For a large number of queries on a large corpus, this is a potentially costly operation.

It is also not immediately clear how to generalise precision and recall from WPA to CWPA. Returning to the example above, where t_1 = `ger:sg:nom:n:perf:aff` is assigned instead of the correct t_2 = `subst:sg:nom:n`, we note that the weights of number, case and gender may now (and should, at least in case of gender!) be different for the two parts of speech involved. Hence, precision needs to be calculated with respect to the weights for the automatically assigned part of speech, and recall — taking into account weights for the gold standard part of speech:

$$P = \frac{\delta_{t_1^* t_2^*} w(t_1^*) + \sum_{c \in C(t_1,t_2)} \delta_{t_1^c t_2^c} w(c|t_1^*)}{w(t_1^*) + \sum_{c \in C(t_1)} w(c|t_1^*)},$$
$$R = \frac{\delta_{t_1^* t_2^*} w(t_2^*) + \sum_{c \in C(t_1,t_2)} \delta_{t_1^c t_2^c} w(c|t_2^*)}{w(t_2^*) + \sum_{c \in C(t_2)} w(c|t_2^*)},$$

where t^* is the PoS of tag t, $w(p)$ is the weight of the part of speech p, $w(c|p)$ is the conditional weight of the category c for PoS p, $C(t)$ is the set of morphosyntactic categories of tag t, $C(t_1, t_2)$ is the set of morphosyntactic categories common to tags t_1 and t_2, t^c is the value of category c in tag t, and δ_{ij} is the Kronecker delta (equal to 1 if $i = j$, and to 0 otherwise). Hence, for the example above, these formulas may be simplified to:

$$P = \frac{\sum_{c \in \{n,c,g\}} w(c|\texttt{ger})}{w(\texttt{ger}) + \sum_{c \in \{n,c,g,a,neg\}} w(c|\texttt{ger})},$$
$$R = \frac{\sum_{c \in \{n,c,g\}} w(c|\texttt{subst})}{w(\texttt{subst}) + \sum_{c \in \{n,c,g\}} w(c|\texttt{subst})},$$

where *n*, *c*, *g*, *a* and *neg* stand for number, case, gender, aspect and negation.

[2] For example, in unification grammars and constraint-based grammars a terminal may be identified only by the values of some of its categories, as in the following simple rule, specifying prepositional phrases as a preposition governing a specific case and a non-empty sequence of words bearing that case: $\mathrm{PP}_{\mathrm{case=C}} \rightarrow \mathrm{P}_{\mathrm{case=C}}\ \mathrm{X}^{+}_{\mathrm{case=C}}$.

3 Experiment

To evaluate behaviour of the proposed metrics, a number of experiments were performed using the manually disambiguated part of the IPI PAN Corpus of Polish (Przepiórkowski, 2005). This subcorpus consists of 880 000 segments. Two taggers of Polish were tested. TaKIPI (Piasecki and Godlewski, 2006) is a tagger which was used for automatic disambiguation of the remaining part of the aforementioned corpus. It is a statistical classifier based on decision trees combined with some automatically extracted, hand-crafted rules. This tagger by default sometimes assigns more than one tag to a segment, what is consistent with the golden standard. There is a setting which allows this behaviour to be switched off. This tagger was tested with both settings. The other tagger is a prototype version of this Brill tagger, presented by Acedański and Gołuchowski in (Acedański and Gołuchowski, 2009).

For comparison, four metrics were used: standard metrics for full tags and only parts of speech, as well as Positional Accuracy and Weighted Positional Accuracy. For the last measure, the weights were obtained by analysing logs of user queries of the Poliqarp corpus search engine. Occurrences of queries involving particular grammatical categories were counted and used as weights. Obtained results are presented in Table 1.

Table 1: Occurrences of particular grammatical categories in query logs of the Poliqarp corpus search engine.

Category	# occurrences
POS	37771
CASE	14055
NUMBER	2074
GENDER	552
ASPECT	222
PERSON	186
DEGREE	81
ACCOMMODABILITY	25
POST-PREP.	8
NEGATION	7
ACCENTABILITY	5
AGGLUTINATION	4

3.1 Scored information retrieval metrics

In § 2 a number of methods of assigning a score to a pair of tags were presented. From now on, let name them *scoring functions*. One could use them directly for evaluation, given that both the tagger and the golden standard always assign a single interpretation to each segment. This is not the case for the corpus we use, hence we propose generalisation of standard information retrieval metrics (precision, recall and F-measure) as well as strong and weak correctness (Karwańska and Przepiórkowski, 2009) to account for scoring functions.

Denote by T_i and G_i the sets of tags assigned by the tagger and the golden standard, accordingly, to the i-th segment of the tagged text. The set of all tags in the tagset is denoted by $\mathbf{T}$. The scoring function used is $score\colon \mathbf{T} \times \mathbf{T} \to [0, 1]$. Also, to save up on notation, we define

$$score(t, A) := \max_{t' \in A} score(t, t')$$

Now, given the text has n segments, we take

$$P = \frac{\sum_{i=1}^{n} \sum_{t \in T_i} score(t, G_i)}{\sum_{i=1}^{n} |T_i|}$$

$$R = \frac{\sum_{i=1}^{n} \sum_{g \in G_i} score(g, T_i)}{\sum_{i=1}^{n} |G_i|}$$

$$F = \frac{2 \cdot P \cdot R}{P + R}$$

$$WC = \frac{\sum_{i=1}^{n} \max_{t \in T_i} score(t, G_i)}{n}$$

$$SC = \frac{\sum_{i=1}^{n} \min(\{score(t, G_i)\colon t \in T_i\} \cup \{score(g, T_i)\colon g \in G_i\})}{n}$$

Intuitions for scored precision and recall are that precision specifies the percent of tags assigned by the tagger which have a high score with some corresponding golden tag. Analogously recall estimates the percent of golden tags which have high scores with some corresponding tag assigned by the tagger. The definition of recall is slightly different than proposed by Ziółko et al. (Ziółko et al., 2007) so that recall is never greater than one.[3]

[3] For example if the golden standard specifies a single tag and the tagger determines two tags which all score 0.6 when compared with the golden, then if we used equations from Ziółko et al., we would get the recall of 1.2.

3.2 Evaluation results

Now the taggers were trained on the same data consisting of 90% segments of the corpus and then tested on the remaining 10%. Results were 10-fold cross-validated. They are presented in Tables 2, 3, 4 and 5.

As expected, the values obtained with PA and WPA fall between the numbers for standard metrics calculated with full tags and only the part of speech. What is worth observing is that the use of WPA makes values for scored precision and recall much closer together. This can be justified by the fact that the golden standard relatively frequently contains more than one interpretation for some tags, which differ only in values of less important grammatical categories. WPA is resilient to such situations.

One may argue that such scoring functions may hide a large number of tagging mistakes occurring in low-weighted categories. But this is not the case as the clearly most common tagging errors reported in both (Piasecki and Godlewski, 2006) and (Acedański and Gołuchowski, 2009) are for CASE, GENDER and NUMBER. Also, the motivation for weighting grammatical categories is to actually ignore errors in not important ones. To be fair, though, one should make sure that the weights used for evaluation match the actual application domain of the analysed tagger, and if no specific domain is known, using a number of measures is recommended.

It should also be noted that for classic information retrieval metrics, the result of weak correctness for TaKIPI is more similar to 92.55% reported by the authors (Piasecki and Godlewski, 2006) than 91.30% shown in (Karwańska and Przepiórkowski, 2009) despite using the same test corpus and very similar methodology[4] as the second paper presents.

4 Conclusion

This paper stems from the observation that the commonly used measure for tagger evaluation, i.e., accuracy, does not distinguish between completely incorrect and partially correct interpretations, even though the latter may be sufficient for some applications. We proposed a way of grading tag assignments, by weighting the importance of particular categories (case, number, etc.) and the part of speech. Three variants of the weighted positional accuracy were presented: one intrinsic and two application-oriented, and an extension of WPA to conditional WPA was discussed. The variant of WPA related to the needs of the users of a corpus search engine for the National Corpus of Polish was implemented and its usefulness was demonstrated. We plan to implement the parsing-oriented WPA in the future.

We conclude that tagger evaluation is far from being a closed chapter and the time has come to adopt more subtle approaches than sheer accuracy, approaches able to cope with morphological richness and oriented towards real applications.

[4]The only difference was not contracting the grammatical category of ACCOMMODABILITY present for masculine numerals in the golden standard.

Abstract

The use of semantic information to improve IR is a long-standing goal. This paper presents a novel Document Expansion method based on a WordNet-based system to find related concepts and words. Expansion words are indexed separately, and when combined with the regular index, they improve the results in three datasets over a state-of-the-art IR engine. Considering that many IR systems are not robust in the sense that they need careful fine-tuning and optimization of their parameters, we explored some parameter settings. The results show that our method is specially effective for realistic, non-optimal settings, adding robustness to the IR engine. We also explored the effect of document length, and show that our method is specially successful with shorter documents.

1 Introduction

Since the earliest days of IR, researchers noted the potential pitfalls of keyword retrieval, such as synonymy, polysemy, hyponymy or anaphora. Although in principle these linguistic phenomena should be taken into account in order to obtain high retrieval relevance, the lack of algorithmic models prohibited any systematic study of the effect of this phenomena in retrieval. Instead, researchers resorted to distributional semantic models to try to improve retrieval relevance, and overcome the brittleness of keyword matches. Most research concentrated on Query Expansion (QE) methods, which typically analyze term co-occurrence statistics in the corpus and in the highest scored documents for the original query in order to select terms for expanding the query terms (Manning et al., 2009). Document expansion (DE) is a natural alternative to QE, but surprisingly it was not investigated until very recently. Several researchers have used distributional methods from similar documents in the collection in order to expand the documents with related terms that do not actually occur in the document (Liu and Croft, 2004; Kurland and Lee, 2004; Tao et al., 2006; Mei et al., 2008; Huang et al., 2009). The work presented here is complementary, in that we also explore DE, but use WordNet instead of distributional methods.

Lexical semantic resources such as WordNet (Fellbaum, 1998) might provide a principled and explicit remedy for the brittleness of keyword matches. WordNet has been used with success in psycholinguistic datasets of word similarity and relatedness, where it often surpasses distributional methods based on keyword matches (Agirre et al., 2009b). WordNet has been applied to IR before. Some authors extended the query with related terms (Voorhees, 1994; Liu et al., 2005), while others have explicitly represented and indexed word senses after performing word sense disambiguation (WSD) (Gonzalo et al., 1998; Stokoe et al., 2003; Kim et al., 2004). More recently, a CLEF task was organized (Agirre et al., 2008; Agirre et al., 2009a) where queries and documents were semantically disambiguated, and participants reported mixed results.

This paper proposes to use WordNet for document expansion, proposing a new method: given

Coling 2008: Poster Volume, pages 9–17,
Beijing, August 2010

a full document, a random walk algorithm over the WordNet graph ranks concepts closely related to the words in the document. This is in contrast to previous WordNet-based work which focused on WSD to replace or supplement words with their senses. Our method discovers important concepts, even if they are not explicitly mentioned in the document. For instance, given a document mentioning *virus*, *software* and *DSL*, our method suggests related concepts and associated words such us *digital subscriber line*, *phone company* and *computer*. Those expansion words are indexed separately, and when combined with the regular index, we show that they improve the results in three datasets over a state-of-the-art IR engine (Boldi and Vigna, 2005). The three datasets used in this study are ResPubliQA (Peñas et al., 2009), Yahoo! Answers (Surdeanu et al., 2008) and CLEF-Robust (Agirre et al., 2009a).

Considering that many IR systems are not robust in the sense that they need careful fine-tuning and optimization of their parameters, we decided to study the robustness of our method, exploring some alternative settings, including default parameters, parameters optimized in development data, and parameters optimized in other datasets. The study reveals that the additional semantic expansion terms provide robustness in most cases.

We also hypothesized that semantic document expansion could be most profitable when documents are shorter, and our algorithm would be most effective for collections of short documents. We artificially trimmed documents in the Robust dataset. The results, together with the analysis of document lengths of the three datasets, show that document expansion is specially effective for very short documents, but other factors could also play a role.

The paper is structured as follows. We first introduce the document expansion technique. Section 3 introduces the method to include the expansions in a retrieval system. Section 4 presents the experimental setup. Section 5 shows our main results. Sections 6 and 7 analyze the robustness and relation to document length. Section 8 compares to related work. Finally, the conclusions and future work are mentioned.

2 Document Expansion Using WordNet

Our key insight is to expand the document with related words according to the background information in WordNet (Fellbaum, 1998), which provides generic information about general vocabulary terms. WordNet groups nouns, verbs, adjectives and adverbs into sets of synonyms (synsets), each expressing a distinct concept. Synsets are interlinked with conceptual-semantic and lexical relations, including hypernymy, meronymy, causality, etc.

In contrast with previous work, we select those concepts that are most closely related to the document as a whole. For that, we use a technique based on random walks over the graph representation of WordNet concepts and relations.

We represent WordNet as a graph as follows: graph nodes represent WordNet concepts (synsets) and dictionary words; relations among synsets are represented by undirected edges; and dictionary words are linked to the synsets associated to them by directed edges. We used version 3.0, with all relations provided, including the gloss relations. This was the setting obtaining the best results in a word similarity dataset as reported by Agirre et al. (2009b).

Given a document and the graph-based representation of WordNet, we obtain a ranked list of WordNet concepts as follows:

1. We first pre-process the document to obtain the lemmas and parts of speech of the open category words.
2. We then assign a uniform probability distribution to the terms found in the document. The rest of nodes are initialized to zero.
3. We compute personalized PageRank (Haveliwala, 2002) over the graph, using the previous distribution as the reset distribution, and producing a probability distribution over WordNet concepts The higher the probability for a concept, the more related it is to the given document.

Basically, personalized PageRank is computed by modifying the random jump distribution vector in the traditional PageRank equation. In our case, we concentrate all probability mass in the concepts corresponding to the words in the docu-

ment.

Let G be a graph with N vertices $v_1, \ldots, v_N$ and d_i be the outdegree of node i; let M be a $N \times N$ transition probability matrix, where $M_{ji} = \frac{1}{d_i}$ if a link from i to j exists, and zero otherwise. Then, the calculation of the *PageRank vector* $\mathbf{Pr}$ over G is equivalent to resolving Equation (1).

$$\mathbf{Pr} = cM\mathbf{Pr} + (1-c)\mathbf{v} \quad (1)$$

In the equation, $\mathbf{v}$ is a $N \times 1$ vector and c is the so called *damping factor*, a scalar value between 0 and 1. The first term of the sum on the equation models the voting scheme described in the beginning of the section. The second term represents, loosely speaking, the probability of a surfer randomly jumping to any node, e.g. without following any paths on the graph. The damping factor, usually set in the $[0.85..0.95]$ range, models the way in which these two terms are combined at each step.

The second term on Eq. (1) can also be seen as a smoothing factor that makes any graph fulfill the property of being aperiodic and irreducible, and thus guarantees that PageRank calculation converges to a unique stationary distribution.

In the traditional PageRank formulation the vector $\mathbf{v}$ is a stochastic normalized vector whose element values are all $\frac{1}{N}$, thus assigning equal probabilities to all nodes in the graph in case of random jumps. In the case of personalized PageRank as used here, $\mathbf{v}$ is initialized with uniform probabilities for the terms in the document, and 0 for the rest of terms.

PageRank is actually calculated by applying an iterative algorithm which computes Eq. (1) successively until a fixed number of iterations are executed. In our case, we used a publicly available implementation[1], with default values for the damping value (0.85) and the number of iterations (30). In order to select the expansion terms, we chose the 100 highest scoring concepts, and get all the words that lexicalize the given concept.

Figure 1 exemplifies the expansion. Given the short document from Yahoo! Answers (cf. Section 4) shown in the top, our algorithm produces the set of related concepts and words shown in the bottom. Note that the expansion produces synonyms, but also other words related to concepts that are not mentioned in the document.

[1] http://ixa2.si.ehu.es/ukb/

3 Including Expansions in a Retrieval System

Once we have the list of words for document expansion, we create one index for the words in the original documents and another index with the expansion terms. This way, we are able to use the original words only, or to also include the expansion words during the retrieval.

The retrieval system was implemented using MG4J (Boldi and Vigna, 2005), as it provides state-of-the-art results and allows to combine several indices over the same document collection. We conducted different runs, by using only the index made of original words (baseline) and also by using the index with the expansion terms of the related concepts.

BM25 was the scoring function of choice. It is one of the most relevant and robust scoring functions available (Robertson and Zaragoza, 2009).

$$w_{Dt}^{BM25} := \frac{tf_{D_t}}{k_1\left((1-b)+b\frac{dl_D}{avdl_D}\right)+tf_{Dt}} idf_t \quad (2)$$

where tf_{D_t} is the term frequency of term t in document D, dl_D is the document length, idf_t is the inverted document frequency (or more specifically the RSJ weight, (Robertson and Zaragoza, 2009)), and k_1 and b are free parameters.

The two indices were combined linearly, as follows (Robertson and Zaragoza, 2009):

$$score(d,e,q) := \sum_{t \in q \cap d} w_{D_t}^{BM25} + \lambda \sum_{t \in q \cap e} w_{E_t}^{BM25} \quad (3)$$

where *D* and *E* are the original and expanded indices, *d, e* and *q* are the original document, the expansion of the document and the query respectively, t is a term, and λ is a free parameter for the relative weight of the expanded index.

You should only need to turn off virus and anti-spy not uninstall. And that's done within each of the softwares themselves. Then turn them back on later after installing any DSL softwares.

06566077-n → *computer software, package*, **software**, *software package, software program, software system*

03082979-n → computer, computing device, computing machine, data processor, electronic computer

Figure 1: Example of a document expansion, with original document on top, and some of the relevant WordNet concepts identified by our algorithm, together with the words that lexicalize them. Words in the original document are shown in bold, synonyms in italics, and other related words underlined.

4 Experimental Setup

We chose three data collections. The first is based on a traditional news collection. DE could be specially interesting for datasets with short documents, which lead our choice of the other datasets: the second was chosen because it contains shorter documents, and the third is a passage retrieval task which works on even shorter paragraphs. Table 1 shows some statistics about the datasets.

One of the collections is the English dataset of the **Robust** task at CLEF 2009 (Agirre et al., 2009a). The documents are news collections from LA Times 94 and Glasgow Herald 95. The topics are statements representing information needs, consisting of three parts: a brief title statement; a one-sentence description; a more complex narrative describing the relevance assessment criteria. We use only the title and the description parts of the topics in our experiments.

The **Yahoo! Answers** corpus is a subset of a dump of the Yahoo! Answers web site[2] (Surdeanu et al., 2008), where people post questions and answers, all of which are public to any web user willing to browse them. The dataset is a small subset of the questions, selected for their linguistic properties (for example they all start with "how {to||do||did||does||can||would||could||should}"). Additionally, questions and answers of obvious low quality were removed. The document set was created with the best answer of each question (only one for each question).

	docs	length	q. train	q. test
Robust	166,754	532	150	160
Yahoo!	89610	104	1000	88610
ResPubliQA	1,379,011	20	100	500

Table 1: Number of documents, average document length, number of queries for train and test in each collection.

The other collection is the English dataset of **ResPubliQA** exercise at the Multilingual Question Answering Track at CLEF 2009 (Peñas et al., 2009). The exercise is aimed at retrieving paragraphs that contain answers to a set of 500 natural language questions. The document collection is a subset of the JRC-Acquis Multilingual Parallel Corpus, and consists of 21,426 documents for English which are aligned to a similar number of documents in other languages[3]. For evaluation, we used the gold standard released by the organizers, which contains a single correct passage for each query. As the retrieval unit is the passage, we split the document collection into paragraphs. We applied the expansion strategy only to passages which had more than 10 words (half of the passages), for two reasons: the first one was that most of these passages were found not to contain relevant information for the task (e.g. "Article 2" or "Having regard to the proposal from the Commission"), and the second was that we thus saved some computation time.

In order to evaluate the quality of our expansion in practical retrieval settings, the next Section re-

[2]Yahoo! Webscope dataset "ydata-yanswers-manner-questions-v1_0" http://webscope.sandbox.yahoo.com/

[3]Note that Table 1 shows the number of paragraphs, which conform the units we indexed.

		base.	expa.	Δ
Robust	MAP	.3781	**.3835****	1.43%
Yahoo!	MRR	.2900	**.2950****	1.72%
	P@1	.2142	**.2183****	1.91%
ResPubliQA	MRR	.3931	**.4077****	3.72%
	P@1	.2860	**.3000****	4.90%

Table 2: Results using default parameters.

		base.	expa.	Δ
Robust	MAP	.3740	**.3823****	2.20%
Yahoo!	MRR	.3070	**.3100****	0.98%
	P@1	.2293	**.2317***	1.05%
ResPubliQA	MRR	.4970	.4942	-0.56%
	P@1	.3980	.3940	-1.01%

Table 3: Results using optimized parameters.

port results with respect to several parameter settings. Parameter optimization is often neglected in retrieval with linguistic features, but we think it is crucial since it can have a large effect on relevance performance and therefore invalidate claims of improvements over the baseline. In each setting we assign different values to the free parameters in the previous section, k_1, b and λ.

5 Results

The main evaluation measure for Robust is mean Average Precision (MAP), as customary. In two of the datasets (Yahoo! and ResPubliQA) there is a single correct answer per query, and therefore we use Mean Reciprocal Rank (MRR) and Mean Precision at rank 1 (P@1) for evaluation. Note that in this setting MAP is identical to MRR. Statistical significance was computed using Paired Randomization Test (Smucker et al., 2007). In the tables throughout the paper, we use * to indicate statistical significance at 90% confidence level, ** for 95% and *** for 99%. Unless noted otherwise, base. refers to MG4J with the standard index, and expa. refers to MG4J using both indices. Best results per row are in bold when significant. Δ reports relative improvement respect to the baseline.

5.1 Default Parameter Setting

The values for k_1 and b are the default values as provided in the w^{BM25} implementation of MG4J, 1.2 and 0.5 respectively. We could not think of a straightforward value for λ. A value of 1 would mean that we are assigning equal importance to original and expanded terms, which seemed an overestimation, so we used 0.1. Table 2 shows the results when using the default setting of parameters. The use of expansion is beneficial in all datasets, with relative improvements ranging from 1.43% to 4.90%.

Setting	System	k_1	b	λ
Default	base.	1.20	0.50	-
	expa.	1.20	0.50	0.100
Robust	base.	1.80	0.64	-
	expa.	1.66	0.55	0.075
Yahoo!	basel.	0.99	0.82	-
	expa.	0.84	0.87	0.146
ResPubliQA	base.	0.09	0.56	-
	expa.	0.13	0.65	0.090

Table 4: Parameters as in the default setting or as optimized in each dataset. The λ parameter is not used in the baseline systems.

5.2 Optimized Parameter Setting

We next optimized all three parameters using the train part of each collection. The optimization of the parameters followed a greedy method called "promising directions" (Robertson and Zaragoza, 2009). The comparison between the baseline and expansion systems in Table 3 shows that expansion helps in Yahoo! and Robust, with statistical significance. The differences in ResPubliQA are not significant, and indicate that expansion terms were not helpful in this setting.

Note that the optimization of the parameters yields interesting effects in the baseline for each of the datasets. If we compare the results of the baseline with default settings (Table 2) and with optimized setting (Table 3), the baseline improves MRR dramatically in ResPubliQA (26% relative improvement), significantly in Yahoo! (5.8%) and decreases MAP in Robust (-0.01%). This disparity of effects could be explained by the fact that the default values are often approximated using TREC-style news collections, which is exactly the genre of the Robust documents, while Yahoo uses shorter documents, and ResPubliQA has the shortest documents.

Table 4 summarizes the values of the parameters in both default and optimized settings. For k_1, the optimization yields very different values. In Robust the value is similar to the default value, but

		base.	expa.	Δ	λ
Rob	MAP	.3781	**.3881****	2.64%	0.18
Y!	MRR	.2900	**.2980****	2.76%	0.27
	P@1	.2142	**.2212****	3.27%	
ResP.	MRR	.3931	**.4221****	7.39%	0.61
	P@1	.2860	**.3180****	11.19%	

Table 5: Results obtained using the λ optimized setting, including actual values of λ.

in ResPubliQA the optimization pushes it down below the typical values cited in the literature (Robertson and Zaragoza, 2009), which might explain the boost in performance for the baseline in the case of ResPubliQA. When all three parameters are optimized together, the values λ in the table range from 0.075 to 0.146. The values of the optimized λ can be seem as an indication of the usefulness of the expanded terms, so we explored this farther.

5.3 Exploring λ

As an additional analysis experiment, we wanted to know the effect of varying λ keeping k_1 and b constant at their default values. Table 5 shows the best values in each dataset, which that the weight of the expanded terms and the relative improvement are highly correlated.

5.4 Exploring Number of Expansion Concepts

One of the free parameters of our system is the number of concepts to be included in the document expansion. We have performed a limited study with the default parameter setting on the Robust setting, using 100, 500 and 750 concepts, but the variations were not statistically significant. Note that with 100 concepts we were actually expanding with 268 words, with 500 concepts we add 1247 words and with 750 concepts we add 1831 words.

6 Robustness

The results in the previous section indicate that optimization is very important, but unfortunately real applications usually lack training data. In this Section we wanted to study whether the parameters can be carried over from one dataset to the other, and if not, whether the extra terms found by DE would make the system more robust to those sub-optimal parameters.

	train		base.	expa.	Δ
Rob.	def.	MAP	.3781	**.3835****	1.43%
	Rob.	MAP	.3740	**.3823****	2.20%
	Y!	MAP	.3786	.3759	-0.72%
	Res.	MAP	.3146	**.3346****	6.35%
Y!	def.	MRR	.2900	**.2950****	1.72%
	Rob.	MRR	.2920	.2920	0.0%
	Y!	MRR	.3070	**.3100****	0.98%
	Res.	MRR	.2600	**.2750****	5.77%
ResP.	def.	MRR	.3931	**.4077****	3.72%
	Rob.	MRR	.3066	**.3655****	19.22%
	Y!	MRR	.3010	**.3459****	14.93%
	Res.	MRR	.4970	.4942	-0.56%

Table 6: Results optimizing parameters with training from other datasets. We also include default and optimization on the same dataset for comparison. Only MRR and MAP results are given.

Table 6 includes a range of parameter settings, including defaults, and optimized parameters coming from the same and different datasets. The values of the parameters are those in Table 4. The results show that when the parameters are optimized in other datasets, DE provides improvement with statistical significance in all cases, except for the Robust dataset when using parameters optimized from Yahoo! and vice-versa.

Overall, the table shows that our DE method either improves the results significantly or does not affect performance, and that it provides robustness across different parameter settings, even with sub-optimal values.

7 Exploring Document Length

The results in Table 6 show that the performance improvements are best in the collection with shortest documents (ResPubliQA). But the results for Robust and Yahoo! do not show any relation to document length. We thus decided to do an additional experiment artificially shrinking the document in Robust to a certain percentage of its original length. We create new pseudo-collection with the shrinkage factors of 2.5%, 10%, 20% and 50%, keeping the first N% words in the document and discarding the rest. In all cases we used the same parameters, as optimized for Robust.

Table 7 shows the results (MAP), with some clear indication that the best improvements are ob-

tained for the shortest documents.

	length	base.	expa.	Δ
2.5%	13	.0794	.0851	7.18%
10%	53	.1757	.1833	4.33%
20%	107	.2292	.2329	1.61%
50%	266	.3063	.3098	1.14%
100%	531	.3740	.3823	2.22%

Table 7: Results (MAP) on Robust when artificially shrinking documents to a percentage of their length. In addition to the shrinking rate we show the average lengths of documents.

8 Related Work

Given the brittleness of keyword matches, most research has concentrated on Query Expansion (QE) methods. These methods analyze the user query terms and select automatically new related query terms. Most QE methods use statistical (or distributional) techniques to select terms for expansion. They do this by analyzing term co-occurrence statistics in the corpus and in the highest scored documents of the original query (Manning et al., 2009). These methods seemed to improve slightly retrieval relevance on average, but at the cost of greatly decreasing the relevance of difficult queries. But more recent studies seem to overcome some of these problems (Collins-Thompson, 2009).

An alternative to QE is to perform the expansion in the document. Document Expansion (DE) was first proposed in the speech retrieval community (Singhal and Pereira, 1999), where the task is to retrieve speech transcriptions which are quite noisy. Singhal and Pereira propose to enhance the representation of a noisy document by adding to the document vector a linearly weighted mixture of related documents. In order to determine related documents, the original document is used as a query into the collection, and the ten most relevant documents are selected.

Two related papers (Liu and Croft, 2004; Kurland and Lee, 2004) followed a similar approach on the TREC ad-hoc document retrieval task. They use document clustering to determine similar documents, and document expansion is carried out with respect to these. Both papers report significant improvements over non-expanded baselines. Instead of clustering, more recent work (Tao et al., 2006; Mei et al., 2008; Huang et al., 2009) use language models and graph representations of the similarity between documents in the collection to smooth language models with some success. The work presented here is complementary, in that we also explore DE, but use WordNet instead of distributional methods. They use a tighter integration of their expansion model (compared to our simple two-index model), which coupled with our expansion method could help improve results further. We plan to explore this in the future.

An alternative to statistical expansion methods is to use lexical semantic knowledge bases such as WordNet. Most of the work has focused on query expansion and the use of synonyms from WordNet after performing word sense disambiguation (WSD) with some success (Voorhees, 1994; Liu et al., 2005). The short context available in the query when performing WSD is an important problems of these techniques. In contrast, we use full document context, and related words beyond synonyms. Another strand of WordNet based work has explicitly represented and indexed word senses after performing WSD (Gonzalo et al., 1998; Stokoe et al., 2003; Kim et al., 2004). The word senses conform a different space for document representation, but contrary to us, these works incorporate concepts for all words in the documents, and are not able to incorporate concepts that are not explicitly mentioned in the document. More recently, a CLEF task was organized (Agirre et al., 2009a) where terms were semantically disambiguated to see the improvement that this would have on retrieval; the conclusions were mixed, with some participants slightly improving results with information from WordNet. To the best of our knowledge our paper is the first on the topic of document expansion using lexical-semantic resources.

We would like to also compare our performance to those of other systems as tested on the same datasets. The systems which performed best in the Robust evaluation campaign (Agirre et al., 2009a) report 0.4509 MAP, but note that they deployed a complex system combining probabilistic and monolingual translation-based models. In ResPubliQA (Peñas et al., 2009), the official eval-

uation included manual assessment, and we cannot therefore reproduce those results. Fortunately, the organizers released all runs, but only the first ranked document for each query was included, so we could only compute P@1. The P@1 of best run was 0.40. Finally (Surdeanu et al., 2008) report MRR figure around 0.68, but they evaluate only in the questions where the correct answer is retrieved by answer retrieval in the top 50 answers, and is thus not comparable to our setting.

Regarding the WordNet expansion technique we use here, it is implemented on top of publicly available software[4], which has been successfully used in word similarity (Agirre et al., 2009b) and word sense disambiguation (Agirre and Soroa, 2009). In the first work, a single word was input to the random walk algorithm, obtaining the probability distribution over all WordNet synsets. The similarity of two words was computed as the similarity of the distribution of each word, obtaining the best results for WordNet-based systems on the word similarity dataset, and comparable to the results of a distributional similarity method which used a crawl of the entire web. Agirre et al. (2009) used the context of occurrence of a target word to start the random walk, and obtained very good results for WordNet WSD methods.

9 Conclusions and Future Work

This paper presents a novel Document Expansion method based on a WordNet-based system to find related concepts and words. The documents in three datasets were thus expanded with related words, which were fed into a separate index. When combined with the regular index we report improvements over MG4J using w^{BM25} for those three datasets across several parameter settings, including default values, optimized parameters and parameters optimized in other datasets. In most of the cases the improvements are statistically significant, indicating that the information in the document expansion is useful. Similar to other expansion methods, parameter optimization has a stronger effect than our expansion strategy. The problem with parameter optimization is that in most real cases there is no tuning dataset available. Our analysis shows that our expansion method is more effective for sub-optimal parameter settings, which is the case for most real-live IR applications. A comparison across the three datasets and using artificially trimmed documents indicates that our method is particularly effective for short documents.

As document expansion is done at indexing time, it avoids any overhead at query time. It also has the advantage of leveraging full document context, in contrast to query expansion methods, which use the scarce information present in the much shorter queries. Compared to WSD-based methods, our method has the advantage of not having to disambiguate all words in the document. Besides, our algorithm picks the most relevant concepts, and thus is able to expand to concepts which are not explicitly mentioned in the document. The successful use of background information such as the one in WordNet could help close the gap between semantic web technologies and IR, and opens the possibility to include other resources like Wikipedia or domain ontologies like those in the Unified Medical Language System.

Our method to integrate expanded terms using an additional index is simple and straightforward, and there is still ample room for improvement. A tighter integration of the document expansion technique in the retrieval model should yield better results, and the smoothed language models of (Mei et al., 2008; Huang et al., 2009) seem a natural choice. We would also like to compare with other existing query and document expansion techniques and study whether our technique is complementary to query expansion approaches.

Abstract

Machine-learned ranking techniques automatically learn a complex document ranking function given training data. These techniques have demonstrated the effectiveness and flexibility required of a commercial web search. However, manually labeled training data (with multiple absolute grades) has become the bottleneck for training a quality ranking function, particularly for a new domain. In this paper, we explore the adaptation of machine-learned ranking models across a set of geographically diverse markets with the market-specific pairwise preference data, which can be easily obtained from clickthrough logs. We propose a novel adaptation algorithm, PairwiseTrada, which is able to adapt ranking models that are trained with multi-grade labeled training data to the target market using the target-market-specific pairwise preference data. We present results demonstrating the efficacy of our technique on a set of commercial search engine data.

1 Introduction

Web search algorithms provide methods for ranking web scale collection of documents given a short query. The success of these algorithms often relies on the rich set of document properties or *features* and the complex relationships between them. Increasingly, machine learning techniques are being used to learn these relationships for an effective ranking function (Liu, 2009). These techniques use a set of labeled *training data* labeled with multiple relevance grades to automatically estimate parameters of a model which directly optimizes a performance metric. Although training data often is derived from editorial labels of document relevance, it can also be inferred from a careful analysis of users' interactions with a working system (Joachims, 2002). For example, in web search, given a query, document preference information can be derived from user clicks. This data can then be used with an algorithm which learns from pairwise preference data (Joachims, 2002; Zheng et al., 2007). However, automatically extracted pairwise preference data is subject to noise due to the specific sampling methods used (Joachims et al., 2005; Radlinski and Joachim, 2006; Radlinski and Joachim, 2007).

One of the fundamental problems for a web search engine with global reach is the development of ranking models for different regional markets. While the approach of training a single model for all markets is attractive, it fails to fully exploit of specific properties of the markets. On the other hand, the approach of training market-specific models requires the huge overhead of acquiring a large training set for each market. As a result, techniques have been developed to create a model for a small market, say a Southeast Asian country, by combining a strong model in another market, say the United States, with a

Coling 2008: Poster Volume, pages 18–26,
Beijing, August 2010

small amount of manually labeled training data in the small market (Chen et al., 2008b). However, the existing Trada method takes only multi-grade labeled training data for adaptation, making it impossible to take advantage of the easily harvested pairwise preference data. In fact, to our knowledge, there is no adaptation algorithm that is specifically developed for pairwise data.

In this paper, we address the development market-specific ranking models by leveraging pairwise preference data. The pairwise preference data contains most market-specific training examples, while a model from a large market may capture the common characteristics of a ranking function. By combining them algorithmically, our approach has two unique advantages. (1) The biases and noises of the pairwise preference data can be depressed by using the base model from the large market. (2) The base model can be tailored to the characteristics of the new market by incorporating the market specific pairwise training data. As the pairwise data has the particular form, the challenge is how to effectively use pairwise data in adaptation. This appeals to the following objective of many web search engines: design algorithms which minimize manually labeled data requirements while maintaining strong performance.

2 Related Work

In recent years, the ranking problem is frequently formulated as a supervised machine learning problem, which combines different kinds of features to train a ranking function. The ranking problem can be formulated as learning a function with pair-wise preference data, which is to minimize the number of contradicting pairs in training data. For example, RankSVM (Joachims, 2002) uses support vector machines to learn a ranking function from preference data; RankNet (Burges et al., 2005a) applies neural network and gradient descent to obtain a ranking function; RankBoost (Freund et al., 1998) applies the idea of boosting to construct an efficient ranking function from a set of weak ranking functions; GBRank (Zheng et al., 2007; Xia et al., 2008) using gradient descent in function spaces, which is able to learn relative ranking information in the context of web search. In addition, Several studies have been focused on learning ranking functions in semi-supervised learning framework (Amini et al., 2008; Duh and Kirchhoff, 2008), where unlabeled data are exploited to enhance ranking function. Another approach to learning a ranking function addresses the problem of optimizing the list-wise performance measures of information retrieval, such as mean average precision or Discount Cumulative Gain (Cao et al., 2007; Xu et al., 2008; Wu et al., 2009; Chen et al., 2008c). The idea of these methods is to obtain a ranking function that is optimal with respect to some information retrieval performance measure.

Model adaptation has previously been applied in the area of natural language processing and speech recognition. This approach has been successfully applied to parsing (Hwa, 1999), tagging (Blitzer et al., 2006), and language modeling for speech recognition (Bacchiani and Roark, 2003). Until very recently, several works have been presented on the topic of model adaptation for ranking (Gao et al., 2009; Chen et al., 2008b; Chen et al., 2009), however, none of them target the model adaptation with the pair-wise learning framework. Finally, multitask learning for ranking has also been proposed as a means of addressing problems similar to those we have encountered in model adaptation (Chen et al., 2008a; Bai et al., 2009; Geng et al., 2009).

3 Background

3.1 Gradient Boosted Decision Trees for Ranking

Assume we have a training data set, $\mathcal{D} = \{\langle (q,d), y\rangle_1, \ldots, \langle (q,d), y\rangle_n\}$, where $\langle (q,d), t\rangle_i$ encodes the labeled relevance, y, of a document, d, given query, q. Each query-document pair, (q,d), is represented by a set of features, $(q,d) = \{x_{i1}, x_{i2}, x_{i3}, ..., x_{im}\}$. These features include, for example, query-document match features, query-specific features, and document-specific features. Each relevance judgment, y, is a relevance grade mapped (e.g. "relevant", "somewhat relevant", "non-relevant") to a real

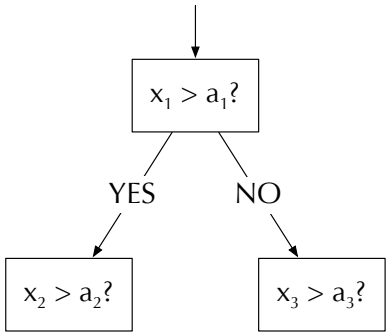

Figure 1: An example of base tree, where x_1, x_2 and x_3 are features and a_1, a_2 and a_3 are their splitting values.

number. Given this representation, we can learn a *gradient boosted decision tree* (GBDT) which models the relationship between document features, (q, d), and the relevance score, y, as a decision tree (Friedman, 2001). Figure 1 shows a portion of such a tree. Given a new query document pair, the GBDT can be used to predict the relevance grade of the document. A ranking is then inferred from these predictions. We refer to this method as GBDT_{reg}.

In the training phase, GBDT_{reg} iteratively constructs regression trees. The initial regression tree minimizes the L_2 loss with respect to the targets, y,

$$L_2(f, y) = \sum_{\langle (q,d), y \rangle} (f(q, d) - y)^2 \qquad (1)$$

As with other boosting algorithms, the subsequent trees minimize the L_2 loss with respect to the residuals of the predicted values and the targets. The final prediction, then, is the sum of the predictions of the trees estimated at each step,

$$f(x) = f^1(x) + \ldots + f^k(x) \qquad (2)$$

where $f^i(x)$ is the prediction of the ith tree.

3.2 Pairwise Training

As alternative to the absolute grades in $\mathcal{D}$, we can also imagine assembling a data set of *relative judgments*. In this case, assume we have a training data set $\mathcal{D}^{\succ} = \{\langle (q, d), (q, d'), \rho \rangle_1, \ldots, \langle (q, d), (q, d'), \rho \rangle_n\}$, where $\langle (q, d), (q, d'), \rho \rangle_i$ encodes the preference, of a document, d, to a second document, d', given query, q. Again, each query-document pair is represented by a set of features. Each preference judgment, $\rho \in \{\succ, \prec\}$, indicates whether document d is preferred to document d' ($d \succ d'$) or not ($d \prec d'$).

Preference data is attractive for several reasons. First, editors can often more easily determine preference between documents than the absolute grade of single documents. Second, relevance grades can often vary between editors. Some editors may tend to overestimate relevance compared to another editor. As a result, judgments need to be rescaled for editor biases. Although preference data is not immune to inter-editor inconsistency, absolute judgments introduce two potential sources of noise: determining a relevance ordering and determining a relevance grade. Third, even if grades can be accurately labeled, mapping those grades to real values is often done in a heuristic or *ad hoc* manner. Fourth, GBDT_{reg} potentially wastes modeling effort on predicting the grade of a document as opposed to focusing on optimizing the rank order of documents, the real goal a search engine. Finally, preference data can often be mined from a production system using assumptions about user clicks.

In order to support preference-based training data, (Zheng et al., 2007) proposed GBRANK based on GBDT_{reg}. The GBRANK training algorithm begins by constructing an initial tree which predicts a constant score, c, for all instances. A pair is contradicting if the $\langle (q, d), (q, d'), \succ \rangle$ and prediction $f(q, d) < f(q, d')$. At each boosting stage, the algorithm constructs a set of contradicting pairs, $\mathcal{D}^{\succ}_{\text{contra}}$. The GBRANK algorithm then adjusts the response variables, $f(q, d)$ and $f(q, d')$, so that $f(q, d) > f(q, d')$. Assume that $(q, d) \succ (q, d')$ and $f(q, d) < f(q, d')$. To correct the order, we modify the target values,

$$\tilde{f}(q, d) = f(q, d) + \tau \qquad (3)$$

$$\tilde{f}(q, d') = f(q, d') - \tau \qquad (4)$$

where $\tau > 0$ is a margin parameter that we

need to assign. In our experiments, we set τ to 1. Note that if preferences are inferred from absolute grades, $\mathcal{D}$, minimizing the L_2 to 0 also minimizes the contradictions.

3.3 Tree Adaptation

Recall that we are also interested in using the information learned from one market, which we will call the *source market*, on a second market, which we will call the *target market*. To this end, the Trada algorithm adapts a GBDT_{reg} model from the source market for the target market by using a small amount of target market absolute relevance judgments (Chen et al., 2008b). Let the $\mathcal{D}_s$ be the data in the source domain and $\mathcal{D}_t$ be the data in target domain. Assume we have trained a model using GBDT_{reg}. Our approach will be to use the decision tree structure learned from $\mathcal{D}_s$ but to adapt the thresholds in each node's feature. We will use Figure 1 to illustrate Trada. The splitting thresholds are a_1, a_2 and a_3 for rank features x_1, x_2 and x_3. Assume that the data set $\mathcal{D}_t$ is being evaluated at the root node v in Figure 1. We will split the using the feature $v_x = x_1$ but will compute a new threshold v'_a using $\mathcal{D}_t$ and the GBDT_{reg} algorithm. Because we are discussing the root node, when we select a threshold b, $\mathcal{D}_t$ will be partitioned into two sets, $\mathcal{D}_t^{>b}$ and $\mathcal{D}_t^{<b}$ representing those instances whose feature x_1 has a value greater and lower than b. The response value for each partition will be the uniform average of instances in that partition,

$$f = \begin{cases} \frac{1}{|\mathcal{D}_t^{>b}|} \sum_{d_i \in \mathcal{D}_t^{>b}} y_i & \text{if } d_i \in \mathcal{D}_t^{>b} \\ \frac{1}{|\mathcal{D}_t^{<b}|} \sum_{d_i \in \mathcal{D}_t^{<b}} y_i & \text{if } d_i \in \mathcal{D}_t^{<b} \end{cases} \quad (5)$$

We would like to select a value for b which minimizes the L_2 loss between y and f in Equation 5; equivalently, b can be selected to minimize the variance of y in each partition. In our implementation, we compute the L_2 loss for all possible values of the feature v'_x and select the value which minimizes the loss.

Once b is determined, the adaptation consists of performing a linear interpolation between the original splitting threshold v_a and the new splitting threshold b as follows:

$$v'_a = pv_a + (1-p)b \quad (6)$$

where p is an adaptation parameter which determines the scale of how we want to adapt the tree to the new task. If there is no additional information, we can select p according to the size of the data set,

$$p = \frac{|\mathcal{D}_s^{<a}|}{|\mathcal{D}_s^{<a}| + |\mathcal{D}_t^{<b}|} \quad (7)$$

In practice, we often want to enhance the adaptation scale since the training data of the extended task is small. Therefore, we add a parameter β to boost the extended task as follows:

$$p = \frac{|\mathcal{D}_s^{<a}|}{|\mathcal{D}_s^{<a}| + \beta|\mathcal{D}_t^{<b}|} \quad (8)$$

The value of β can be determined by cross-validation. In our experiments, we set β to 1.

The above process can also be applied to adjust the response value of nodes as follows:

$$v'_f = pv_f + (1-p)f \quad (9)$$

where v'_f is the adapted response at a node, v_f is its original response value of source model, and f is the response value (Equation 5).

The complete Trada algorithm used in our experiments is presented in Algorithm 1.

Algorithm 1 Tree Adaptation Algorithm

TRADA$(v, \mathcal{D}_t, p)$
1 $b \leftarrow$ COMPUTE-THRESHOLD$(v_x, \mathcal{D}_t)$
2 $v'_a \leftarrow pv_a + (1-p)b$
3 $v'_f \leftarrow pv_f + (1-p)$MEAN-RESPONSE$(\mathcal{D}_t)$

4 $\mathcal{D}'_t \leftarrow \{x \in \mathcal{D}_t : x_i < v'_a\}$
5 $v'_< \leftarrow$ TRADA$(v_<, \mathcal{D}'_t, p)$

6 $\mathcal{D}''_t \leftarrow \{x \in \mathcal{D}_t : x_i > v'_a\}$
7 $v'_> \leftarrow$ TRADA$(v_>, \mathcal{D}''_t, p)$

8 **return** v'

The Trada algorithm can be augmented with a second phase which directly incorporates the target training data. Assume that our source model, $\mathcal{M}_s$, was trained using source data, $\mathcal{D}_s$. Recall that $\mathcal{M}_s$ can be decomposed as a sum of regression tree output, $f_{\mathcal{M}_s}(x) = f^1_{\mathcal{M}_s}(x) + \ldots + f^k_{\mathcal{M}_s}(x)$. *Additive tree adaptation* refers augmenting this summation with a set of regression trees trained on the residuals between the model, $\mathcal{M}_s$, and the target training data, $\mathcal{D}_t$. That is, $f_{\mathcal{M}_t}(x) = f^1_{\mathcal{M}_s}(x) + \ldots + f^k_{\mathcal{M}_s}(x) + f_{\mathcal{M}_t}(x)^{k+1} + \ldots + f_{\mathcal{M}_t}(x)^{k+k'}$. In order for us to perform additive tree adaptation, the source and target data must use the same absolute relevance grades.

4 Pairwise Adaptation

Both GBRANK and Trada can be used to reduce the requirement on editorial data. GBRANK achieves the goal by leveraging preference data, while Trada does so by leveraging data from a different search market. A natural extension to these methods is to leverage both sources of data simultaneously. However, no algorithm has been proposed to do this so far in the literature. We propose an adaptation method using pairwise preference data.

Our approach shares the same intuition as Trada: maintain the tree structure but adjust decision threshold values against some target value. However, an important difference is that our adjustment of threshold values does not regress against some target grade values; rather its objective is to improve the ordering of documents. To make use of preference data in the tree adaptation, we follow the method used in GBRANK to adjust the target values whenever necessary to preserve correct document order. Given a base model, $\mathcal{M}_s$, and preference data, $\mathcal{D}_t^{\succ}$, we can use Equations 3 and 4 to *infer* target values. Specifically, we construct a set $\mathcal{D}^{\succ}_{\text{contra}}$ from $\mathcal{D}_t^{\succ}$ and $\mathcal{M}_s$. For each item (q, d) in $\mathcal{D}^{\succ}_{\text{contra}}$, we use the value of $\tilde{f}(q, d)$ as the target. These tuples, $\langle (q, d), \tilde{f}(q, d) \rangle$ along with $\mathcal{M}_s$ are then are provided as input to Trada. Our approach is described in Algorithm 2.

Compared to Trada, Pairwise-Trada has two important differences. First, Pairwise-Trada can use a source GBDT model trained either against absolute or pairwise judgments. When an organization maintains a set of ranking models for different markets, although the underlying modeling method may be shared (e.g. GBDT), the learning algorithm used may be market-specific (e.g. GBRANK or GBDT_{reg}). Unfortunately, classic Trada relies on the source model being trained using GBDT_{reg}. Second, Pairwise-Trada can be adapted using pairwise judgments. This means that we can expand our adaptation data to include click feedback, which is easily obtainable in practice.

Algorithm 2 Pairwise Tree Adaptation Algorithm

PAIRWISE-TRADA($\mathcal{M}_s, \mathcal{D}_t^{\succ}, p$)

1 $\mathcal{D}_{\text{contra}} \leftarrow$ FIND-CONTRADICTIONS($\mathcal{M}_s, \mathcal{D}_t^{\succ}$)
2 $\tilde{\mathcal{D}}_t \leftarrow \{\langle (q, d), \tilde{f}(q, d) \rangle : (q, d) \in \mathcal{D}_{\text{contra}}\}$
3 **return** TRADA(ROOT($\mathcal{M}_s$), $\tilde{\mathcal{D}}_t, p$)

5 Methods and Materials

The proposed algorithm is a straightforward modification of previous ones. The question we want to examine in this section is whether this simple modification is effective in practice. In particular, we want to examine whether pairwise adaptation is better than the original adaptation Trada using grade data, and whether the pairwise data from a market can help improve the ranking function on a different market.

Our experiments evaluate the performance of Pairwise-Trada for web ranking in ten target markets. These markets, listed in Table 1, cover a variety of languages and cultures. Furthermore, resources, in terms of documents, judgments, and click-through data, also varies across markets. In particular, editorial query-document judgments range from hundreds of thousands (e.g. SEA_1) to tens of thousands (e.g. SEA_5). Editors graded query-document pairs on a five-point relevance scale, resulting in our data set $\mathcal{D}$. Preference labels, $\mathcal{D}^{\succ}$, are inferred from these judgments.

We also include a second set of experiments which incorporate click data.[1] In these experiments, we infer a preference from click data by assuming the following model. The user is presented with ten results. An item $i \succ j$ if i the following conditions hold: i is positioned below j, i receives a click, and j does not receive a click.

In our experiments, we tested the following runs,

- GBDT_{reg} trained using only $\mathcal{D}_s$ or $\mathcal{D}_t$
- GBRANK trained using only $\mathcal{D}_s^{\succ}$ or $\mathcal{D}_t^{\succ}$
- GBRANK trained using only $\mathcal{D}_s^{\succ}$, $\mathcal{D}_t^{\succ}$, and $\mathcal{C}_t$
- Trada with both GBDT_s and GBRANK_s, adapted with $\mathcal{D}_t$.
- Pairwise-Trada with both GBDT_s and GBRANK_s, adapted with $\mathcal{D}_t^{\succ}$ and $\mathcal{C}_t$ at different ratios.

In the all experiments, we use 400 additive trees when additive adaptation is used.

All models are evaluated using discounted cumulative gain (DCG) at rank cutoff 5 (Järvelin and Kekäläinen, 2002).

6 Results

6.1 Adaptation with Manually Labeled Data

In Table 1, we show the results for all of our experimental conditions.

We can make a few observations about the non-adaptation baselines. First, models trained on the (limited) target editorial data, GBDT_t and GBRANK_t, tend to outperform those trained only on the source editorial data, GBDT_s and GBRANK_s. The critical exception is SEA_5, the market with the fewest judgments. We believe that this behavior is a result of similarity between the United States source data and the SEA_5 target market; both the source and target query populations share the same language, a property not exhibited in other markets. Notice that other small markets such as LA_2 and LA_3 see modest improvements when using target-only runs compared to source-only runs. Second, GBRANK tends to outperform GBDT when only trained on the source data. This implies that we should prefer a base model which is based on GBRANK, something that is difficult to combine with classic Trada. Third, by comparing GBRANK and GBDT when only trained on the target data, we notice that the effectiveness of GBRANK depends on the amount of training data. For markets where there training data is plentiful (e.g. SEA_1), GBRANK outperforms GBDT. On the other hand, for smaller markets (e.g. LA_3), GBDT outperforms GBRANK.

In general, the results confirm the hypothesis that adaptation runs outperform all of non-adaptation baselines. This is the case for both Trada and Pairwise-Trada. As with the baseline runs, the Australian market sees different performance as a result of the combination of a small target editorial set and a representative source domain. This effect has been observed in previous results (Chen et al., 2009).

We can also make a few observations by comparing the adaptation runs. Trada works better with a GBDT base model than with a GBRANK base model. We We believe this is the case because the absolute regression targets are difficult to compare with the unbounded output of GBRANK. Pairwise-Trada on the other hand tends to perform better with a GBRANK base model than with a GBDT base model. There are a few exceptions, SEA_3 and LA_2, where Pairwise-Trada works better with a GBDT base model. Comparing Trada to Pairwise-Trada, we find that using preference targets tends to improve performance for some markets but not all. The underperformance of Pairwise-Trada tends to occur in smaller markets such as LA_1, LA_2, and LA_3. This is similar to the behavior we observed in the non-adaptation runs and suggests that, in operation, a modeler may have to decide on the training algorithm based on the amount of data available.

[1] For technical reasons, this data set is slightly different from the results we show with the purely editorial data. Therefore the size of the training and testing sets are different, but not to a significant degree.

Table 2: Adaptation incorporating click data. Bolded numbers indicate statistically significant improvements over the baseline. Markets ordered as in Table 1.

6.2 Incorporating Click Data

One of the advantages of Pairwise-Trada is the ability to incorporate multiple sources of pairwise preference data. In this paper, we use the heuristic rule approach which is introduced by (Dong et al., 2009) to extract pairwise preference data from the click log of the search engine. This approach yields both skip-next and skip-above pairs (Joachims et al., 2005), which are sorted by confidence descending order respectively. In these experiments, we combine manually generated preferences with those gathered from click data. We present these results in Table 2.

We notice that no matter the source of preference data, Pairwise-Trada outperforms the baseline GBRANK model. The magnitude of the improvement depends on the source data used. Comparing the editorial-only to the click-only models, we notice that click-only models outperform editorial-only models for smaller markets (SEA_4, LA_1, and SEA_5). This is likely the case because the relative quantity of click data with respect to editorial data is higher in these markets. This is despite the fact that the click data may be noisier than the editorial data. The best performance, though, comes when we combine both editorial and click data.

6.3 Additive tree adaptation

Recall that Pairwise-Trada consists of two parts: parameter adaptation and additive tree adaptation. In this section, we examine the contribution to performance each part is responsible for. Figure 2 illustrates the adaptation results for the LA_1 market. In this experiment, we use a United States base model and 100K LA_1 editorial judgments for adaptation. Pairwise-Trada is performed on top of differently sized base models with 600, 900 and 1200 trees. The original base model has 1200 trees; we selected the first 600, 900 or full 1200 trees for experiments. The number of trees used in the additive tree adaptation step ranges up to 600 trees. From Figure 2 we can see that the additive adaptation can

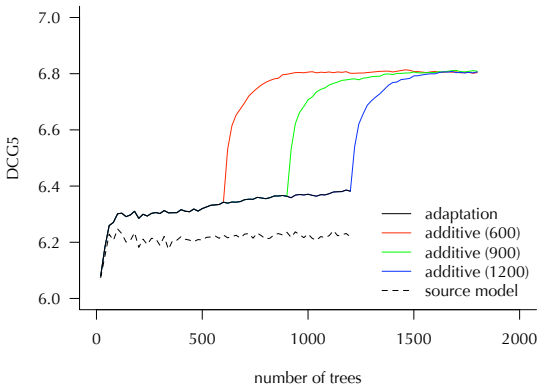

Figure 2: Illustration of additive tree adaptation for LA_1. The curves are average performance over a range of parameter settings.

significantly increase DCG over simple parameter adaptation and is therefore a critical step of Pairwise-Trada. When the number of trees in the additive tree adaptation step reaches roughly 400, the DCG plateaus.

7 Conclusion

We have proposed a model for adapting retrieval models using preference data instead of absolute relevance grades. Our experiments demonstrate that, when much editorial data is present, our method, Pairwise-Trada, may be preferable to competing methods based on absolute relevance grades. However, in real world systems, we often have access to sources of preference data beyond those resulting from editorial judgments. We demonstrated that Pairwise-Trada can exploit such data and boost performance significantly. In fact, *if we omit editorial data altogether we see performance improvements over the baseline model*. This suggests that, in principle, we can train a single, strong source model and improve it using target click data alone. Despite the fact that the modification we made is quite simple, we showed that modification is effective in practice. This tends to validate the general principle of using pairwise data from a different market. This principle can be easily used in other frameworks such as neural networks (Burges et al., 2005b). Therefore, the proposed method also points to a new direction for future improvements of search engines.

There are several areas of future work. First, we believe that detecting other sources of preference data from user behavior can further improve the performance of our model. Second, we only used a single source model in our experiments. We would also like to explore the effect of learning from an ensemble of source models. The importance of each may depend on the similarity to the target domain. Finally, we would also like to more accurately understand the queries where click data improves adaptation and those where editorial judgments is required. This sort of knowledge will allow us to train systems which maximally exploit our editorial resources.

Abstract

The treatment of factual data has been widely studied in different areas of Natural Language Processing (NLP). However, processing subjective information still poses important challenges. This paper presents research aimed at assessing techniques that have been suggested as appropriate in the context of subjective - Opinion Question Answering (OQA). We evaluate the performance of an OQA with these new components and propose methods to optimally tackle the issues encountered. We assess the impact of including additional resources and processes with the purpose of improving the system performance on two distinct blog datasets. The improvements obtained for the different combination of tools are statistically significant. We thus conclude that the proposed approach is adequate for the OQA task, offering a good strategy to deal with opinionated questions.

1 Introduction

The State of the Blogosphere 2009 survey published by Technorati [1] concludes that in the past years the blogosphere has gained a high influence on a high variety of topics, ranging from cooking and gardening, to economics, politics and scientific achievements. The development of the Social Web and the new communication frameworks also influenced the way information is transmitted through communities. Blogs are part of the so-called new textual genres. They have distinctive features when compared to the traditional ones, such as newspaper articles. Blog language contains formal and informal expressions, and other elements, as repeated punctuation or emoticons (used to stress upon different text elements). With the growth in the content of the blogosphere, the quantity of subjective data of the Web is increasing exponentially (Cui et al., 2006). As it is being updated in real-time, this data becomes a source of timely information on many topics, exploitable by different applications. In order to properly manage the content of this subjective information, its processing must be automated. The NLP task, which deals with the classification of opinionated content is called Sentiment Analysis (SA). Research in this field aims at discovering appropriate mechanisms to properly retrieve, extract and classify opinions expressed in text. While techniques to retrieve objective information have been widely studied, implemented and evaluated, opinion-related tasks still represent an important challenge. As a consequence, the aim of our research is to study, implement and evaluate appropriate methods for the task of Question Answering (QA) in the opinion treatment framework.

2 Motivation and Contribution

Research in opinion-related tasks gained importance in the past years. However, there are still many aspects that require analysis and im-

[1] http://technorati.com/

Coling 2008: Poster Volume, pages 27–35,
Beijing, August 2010

provement, especially for approaches that combine SA with other NLP tasks such as QA or automatic summarization. The TAC 2008 Opinion Pilot task and the subsequent research performed on the competition data have demonstrated that answering opinionated questions and summarizing subjective information are significantly different from the equivalent tasks in the same context, but dealing with factual data. This finding was confirmed by the recent work by (Kabadjov et al., 2009). The first motivation of our work is the need to detect and explore the challenges raised by opinion QA (OQA), as compared to factual QA. To this aim, we analyze the improvements that can be brought at the different steps of the OQA process: *question treatment* (identification of expected polarity – EPT, expected source – ES and expected target –ET-), *opinion retrieval* (at the level of one and three-sentences long snippets, using topic-related words or using paraphrases), *opinion analysis* (using topic detection and anaphora resolution). This preliminary research is motivated by the conclusions drawn by previous studies (Balahur et al., 2009). Our purpose is to verify if the inclusion of new elements and methods - source and target detection (using semantic role labeling (SRL)), topic detection (using Latent Semantic Analysis), paraphrasing and joint topic-sentiment analysis (classification of the opinion expressed only in sentences related to the topic), followed by anaphora resolution (using a system whose performance is not optimal), affects the results of the system and how. Our contribution to this respect is the identification of the challenges related to OQA compared to traditional QA. A further contribution consists in adding the appropriate methods, tools and resources to resolve the identified challenges. With the purpose of testing the effect of each tool, resource and technique, we carry out a separate and a global evaluation. An additional motivation of our work is the fact that although previous approaches showed that opinion questions have longer answers than factual ones, the research done in OQA so far has only considered a sentence-level approach. Another contribution this paper brings is the retrieval at 1 and 3-sentence level and the retrieval based on similarity to query paraphrases enriched with topic-related words). We believe retrieving longer text could cause additional problems such as redundancy, coreference and temporal expressions or the need to apply contextual information. Paraphrasing, on the other hand, had account for language variability in a more robust manner; however, the paraphrase collections that are available at the moment are known to be noisy. The following sections are structured as follows: Section 3 presents the related work in the field and the competitions organized for systems tackling the OQA task. In Section 4 we describe the corpora used for the experiments we carried out and the set of questions asked over each of them. Section 5 presents the experimental settings and the different system configurations we assessed. Section 6 shows the results of the evaluations, discusses the improvements and drops in performance using different configurations. We finally conclude on our approaches in Section 7, proposing the lines for future work.

3 Related Work

QA can be defined as the task in which given a set of questions and a collection of documents, an automatic NLP system is employed to retrieve the answer to the queries in Natural Language (NL). Research focused on building factoid QA systems has a long tradition; however, it is only recently that researchers have started to focus on the development of OQA systems. (Stoyanov et al., 2005) and (Pustejovsky and Wiebe, 2006) studied the peculiarities of opinion questions. (Cardie et al., 2003) employed opinion summarization to support a Multi-Perspective QA system, aiming at identifying the opinion-oriented answers for a given set of questions. (Yu and Hatzivassiloglou, 2003) separated opinions from facts and summarized them as answer to opinion questions. (Kim and Hovy, 2005) identified opinion holders, which are a key component in retrieving the correct answers to opinion questions. Due to the realized importance of blog data, recent years have also marked the beginning of NLP research focused on the development of opinion QA systems and the organization of international conferences encouraging the creation of effective QA systems both for fact and subjective texts. The TAC 2008[2] QA track proposed a collection

[2] http://www.nist.gov/tac/

of factoid and opinion queries called "rigid list" (factoid) and "squishy list" (opinion) respectively, to which the traditional QA systems had to be adapted. Some participating systems treated opinionated questions as "other" and thus they did not employ opinion specific methods. However, systems that performed better in the "squishy list" questions than in the "rigid list" implemented additional components to classify the polarity of the question and of the extracted answer snippet. The Alyssa system (Shen et al, 2007) uses a Support Vector Machines (SVM) classifier trained on the MPQA corpus (Wiebe et al., 2005), English NTCIR3 data and rules based on the subjectivity lexicon (Wilson et al., 2005). (Varma et al., 2008) performed query analysis to detect the polarity of the question using defined rules. Furthermore, they filter opinion from fact retrieved snippets using a classifier based on Naïve Bayes with unigram features, assigning for each sentence a score that is a linear combination between the opinion and the polarity scores. The PolyU (Venjie et al., 2008) system determines the sentiment orientation of the sentence using the Kullback-Leibler divergence measure with the two estimated language models for the positive versus negative categories. The QUANTA (Li et al., 2008) system performs opinion question sentiment analysis by detecting the opinion holder, the object and the polarity of the opinion. It uses a semantic labeler based on PropBank[4] and manually defined patterns. Regarding the sentiment classification, they extract and classify the opinion words. Finally, for the answer retrieval, they score the retrieved snippets depending on the presence of topic and opinion words and only choose as answer the top ranking results. Other related work concerns opinion holder and target detection. NTCIR 7 and 8 organized MOAT (the Multilingual Opinion Analysis Task), in which most participants employed machine learning approaches using syntactic patterns learned on the MPQA corpus (Wiebe et al., 2005). Starting from the abovementioned research, our aim is to take a step forward to present approaches and employ opinion specific methods focused on improving the performance of our OQA. We perform the retrieval at 1 sentence and 3 sentence-level and also determine the expected source (ES) and the expected target (ET) of the questions, which are fundamental to properly retrieve the correct answer. These two elements are selected employing semantic roles (SR). The expected answer type (EAT) is determined using Machine Learning (ML) using Support Vector Machine (SVM), by taking into account the interrogation formula, the subjectivity of the verb and the presence of polarity words in the target SR. In the case of expected opinionated answers, we also compute the expected polarity type (EPT) – by applying opinion mining (OM) on the affirmative version of the question (e.g. for the question *"Why do people prefer Starbucks to Dunkin Donuts?"*, the affirmative version is *"People prefer Starbucks to Dunkin Donuts because X"*). These experiments are presented in more detail in Section 5.

4 Corpora

In order to carry out the present research for detecting and solving the complexities of opinion QA, we employed two corpora of blog posts: *EmotiBlog* (Boldrini *et al.*, 2009a) and the TAC 2008 Opinion Pilot test collection (part of the Blog06 corpus).

The TAC 2008 Opinion Pilot test collection is composed by documents with the answers to the opinion questions given on 25 targets. *EmotiBlog* is a collection of blog posts in English extracted form the Web. As a consequence, it represents a genuine example of this textual genre. It consists in a monothematic corpus about the Kyoto Protocol, annotated with the improved version of *EmotiBlog* (Boldrini *et al.*, 2009b). It is well know that Opinion Mining (OM) is a very complex task due to the high variability of the language employed. Thus, our objective is to build an annotation model that is able to capture the whole range of phenomena specific to subjectivity expression. Additional criteria employed when choosing the elements to be annotated were effectiveness and noise minimization. Thus, from the first version of the model, the elements which did not prove to be statistically relevant have been eliminated. The elements that compose the improved version of the annotation model are presented in Table 1.

[3] http://research.nii.ac.jp/ntcir/

[4] http://verbs.colorado.edu/~mpalmer/projects/ace.html

Elements	Description
Obj. speech	Confidence, comment, source, target.
Subj. speech	Confidence, comment, level, emotion, phenomenon, polarity, source and target.
Adjectives/Adverbs	Confidence, comment, level, emotion, phenomenon, modifier/not, polarity, source and target.
Verbs/ Names	Confidence, comment, level, emotion, phenomenon, polarity, mode, source and target.
Anaphora	Confidence, comment, type, source and target.
Capital letter/ Punctuation	Confidence, comment, level, emotion, phenomenon, polarity, source and target.
Phenomenon	Confidence, comment, type, collocation, saying, slang, title, and rhetoric.
Reader/Author Interpr. (obj.)	Confidence, comment, level, emotion, phenomenon, polarity, source and target.
Emotions	Confidence, comment, accept, anger, anticipation, anxiety, appreciation, bad, bewilderment, comfort, compassion…

Table 1: *EmotiBlog* improved structure

The first distinction consists in separating objective and subjective speech. Subsequently, a finer-grained annotation is employed for each of the two types of data. Objective sentences are annotated with source and target (when necessary, also the level of confidence of the annotator and a comment). Subjective elements can be annotated at a sentence level, but they also have to be labeled at a word and/or phrase level. *EmotiBlog* also contains annotations of anaphora at a cross-document level (to interpret the storyline of the posts) and the sentence type (simple sentence or title, but also saying or collocation). Finally, the Reader and the Writer interpretation have to be marked in objective sentences. These elements are employed to mark and interpret correctly an apparent objective discourse, whose aim is to implicitly express an opinion (e.g. *"The camera broke in two days"*). The first is useful to extract what is the interpretation of the reader (for example if the writer says *The result of their governing was an increase of 3.4% in the unemployment rate* instead of *The result of their governing was a disaster for the unemployment rate*) and the second to understand the background of the reader (i.e.. *These criminals are not able to govern* instead of saying *the x party is not able to govern*). From this sentence, for example, the reader can deduce the political ideas of the writer. The questions whose answers are annotated with *EmotiBlog* are the subset of opinion questions in English presented in (Balahur et al., 2009). The complete list of questions is shown in Table 2.

N	Question
2	What motivates people's negative opinions on the Kyoto Protocol?
5	What are the reasons for the success of the Kyoto Protocol?
6	What arguments do people bring for their criticism of media as far as the Kyoto Protocol is concerned?
7	Why do people criticize Richard Branson?
11	What negative opinions do people have on Hilary Benn?
12	Why do Americans praise Al Gore's attitude towards the Kyoto protocol?
15	What alternative environmental friendly resources do people suggest to use instead of gas en the future?
16	Is Arnold Schwarzenegger pro or against the reduction of CO2 emissions?
18	What improvements are proposed to the Kyoto Protocol?
19	What is Bush accused of as far as political measures are concerned?
20	What initiative of an international body is thought to be a good continuation for the Kyoto Protocol?

Table 2: Questions over the *EmotiBlog* corpus

The main difference between the two corpora employed is that *Emotiblog* is monothematic, containing only posts about the Kyoto Protocol, while the TAC 2008 corpus contains documents on a multitude of subjects. Therefore, different techniques must be adjusted in order to treat each of them.

5 Experiments

5.1 Question Analysis

In order to be able to extract the correct answer to opinion questions, different elements must be considered. As stated in (Balahur et al., 2009) we need to determine both the expected answer type (EAT) of the question – as in the case of factoid ones - as well as new elements – such as expected polarity type (EPT). However, opinions are directional – i.e., they suppose the existence of a source and a target to which they are addressed. Thus, we introduce two new elements in the question analysis – expected source (ES) and expected target (ET). These two elements are selected by applying SR and choosing the source as the agent in the sentence and the direct object (patient) as the target of the opinion. Of course, the source and target of the

opinions expressed can also be found in other roles, but at this stage we only consider these cases. The expected answer type (EAT) (e.g. opinion or other) is determined using Machine Learning (ML) using Support Vector Machine (SVM), by taking into account the interrogation formula, the subjectivity of the verb and the presence of polarity words in the target SR. In the case of expected opinionated answers, we also compute the expected polarity type (EPT) – by applying OM on the affirmative version of the question. An example of such a transformation is: given the question *"What are the reasons for the success of the Kyoto Protocol?"*, the affirmative version of the question is *"The reasons for the success of the Kyoto Protocol are X".*

5.2 Candidate Snippet Retrieval

In the answer retrieval stage, we employ four strategies:

1. Using the JIRS (JAVA Information Retrieval System) IR engine (Gómez et al., 2007) to find relevant snippets. JIRS retrieves passages (of the desired length), based on searching the question structures (n-grams) instead of the keywords, and comparing them.

2. Using the "Yahoo" search engine to retrieve the first 20 documents that are most related to the query. Subsequently, we apply LSA on the retrieved documents and extract the words that are most related to the topic. Finally, we expand the query using words that are very similar to the topic and retrieve snippets that contain at least one of them and the ET.
3. Generating equivalent expressions for the query, using the DIRT paraphrase collection (Lin and Pantel, 2001) and retrieving candidate snippets of length 1 and 3 (length refers to the number of sentences retrieved) that are similar to each of the new generated queries and contain the ET. Similarity is computed using the cosine measure. Examples of alternative queries for *"People like George Clooney"* are *"People adore George Clooney", "People enjoy George Clooney", "People prefer George Clooney"*.
4. Enriching the equivalent expressions for the query in 3. with the topic-related words discovered in 2. using LSA.

5.3 Polarity and topic-polarity classification of snippets

In order to determine the correct answers from the collection of retrieved snippets, we must filter for the next processing stage only the candidates that have the same polarity as the question EPT. For polarity detection, we use a combined system employing SVM ML on unigram and bigram features trained on the NTCIR MOAT 7 data and an unsupervised lexicon-based system. In order to compute the features for each of the unigrams and bigrams, we compute the tf-idf scores.

The unsupervised system uses the Opinion Finder lexicon to filter out subjective sentences – that contain more than two subjective words or a subjective word and a valence shifter (obtained from the General Inquirer resource). Subsequently, it accounts for the presence of opinionated words from four different lexicons – MicroWordNet (Cerini et al., 2007), WordNet Affect (Strapparava and Valitutti, 2004) Emotion Triggers (Balahur and Montoyo, 2008) and General Inquirer (Stone et al., 1966). For the joint topic-polarity analysis, we first employ LSA to determine the words that are strongly associated to the topic, as described in Section 5.2 (second list item). Consequently, we compute the polarity of the sentences that contain at least one topic word and the question target.

5.4 Filtering using SR

Finally, answers are filtered using the *Semrol* system for SR labeling described in (Moreda, 2008). Subsequently, we filter all snippets with the required target and source as agent or patient. *Semrol* receives as input plain text with information about grammar, syntax, word senses, Named Entities and constituents of each verb. The system output is the given text, in which the semantic roles information of each constituent is marked. Ambiguity is resolved

depending on the machine algorithm employed, which in this case is TIMBL[5].

6 Evaluation and Discussion

We evaluate our approaches on both the *EmotiBlog* question collection, as well as on the TAC 2008 Opinion Pilot test set. We compare them against the performance of the system evaluated in (Balahur et al., 2009) and the best (Copeck et al., 2008) and worst (Varma et al., 2008) scoring systems (as far as F-measure is concerned) in the TAC 2008 task. For both the TAC 2008 and *EmotiBlog* sets of questions, we employ the SR system in SA and determine the ES, ET and EPT. Subsequently, for each of the two corpora, we retrieve 1-phrase and 3-phrase snippets. The retrieval of the of the *EmotiBlog* candidate snippets is done using query expansion with LSA and filtering according to the ET. Further on, we apply sentiment analysis (SA) using the approach described in Section 5.3 and select only the snippets whose polarity is the same as the determined question EPT. The results are presented in Table 3.

Q No.	**No.** A	**Baseline** (Balahur et al., 2009)				**1 phrase + ET+SA**				**3 phrases +ET+SA**			
		@1	@5	@10	@50	@1	@5	@10	@50	@1	@5	@10	@20
2	5	0	2	3	4	1	2	3	4	1	2	3	4
5	11	0	0	0	0	0	2	2	2	1	2	3	4
6	2	0	0	1	2	1	1	2	2	0	1	2	2
7	5	0	0	1	3	1	1	1	3	0	2	2	4
11	2	1	1	1	1	0	0	0	0	0	0	0	1
12	3	0	1	1	1	0	1	2	3	0	0	1	2
15	1	0	0	1	1	0	0	1	1	1	1	1	1
16	6	1	4	4	4	0	1	1	2	1	2	2	6
18	1	0	0	0	0	0	0	0	0	0	0	0	0
19	27	1	5	6	18	0	1	1	2	0	1	1	1
20	4	0	0	0	0	0	0	1	1	0	0	1	2

Table 3: Results for questions over EmotiBlog

[5] http://ilk.uvt.nl/downloads/pub/papers/Timbl_6.2_Manual.pdf and http://ilk.uvt.nl/timbl/

The retrieval of the TAC 2008 1-phrase and 3-phrase candidate snippets was done using JIRS and, in a second approach, using the cosine similarity measure between alternative queries generated using paraphrases and candidate snippets. Subsequently, we performed different evaluations, in order to assess the impact of using different resources and tools. Since the TAC 2008 had a limit of the output of 7000 characters, in order to compute a comparable F-measure, at the end of each processing chain, we only considered the snippets for the 1-phrase retrieval and for the 3-phases one until this limit was reached.

1. In the first evaluation, we only apply the sentiment analysis tool and select the snippets that have the same polarity as the question EPT and the ET is found in the snippet. (i.e. *What motivates peoples negative opinions on the Kyoto Protocol? The Kyoto Protocol becomes deterrence to economic development and international cooperation/ Secondly, in terms of administrative aspect, the Kyoto Protocol is difficult to implement.* - same EPT and ET)
   We also detected cases of same polarity but no ET, e.g. *These attempts mean annual expenditures of $700 million in tax credits in order to endorse technologies, $3 billion in developing research and $200 million in settling technology into developing countries* – EPT negative but not same ET.
2. In the second evaluation, we add the result of the LSA process to filter out the snippets from 1., containing the words related to the topic starting from the retrieval performed by Yahoo, which extracts the first 20 documents about the topic.
3. In the third evaluation, we filter the results in 2 by applying the *Semrol* system and setting the condition that the ET and ES are the agent or the patient of the snippet.
4. In the fourth evaluation setting, we replaced the set of snippets retrieved using JIRS with the ones obtained by generating alternative queries using paraphrases (as explained in the third method in section 5.2.). We subsequently filtered these results based on their polarity (so that it corresponds to the EPT) and on the condition that the source and target of the opinion (identified through SRL using Semrol) correspond to the ES and ET.

5. In the fourth evaluation setting, we replaced the set of snippets retrieved using JIRS with the ones obtained by generating alternative queries using paraphrases, enriched with the topic words determined using LSA. We subsequently filtered these results based on their polarity (so that it corresponds to the EPT) and on the condition that the source and target of the opinion (identified through SRL using Semrol) correspond to the ES and ET.

System	F-measure
Best TAC	0.534
Worst TAC	0.101
JIRS + SA+ET (1 phrase)	0.377
JIRS + SA+ET (3 phrases)	0.431
JIRS + SA+ET+LSA (1 phrase)	0.489
JIRS + SA+ET+LSA (3 phrases)	0.505
JIRS + SA+ET+LSA+SR (1 phrase)	0. 533
JIRS + SA+ET+LSA+SR (3 phrases)	0.571
PAR+SA+ET+SR(1 phrase)	0.345
PAR+SA+ET+SR(2 phrase)	0.386
PAR_LSA+SA+ET+SR (1 phrase)	0.453
PAR_LSA+SA+ET+SR (3 phrases)	0.434

Table 4: Results for the TAC 2008 test set

From the results obtained (Table 3 and Table 4), we can draw the following conclusions. Firstly, the hypothesis that OQA requires the retrieval of longer snippets was confirmed by the improved results, both in the case of *EmotiBlog*, as well as the TAC 2008 corpus. Secondly, opinion questions require the use of joint topic-sentiment analysis. As we can see from the results, the use of topic-related words when computing of the affect influences the results in a positive manner and joint topic-sentiment analysis is especially useful for the cases of questions asked on a monothematic corpus. Thirdly, another conclusion that we can draw is that target and source detection are highly relevant steps at the time of answer filtering, not only helping the more accurate retrieval of answers, but also at placing at the top of the retrieval the relevant results (as more relevant information is contained within these 7000 characters). The use of paraphrases at the retrieval stage was shown to produce a significant drop in results, which we explain by the noise introduced and the fact that more non-relevant answer candidates were introduced among the results. Nonetheless, as we can see from the overall relatively low improvement in the results, much remains to be done in order to appropriately tackle OQA. As seen in the results, there are still questions for which no answer is found (e.g. 18). This is due to the fact that the treatment of such questions requires the use of inference techniques that are presently unavailable (i.e. define terms such as *"improvement"*, possibly as *"X better than Y"*, in which case opinion extraction from comparative sentences should be introduced in the model).

The results obtained when using all the components for the 3-sentence long snippets significantly improve the results obtained by the best system participating in the TAC 2008 Opinion Pilot competition (determined using a paired t-test for statistical significance, with confidence level 5%). Finally, from the analysis of the errors, we could see that even though some tools are in theory useful and should produce higher improvements – such as SR – their performance in reality does not produce drastically higher results. The idea to use paraphrases for query expansion also proved to decrease the system performance. From preliminary results obtained using JavaRap[6] for coreference resolution, we also noticed that the performance of the OQA lowered, although theoretically it should have improved.

7 Conclusions ad Future Work

In this paper, we presented and evaluated different methods and techniques with the objective of improving the task of QA in the context of opinion data. From the evaluations performed using different NLP resources and tools, we concluded that joint topic-sentiment analysis, as well as the target and source identification, are crucial for the correct performance of this task. We have also demonstrated that by retrieving longer answers, the results have improved. We tested, within a simple setting, the impact of using paraphrases in the context of opinion questions and saw that their use lowered the system results. Although such paraphrase col-

[6]http://wing.comp.nus.edu.sg/~qiu/NLPTools/JavaRAP.htm

lections include a lot of noise and have been shown to decrease system performance even in the case of factual questions, we believe that other types of paraphrasing methods should be investigated in the context of OQA. We thus showed that opinion QA requires the development of appropriate strategies at the different stages of the task (recognition of subjective questions, detection of subjective content of the questions, source and target identification, retrieval and classification of the candidate answer data). Due to the high level of complexity of subjective language, our future work will be focused on testing higher-performing tools for coreference resolution, other (opinion) paraphrases collections and paraphrasing methods and the employment of external knowledge sources that refine the semantics of queries. We also plan to include other SA methods and extend the semantic roles considered for ET and ES, with the purpose of checking if they improve or not the performance of the QA system.

Robust Sentiment Detection on Twitter from Biased and Noisy Data

Abstract

In this paper, we propose an approach to automatically detect sentiments on Twitter messages (tweets) that explores some characteristics of how tweets are written and meta-information of the words that compose these messages. Moreover, we leverage sources of noisy labels as our training data. These noisy labels were provided by a few sentiment detection websites over twitter data. In our experiments, we show that since our features are able to capture a more abstract representation of tweets, our solution is more effective than previous ones and also more robust regarding biased and noisy data, which is the kind of data provided by these sources.

1 Introduction

Twitter is one of the most popular social network websites and has been growing at a very fast pace. The number of Twitter users reached an estimated 75 million by the end of 2009, up from approximately 5 million in the previous year. Through the twitter platform, users share either information or opinions about personalities, politicians, products, companies, events (Prentice and Huffman, 2008) etc. This has been attracting the attention of different communities interested in analyzing its content.

Sentiment detection of tweets is one of the basic analysis utility functions needed by various applications over twitter data. Many systems and approaches have been implemented to automatically detect sentiment on texts (e.g., news articles, Web reviews and Web blogs) (Pang et al., 2002; Pang and Lee, 2004; Wiebe and Riloff, 2005; Glance et al., 2005; Wilson et al., 2005). Most of these approaches use the raw word representation (n-grams) as features to build a model for sentiment detection and perform this task over large pieces of texts. However, the main limitation of using these techniques for the Twitter context is messages posted on Twitter, so-called tweets, are very short. The maximum size of a tweet is 140 characters.

In this paper, we propose a 2-step sentiment analysis classification method for Twitter, which first classifies messages as subjective and objective, and further distinguishes the subjective tweets as positive or negative. To reduce the labeling effort in creating these classifiers, instead of using manually annotated data to compose the training data, as regular supervised learning approaches, we leverage sources of noisy labels as our training data. These noisy labels were provided by a few sentiment detection websites over twitter data. To better utilize these sources, we verify the potential value of using and combining them, providing an analysis of the provided labels, examine different strategies of combining these sources in order to obtain the best outcome; and, propose a more robust feature set that captures a more abstract representation of tweets, composed by meta-information associated to words and specific characteristics of how tweets are written. By using it, we aim to handle better: the problem of lack of information on tweets, helping on the generalization process of the classification algorithms; and the noisy and biased labels provided by those websites.

The remainder of this paper is organized as follows. In Section 2, we provide some context about messages on Twitter and about the websites used as label sources. We introduce the features used in the sentiment detection and also provide a deep analysis of the labels generated by those sources in Section 3. We examine different strategies of

Coling 2008: Poster Volume, pages 36–44,
Beijing, August 2010

combining these sources and present an extensive experimental evaluation in Section 4. Finally, we discuss previous works related to ours in Section 5 and conclude in Section 6, where we outline directions and future work.

2 Preliminaries

In this section, we give some context about Twitter messages and the sources used for our data-driven approach.

Tweets. The Twitter messages are called tweets. There are some particular features that can be used to compose a tweet (Figure 1 illustrates an example): "RT" is an acronym for retweet, which means the tweet was forwarded from a previous post; "@twUser" represents that this message is a reply to the user "twUser"; "#obama" is a tag provided by the user for this message, so-called hashtag; and "http://bit.ly/9K4n9p" is a link to some external source. Tweets are limited to 140 characters. Due to this lack of information in terms of words present in a tweet, we explore some of the tweet features listed above to boost the sentiment detection, as we will show in detail in Section 3.

Data Sources. We collected data from 3 different websites that provide almost real-time sentiment detection for tweets: Twendz, Twitter Sentiment and TweetFeel. To collect data, we issued a query containing a common stopword "of", as we are interested in collecting generic data, and retrieved tweets from these sites for three weeks, archiving the returned tweets along with their sentiment labels. Table 1 shows more details about these sources. Two of the websites provide 3-class detection: positive, negative and neutral and one of them just 2-class detection. One thing to note is our crawling process obtained a very different number of tweets from each website. This might be a result of differences among their sampling processes of Twitter stream or some kind of filtering process to output. For instance, a site may only present the tweets it has more confidence about their sentiment. In Section 3, we present a deep analysis of the data provided by these sources, showing if they are useful to build a sentiment classification.

```
RT @twUser: Obama  is the first U.S. president not to
have seen a new state added in his lifetime.
http://bit.ly/9K4n9p  #obama
```

Figure 1: Example of a tweet.

3 Twitter Sentiment Detection

Our goal is to categorize a tweet into one of the three sentiment categories: positive, neutral or negative. Similar to (Pang and Lee, 2004; Wilson et al., 2005), we implement a 2-step sentiment detection framework. The first step targets on distinguishing subjective tweets from non-subjective tweets (subjectivity detection). The second one further classifies the subjective tweets into positive and negative, namely, the polarity detection. Both classifiers perform prediction using an abstract representation of the sentences as features, as we show later in this section.

3.1 Features

A variety of features have been exploited on the problem of sentiment detection (Pang and Lee, 2004; Pang et al., 2002; Wiebe et al., 1999; Wiebe and Riloff, 2005; Riloff et al., 2006) including unigrams, bigrams, part-of-speech tags etc. A natural choice would be to use the raw word representation (n-grams) as features, since they obtained good results in previous works (Pang and Lee, 2004; Pang et al., 2002) that deal with large texts. However, as we want to perform sentiment detection on very short messages (tweets), this strategy might not be effective, as shown in our experiments. In this context, we are motivated to develop an abstract representation of tweets. We propose the use of two sets of features: meta-information about the words on tweets and characteristics of how tweets are written.

Meta-features. Given a word in a tweet, we map it to its part-of-speech using a part-of-speech dictionary[1]. Previous approaches (Wiebe and Riloff, 2005; Riloff et al., 2003) have shown that the effectiveness of using POS tags for this task. The intuition is certain POS tags are good indicators for sentiment tagging. For example, opinion messages are more likely containing adjec-

[1]The pos dictionary we used in this paper is available at: http://wordlist.sourceforge.net/pos-readme.

Data sources	URL	# Tweets	Sentiments
Twendz	http://twendz.waggeneredstrom.com/	254081	pos/neg/neutral
Twitter Sentiment	http://twittersentiment.appspot.com/	79696	pos/neg/neutral
TweetFeel	http://www.tweetfeel.com/	13122	pos/neg

Table 1: Information about the 3 data sources.

tives or interjections. In addition to POS tags, we map the word to its prior subjectivity (weak and strong subjectivity), also used by (Wiebe and Riloff, 2005), and polarity (positive, negative and neutral). The prior polarity is switched from positive to negative or vice-versa when a negative expression (as, e.g., "don't", "never") precedes the word. We obtained the prior subjectivity and polarity information from subjectivity lexicon of about 8,000 words used in (Riloff and Wiebe, 2003)[2]. Although this is a very comprehensive list, slang and specific Web vocabulary are not present on it, e.g., words as "yummy" or "ftw". For this reason, we collected popular words used on online discussions from many online sources and added them to this list.

Tweet Syntax Features. We exploited the syntax of the tweets to compose our features. They are: retweet; hashtag; reply; link, if the tweet contains a link; punctuation (exclamation and questions marks); emoticons (textual expression representing facial expressions); and upper cases (the number of words that starts with upper case in the tweet).

The frequency of each feature in a tweet is divided by the number of the words in the tweet.

3.2 Subjectivity Classifier

As we mentioned before, the first step in our tweet sentiment detection is to predict the subjectivity of a given tweet. We decided to create a single classifier by combining the objectivity sentences from Twendz and Twitter Sentiment (objectivity class) and the subjectivity sentences from all 3 sources. As we do not know the quality of the labels provided by these sources, we perform a cleaning process over this data to assure some reasonable quality. These are the steps:

1. Disagreement removal: we remove the tweets that are disagreed between the data sources in terms of subjectivity;

2. Same user's messages: we observed that the users with the highest number of messages in our dataset are usually those ones that post some objective messages, for example, advertising some product or posting some job recruiting information. For this reason, we allowed in the training data only one message from the same user. As we show later, this boosts the classification performance, mainly because it removes tweets labeled as subjective by the data sources but are in fact objective;

3. Top opinion words: to clean the objective training set, we remove from this set tweets that contain the top-n opinion words in the subjectivity training set, e.g., words as cool, suck, awesome etc.

As we show in Section 4, this process is in fact able to remove certain noisy in the training data, leading to a better performing subjectivity classifier.

To illustrate which of the proposed features are more effective for this task, the top-5 features in terms of information gain, based on our training data, are: positive polarity, link, strong subjective, upper case and verbs. Three of them are meta-information (positive polarity, strong subjective and verbs) and the other two are tweet syntax features (link and upper case). Here is a typical example of a objective tweet in which the user pointed an external link and used many upper case words: "Starbucks Expands Pay-By-IPhone Pilot to 1,000 Stores—Starbucks customers with Apple iPhones or iPod touches can .. http://oohja.com/x9UbC".

[2]The subjectivity lexicon is available at http://www.cs.pitt.edu/mpqa/

3.3 Polarity Classifier

The second step of our sentiment detection approach is polarity classification, i.e., predicting positive or negative sentiment on subjective tweets. In this section, first we analyze the quality of the polarity labels provided by the three sources, and whether their combination has the potential to bring improvement. Second, we present some modifications in the proposed features that are more suitable for this task.

3.3.1 Analysis of the Data Sources

The 3 data sources used in this work provide some kind of polarity labels (see Table 1). Two questions we investigate regarding these sources are: (1) how useful are these polarity labels? and (2) does combining them bring improvement in accuracy?

We take the following aspects into consideration:

- Labeler quality: if the labelers have low quality, combine them might not bring much improvement (Sheng et al., 2008). In our case, each source is treated as a labeler;
- Number of labels provided by the labelers: if the labels are informative, i.e., the probability of them being correct is higher than 0.5, the more the number of labels, the higher is the performance of a classifier built from them (Sheng et al., 2008);
- Labeler bias: the labeled data provided by the labelers might be only a subset of the real data distribution. For instance, labelers might be interested in only providing labels that they are more confident about;
- Different labeler bias: if labelers make similar mistakes, the combination of them might not bring much improvement.

We provide an empirical analysis of these datasets to address these points. First, we measure the polarity detection quality of a source by calculating the probability p of a label from this source being correct. We use the data manually labeled for assessing the classifiers' performance (testing data, see Section 4) to obtain the correct labels of a data sample. Table 2 shows their values. We can conclude from these numbers that the 3 sources provide a reasonable quality data. This means that combining them might bring some improvement to the polarity detection instead of, for instance, using one of them in isolation. An aspect that is overlooked by quality is the bias of the data. For instance, by examining the data from TwitterFeel, we found out that only 4 positive words ("awesome","rock","love" and "beat") cover 95% of their positive examples and only 6 negative words ("hate","suck","wtf","piss","stupid" and "fail") cover 96% of their negative set. Clearly, the data provided by this source is biased towards these words. This is probably the reason why this website outputs such fewer number of tweets compared to the other websites (see Table 1) as well as why its data has the smallest entropy among the sources (see Table 2).

Data sources	Quality	Entropy
Twendz	0.77	8.3
TwitterSentiment	0.82	7.9
TweetFeel	0.89	7.5

Table 2: Quality of the labels and entropy of the tweets provided by each data source for the polarity detection.

The quality of the data and its individual bias have certainly impact in the combination of labels. However, there is other important aspect that one needs to consider: different bias between the labelers. For instance, if labelers a and b make similar decisions, we expect that combining their labels would not bring much improvement. Therefore, the diversity of labelers is a key element in combining them (Polikar, 2006). One way to measure this is by calculating the agreement between the labels produced by the labelers. We use the kappa coefficient (Cohen, 1960) to measure the degree of agreement between two sources. Table 3 presents the coefficients for each par of data source. All the coefficients are between 0.4 and 0.6, which represents a moderate agreement between the labelers (Landis and Koch, 1977). This means that in fact the sources provide different bias regarding polarity detection.

Data sources	Kappa
Twendz/TwitterSentiment	0.58
TwitterSentiment/TweetFeel	0.58
Twendz/TweetFeel	0.44

Table 3: Kappa coefficient between pairs of sources.

From this analysis we can conclude that combining the labels provided by the 3 sources can improve the performance of the polarity detection instead of using one of them in isolation because they provide diverse labels (moderate kappa agreement) of reasonable quality, although there is some issues related to bias of the labels provided by them. In our experimental evaluation in Section 4, we present results obtained by different strategies of combining these sources that confirm these findings.

3.3.2 Polarity Features

The features used in the polarity detection are the same ones used in the subjectivity detection. However, as one would expect the set of the most discriminative features is different between the two tasks. For subjectivity detection, the top-5 features in terms of information gain, based on the training data, are: negative polarity, positive polarity, verbs, good emoticons and upper case. For this task, the meta-information of the words (negative polarity, positive polarity and verbs) is more important than specific features from Twitter (good emoticons and upper case), whereas for the subjectivity detection, tweet syntax features have a higher relevance.

This analysis show that prior polarity is very important for this task. However, one limitation of using it from a generic list is its values might not hold for some specific scenario. For instance, the polarity of the word "spot" is positive according to this list. However, looking at our training data almost half of the occurrences of this word appears in the positive set and the other half in the negative set. Thus, it is not correct to assume that prior polarity of "spot" is 1 for this particular data. This example illustrates our strategy to weight the prior polarities: for each word w with prior polarity defined by the list, we calculate the prior polarity of w, $pol(w)$, based on the distribution of w in the positive and negative sets. Thus, $pol_{pos}(w) = count(w, pos)/count(w)$ and $pol_{neg}(w) = 1 - pol_{pos}(w)$. We assume the polarity of a word is associated with the polarity of the sentence, which seems to be reasonable since we are dealing with very short messages. Although simple, this strategy is able to improve the polarity detection, as we show in Section 4.

4 Experiments

We have performed an extensive performance evaluation of our solution for twitter sentiment detection. Besides analyzing its overall performance, our goals included: examining different strategies to combine the labels provided by the sources; comparing our approach to previous ones in this area; and evaluating how robust our solution is to the noisy and biased data described in Section 3.

4.1 Experimental Setup

Data Sets. For the subjectivity detection, after the cleansing processing (see Section 3), the training data contains about 200,000 tweets (roughly 100,000 tweets were labeled by the sources as subjective ones and 100,000 objective ones), and for polarity detection, 71046 positive and 79628 negative tweets. For test data, we manually labeled 1,000 tweets as positive, negative and neutral. We also built a development set (1,000 tweets) to tune the parameters of the classification algorithms.

Approaches. For both tasks, subjectivity and polarity detection, we compared our approach with previous ones reported in the literature. Detailed explanation about them are as follows:

- ReviewSA: this is the approach proposed by Pang and Lee (Pang and Lee, 2004) for sentiment analysis in regular online reviews. It performs the subjectivity detection on a sentence-level relying on the proximity between sentences to detect subjectivity. The set of sentences predicted as subjective is then classified as negative or positive in terms of polarity using the unigrams that

compose the sentences. We used the implementation provided by LingPipe (LingPipe, 2008);

- Unigrams: Pang et al. (Pang et al., 2002) showed unigrams are effective for sentiment detection in regular reviews. Based on that, we built unigram-based classifiers for the subjectivity and polarity detections over the training data. Another approach that uses unigrams is the one used by TwitterSentiment website. For polarity detection, they select the positive examples for the training data from the tweets containing good emoticons and negative examples from tweets containing bad emoticons. (Go et al., 2009). We built a polarity classifier using this approach (Unigrams-TS).

- TwitterSA: TwitterSA exploits the features described in Section 3 in this paper. For the subjectivity detection, we trained a classifier from the two available sources, using the cleaning process described in Section 3 to remove noise in the training data, TwitterSA(cleaning), and other classifier trained from the original data, TwitterSA(no-cleaning). For the polarity detection task, we built a few classifiers to compare their performances: TwitterSA(single) and TwitterSA(weights) are two classifiers we trained using combined data from the 3 sources. The only difference is TwitterSA(weights) uses the modification of weighting the prior polarity of the words based on the training data. TwitterSA(voting) and TwitterSA(maxconf) combine classification outputs from 3 classifiers respectively trained from each source. TwitterSA(voting) uses majority voting to combine them and TwitterSA(maxconf) picks the one with maximum confidence score.

We use Weka (Witten and Frank, 2005) to create the classifiers. We tried different learning algorithms available on Weka and SVM obtained the best results for Unigrams and TwitterSA. Experimental results reported in this section are obtained using SVM.

4.2 Subjectivity Detection Evaluation

Table 4 shows the error rates obtained by the different subjectivity detection approaches. TwitterSA achieved lower error rate than both Unigrams and ReviewSA. As a result, these numbers confirm that features inferred from meta-information of words and specific syntax features from tweets are better indicators of the subjectivity than unigrams. Another advantage of our approach is since it uses only 20 features, the training and test times are much faster than using thousands of features like Unigrams. One of the reasons why TwitterSA obtained such a good performance was the process of data cleansing (see Section 3). The label quality provided by the sources for this task was very poor: 0.66 for Twendz and 0.68 for TwitterSentiment. By cleaning the data, the error decreased from 19.9, TwitterSA(no-cleaning), to 18.1, TwitterSA(cleaning). Regarding ReviewSA, its lower performance is expected since tweets are composed by single sentences and ReviewSA relies on the proximity between sentences to perform subjectivity detection.

We also investigated the influence of the size of training data on classification performance. Figure 2 plots the error rates obtained by TwitterSA and Unigrams versus the number of training examples. The curve corresponding to TwitterSA showed that it achieved good performances even with a small training data set, and kept almost constant as more examples were added to the training data, whereas for Unigrams the error rate decreased. For instance, with only 2,000 tweets as training data, TwitterSA obtained 20% of error rate whereas Unigrams 34.5%. These numbers show that our generic representation of tweets produces models that are able to generalize even with a few examples.

4.3 Polarity Detection Evaluation

We provide the results for polarity detection in Table 5. The best performance was obtained by TwitterSA(maxconf), which combines results of the 3 classifiers, respectively trained from each source, by taking the output by the most confident classifier, as the final prediction. TwitterSA(maxconf) was followed by TwitterSA(weights) and TwitterSA(single), both cre-

ated from a single training data. This result shows that computing the prior polarity of the words based on the training data TwitterSA(weights) brings some improvement for this task. TwitterSA(voting) obtained the highest error rate among the TwitterSA approaches. This implies that, in our scenario, the best way of combining the merits of the individual classifiers is by using a confidence score approach.

Unigrams also achieved comparable performances. However, when reducing the size of the training data, the performance gap between TwitterSA and Unigrams is much wider. Figure 3 shows the error rate of both approaches[3] in function of the training size. Similar to subjectivity detection, the training size does not have much influence in the error rate for TwitterSA. However for Unigrams, it decreased significantly as the training size increased. For instance, for a training size with 2,000 tweets, the error rate for Unigrams was 46% versus 23.8% for our approach. As for subjectivity detection, this occurs because our features are in fact able to capture a more general representation of the tweets.

Another advantage of TwitterSA over Unigrams is that it produces more robust models. To illustrate this, we present the error rates of Unigrams and TwitterSA where the training data is composed by data from each source in isolation. For the TweetFeel website, where data is very biased (see Section 3), Unigrams obtained an error rate of 44.5% whereas over a sample of the same size of the combined training data (Figure 3), it obtained an error rate of around 30%. Our approach also performed worse over this data than the general one, but still had a reasonable error rate, 25.1%. Regarding the Twendz website, which is the noisiest one (Section 3), Unigrams also obtained a poor performance comparing it against its performance over a sample of the general data with a same size (see Table 5 and Figure 3). Our approach, on the other hand, was not much influenced by the noise (22.9% on noisy data and around 20% on the sample of same size of the general data). Finally, since the data quality provided by TwitterSentiment is better than the previous sources (Table 2), there was not much impact over both classifiers created from it.

From this analysis over real data, we can conclude that our approach produces (1) an effective polarity classifier even when only a small number of training data is available; (2) a robust model to bias and noise in the training data; and (3) combining data sources with such distinct characteristics, as our data analysis in Section 3 pointed out, is effective.

[3]For this experiment, we used the TwitterSA(single) configuration.

Approach	Error rate

5 Related Work

There is a rich literature in the area of sentiment detection (see e.g., (Pang et al., 2002; Pang and Lee, 2004; Wiebe and Riloff, 2005; Go et al., 2009; Glance et al., 2005). Most of these approaches try to perform this task on large texts, as e.g., newspaper articles and movie reviews. Another common characteristic of some of them is the use of n-grams as features to create their models. For instance, Pang and Lee (Pang and Lee, 2004) explores the fact that sentences close in a text might share the same subjectivity to create a better subjectivity detector and, similar to (Pang et al., 2002), uses unigrams as features for the polarity detection. However, these approaches do not obtain a good performance on detecting sentiment on tweets, as we showed in Section 4, mainly because tweets are very short messages. In addition to that, since they use a raw word representation, they are more sensible to bias and noise, and need a much higher number of examples in the training data than our approach to obtain a reasonable performance.

The Web sources used in this paper and some other websites provide sentiment detection for tweets. A great limitation to evaluate them is they do not make available how their classification was built. One exception is TwitterSentiment (Go et al., 2009), for instance, which considers tweets with good emoticons as positive examples and tweets with bad emoticons as negative examples for the training data, and builds a classifier using unigrams and bigrams as features. We showed in Section 4 that our approach works better than theirs for this problem, obtaining lower error rates.

6 Conclusions and Future Work

We have presented an effective and robust sentiment detection approach for Twitter messages, which uses biased and noisy labels as input to build its models. This performance is due to the fact that: (1) our approach creates a more abstract representation of these messages, instead of using a raw word representation of them as some previous approaches; and (2) although noisy and biased, the data sources provide labels of reasonable quality and, since they have different bias, combining them also brought some benefits.

The main limitation of our approach is the cases of sentences that contain antagonistic sentiments. As future work, we want to perform a more fine grained analysis of sentences in order to identify its main focus and then based the sentiment classification on it.

Benchmarking for syntax-based sentential inference

Abstract

We propose a methodology for investigating how well NLP systems handle meaning preserving syntactic variations. We start by presenting a method for the semi automated creation of a benchmark where entailment is mediated solely by meaning preserving syntactic variations. We then use this benchmark to compare a semantic role labeller and two grammar based RTE systems. We argue that the proposed methodology (i) supports a modular evaluation of the ability of NLP systems to handle the syntax/semantic interface and (ii) permits focused error mining and error analysis.

1 Introduction

First launched in 2005, the Recognising Textual Inference Challenge (RTE)[1] aims to assess in how far computer systems can emulate a human being in determining whether a short text fragment H referred to as the hypothesis, follows from or is contradicted by a text fragment T. In the RTE benchmarks, the hypothesis is a short constructed sentence whilst the text fragments are short passages of naturally occurring texts. As a result, the RTE challenge permits evaluating the capacity of NLP systems to handle local textual inference on real data, an enabling technology for any applications involving document interpretation.

In this paper, we focus on entailments based on meaning entailing, syntactic transformations such as:

(1) The man gives the woman the flowers that smell nice $\Rightarrow$ The flowers which are given to the woman smell nice

[1] http://www.pascal-network.org/Challenges/RTE

We start (Section 2) by motivating the approach. We argue that the proposed evaluation methodology (i) interestingly complements the RTE challenge in that it permits a modular, analytic evaluation of the ability of NLP systems to handle syntax-based, sentential inference and (ii) permits focused error mining and analysis .

In Section 3, we go on to describe the benchmark construction process. Each item of the constructed benchmark associates two sentences with a truth value (true or false) indicating whether or not the second sentence can be understood to follow from the first. The construction of these benchmark items relies on the use of a grammar based surface realiser and we show how this permits automatically associating with each inference item, an entailment value (true or false) and a detailed syntactic annotation reflecting the syntactic constructs present in the two sentences constituting each benchmark item.

In section 4, we use the benchmark to evaluate and compare three systems designed to recognise meaning preserving syntactic variations namely, a semantic role labeller, Johan Bos' Nutcracker RTE system (where the syntax/semantic interface is handled by a semantic construction module working on the output of combinatory categorial grammar parser) and the Afazio system, a hybrid system combining statistical parsing, symbolic semantic role labelling and sentential entailment detection using first order logic. We give the evaluation figures for each system. Additionally, we show how the detailed syntactic annotations automatically associated with each benchmark item by the surface realiser can be used to identify the most likely source of errors that is, the syntactic constructs that most frequently co-occur with en entailment recognition error.

Coling 2008: Poster Volume, pages 45–53,
Beijing, August 2010

2 Motivations

Arguably focusing on meaning entailing syntactic transformations is very weak. Indeed, one of the key conclusions at the second RTE Challenge Workshop was that entailment modeling requires vast knowledge resources that correspond to different types of entailment reasoning e.g., ontological and lexical relationships, paraphrases and entailment rules, meaning entailing syntactic transformations and last but not least, world knowledge. Further, Manning (2006) has strongly argued against circumscribing the RTE data to certain forms of inference such as for instance, inferences based solely on linguistic knowledge. Finally, it is also often insisted that naturally occurring data should be favored over constructed data.

While we agree that challenges such as the RTE challenge are useful in testing systems abilities to cope with real data, we believe there is also room for more focused evaluation setups.

Focusing on syntax based entailments. As mentioned above, syntax based entailment is only one of the many inference types involved in determining textual entailment. Nevertheless, a manual analysis of the RTE1 data by (Vanderwende et al., 2005) indicates that 37% of the examples could be handled by considering syntax alone. Similarly, (Garoufi, 2007) shows that 37.5% of the RTE2 data does not involve deep reasoning and more specifically, that 33.8% of the RTE2 data involves syntactic or lexical knowledge only. Hence although the holistic, blackbox type of evaluation practiced in the RTE challenge is undeniably useful in assessing the ability of existing systems to handle local textual inference, a more analytic, modular kind of evaluation targeting syntax-based entailment reasoning is arguably also of interest.

Another interesting feature of the SSI (syntax-based sentential entailment) task we propose is that it provides an alternative way of evaluating semantic role labelling (SRL) systems. Typically, the evaluation of SRL systems relies on a hand annotated corpus such as PropBank or the FrameNet corpus. The systems precision and recall are then computed w.r.t. this reference corpus. As has been repeatedly argued (Moll and Hutchinson, 2003; Galliers and Jones, 1993), intrinsic evaluations may be of very limited value. For semantically oriented tools such as SRL systems, it is important to also assess their results w.r.t. the task which they are meant support namely reasoning : Do the semantic representations built by SRL help in making the correct inferences ? Can they be used, for instance, to determine whether a given sentence answers a given question ? or whether the content of one sentence follow from that another ? As explained in (Giampiccolo et al., 2007), entailment recognition is a first, major step towards answering these questions. Accordingly, instead of comparing the representations produced by SRL systems against a gold standard, the evaluation scheme presented here, permits evaluating them w.r.t. their ability to capture syntax based sentential inference.

It is worth adding that, although the present paper focuses on entailments strictly based on syntax, the proposed methodology should straightforwardly extend to further types of entailment such as in particular, entailments involving lexical relations (synonymy, antonymy, etc.) or entailments involving more complex semantic phenomena such as the interplay between different classes of complement taking verbs, polarity and author commitment discussed in (Nairn et al., 2006). This is because as we shall see in section 3, our approach is based on an extensive, hand written grammar of English integrating syntax and semantics. By modifying the grammar, the lexicon and/or the semantics, data of varying linguistic type and complexity can be produced and used for evaluation.

Hand constructed vs. naturally occurring data. Although in the 90s, hand tailored testsuites such as (Lehmann et al., 1996; Cooper et al., 1995) were deemed useful for evaluating NLP systems, it is today generally assumed that, for evaluation purposes, naturally occurring data is best. We argue that constructed data can interestingly complement naturally occurring data.

To start with, we agree with (Crouch et al., 2006; Cohen et al., 2008) that science generally benefits from combining laboratory and field studies and more specifically, that computational linguistics can benefit from evaluating systems on

a combination of naturally occurring and constructed data.

Moreover, constructed data need not be hand constructed. Interestingly, automating the production of this data can help provide better data annotation as well as better and better balanced data coverage than both hand constructed data and naturally occurring data. Indeed, as we shall show in section 4, the benchmark creation process presented here supports a detailed and fully automated annotation of the syntactic properties associated with each benchmark item. As shown in section 5, this in turn allows for detailed error mining making it possible to identify the most likely causes of system errors. Additionally, the proposed methodology permits controlling over such benchmark parameters as the size of the data set, the balance between true and false entailments, the correlation between word overlap and entailment value and/or the specific syntactic phenomena involved. This is in contrast with the RTE data collection process where "the distribution of examples is arbitrary to a large extent, being determined by manual selection[2]" (Giampiccolo et al., 2007). As has been repeatedly pointed out (Burchardt et al., 2007; Garoufi, 2007), the RTE datasets are poorly balanced w.r.t., both the frequency and the coverage of the various phenomena interacting with textual inference.

3 Benchmark

We now present the content of an SSI benchmark and the method for constructing it.

An SSI benchmark item (cf. e.g., Figure 1) consists of two sentences and a truth value (true or false) indicating whether or not the second sentence can be understood to follow from the first. In addition, each sentence is associated with a detailed syntactic annotation describing the syntactic constructs present in the sentence.

The benchmark construction process consists of two main steps. First, a generation bank is built. Second, this generation bank is drawn upon

T: The man gives the woman the flowers that smell nice
smell:{n0Va1,active,relSubj,canAdj}
give:{n0Vn2n1,active,canSubj,canObj,canIObj}
H: The flowers are given to the woman
give:{n0Vn1Pn2,shortPassive,canSubj,canIObj}
Entailment: TRUE

Figure 1: An SSI Benchmark item

to construct a balanced data set for SSI evaluation. We now describe each of these processes in turn.

Constructing a generation bank We use the term "generation bank" to refer to a dataset whose items are produced by a surface realiser i.e., a sentence generator. A surface realiser in turn is a program which associates with a given semantic representation, the set of sentences verbalising the meaning encoded by that representation. To construct our generation bank, we use the GenI surface realiser (Gardent and Kow, 2007). This realiser uses a Feature based Tree Adjoining Grammar (FTAG) augmented with a unification sematics as proposed in (Gardent and Kallmeyer, 2003) to produce all the sentences associated by the grammar with a given semantic representation. Interestingly, the FTAG used has been compiled out of a factorised representation and as a result, each elementary grammar unit (i.e., elementary FTAG tree) and further each parse tree, is associated with a list of items indicating the syntactic construct(s) captured by that unit/tree[3]. In short, GenI permits associating with a given semantics, a set of sentences and further for each of these sentences, a set of items indicating the syntactic construct(s) present in the syntactic tree of that sentence. For instance, the sentences and the syntactic constructs associated by GenI with the semantics given in (2) are those given in (3).

(2) A:give(B C D E) G:the(C) F:man(C) H:the(D) I:woman(D) J:the(E) K:flower(E) L:passive(B) L:smell(M E N) O:nice(N)

(3) a. The flower which smells nice is given to the woman by the man

[2]The short texts of the RTE benchmarks are automatically extracted from real texts using different applications (e.g., Q/A, summarisation, information extraction, information retrieval systems) but the query used to retrieve these texts is either constructed manually or post-edited.

[3]Space is lacking to give a detailed explanation of this process here. We refer the reader to (Gardent and Kow, 2007) for more details on how GenI associates with a given semantics, a set of sentences and for each sentence a set of items indicating the syntactic construct(s) present in the syntactic tree of that sentence.

give:n0Vn1Pn2-Passive-CanSubj-ToObj-ByAgt, smell:n0V-active-OvertSubjectRelative

h. The flower that is given to the woman by the man smells nice
give:n0Vn1Pn2-Passive-CovertSubjectRelative, smell:n0V-active

The tagset of syntactic annotation covers the subcategorisation type of the verb, a specification of the verb mood and a description of how arguments are realised.

The semantic representation language used is a simplified version of the flat semantics used in e.g., (Copestake et al., 2005) which is sufficient for the cases handled in the present paper. The grammar and therefore the generator, can however easily be modified to integrate the more sophisticated version proposed in (Gardent and Kallmeyer, 2003) and thereby provide an adequate treatment of scope.

Constructing an SSI benchmark. Given a generation bank, false and true sentential entailment pairs can be automatically produced by taking pairs of sentences $\langle S_1, S_2 \rangle$ and comparing their semantics: if the semantics of S_2 is entailed by the semantics of S_1, the pair is marked as TRUE else as FALSE. The syntactic annotations associated in the generation bank with each sentence are carried over to the SSI benchmark thereby ensuring that the overall information contained in each SSI benchmark is as illustrated in Figure 1 namely, two pairs of syntactically annotated sentences and a truth value indicating (non) entailment.

To determine whether a sentence textually entails another we translate their flat semantic representation into first order logic and check for logical entailment. Differences in semantic representations which are linked to functional surface differences such as active/passive or the presence/absence of a complementizer (*John sees Mary leaving/John sees that Mary leaves*) are dealt with by (automatically) removing the corresponding semantic literals from the semantic representation before translating it to first order logic. In other words, active/passive variants of the same sentence are deemed semantically equivalent.

Note that contrary to what is assumed in the RTE challenge, entailment is here logical rather than textual (i.e., determined by a human) entailment. By using logical, rather than textual (i.e., human based) entailment, it is possible that some cases of syntax mediated textual entailments are not taken into account. However, intuitively, it seems reasonable to assume that for most of the entailments mediated by syntax alone, logical and textual entailments coincide.

3.1 The SSI benchmark

Using the methodology just described, we first produced a generation bank of 226 items using 81 input formula distributed over 4 verb types. From this generation bank, a total of 6 396 SSI-pairs were built with a ratio of 42.6% true and 57.4% false entailments.

For our experiment, we extracted from this SSI-suite, 1000 pairs with an equal proportion of true and false entailments and a 7/23/30/40 distribution of four subcategorisation types namely, adjectival predicative (n0Va1 e.g., *The cake tastes good*), intransitive (n0V), transitive (n0Vn1) and ditransitive (n0Vn2n1)[4]. We furthermore con-

[4]The subcategorisation type of an SSI item is determined manually and refers either to the main verb if the sentence is

strained the suite to respect a neutral correlation between word overlap and entailment. Following (Garoufi, 2007), we define this correlation as follows. The word overlap $wo(T, H)$ between two sentences T and H is the ratio of common lemmas between T and H on the number of lemmas in H (non content words are ignored). If entailment holds, the word overlap/entailment correlation value of the sentence pair is $wo(T, H)$. Otherwise it is $1 - wo(T, H)$. The 1000 items of the SSI suite used in our experiment were chosen in such a way that the word overlap/entailment correlation value of the SSI suite is 0.49.

In sum, the SSI suite used for testing exhibits the following features. First, it is balanced w.r.t. entailment. Second, it displays good syntactic variability based both on the constrained distribution of the four subcategorisation types and on the use of the XTAG grammar to construct sentences from abstract representations (cf. the paraphrases in (3) generated by GenI from the representation given in (2)). Third, it contains 1000 items and could easily be extended to cover more and more varied data. Fourth, it is specifically tailored to check systems on their ability to deal with syntax based sentential entailment: word overlap is high, syntactic variability is provided and the correlation between word overlap and entailment is not biased.

4 System evaluation and comparison

SRL and grammar based systems equipped with a compositional semantics are primary targets for an SSI evaluation. Indeed these systems aim to abstract away from syntactic differences by producing semantic representations of a text which capture predicate/argument relations independent of their syntactic realisation.

We evaluated three such systems on the SSI benchmark namely, NutCracker, (Johansson and Nugues, 2008)'s Semantic Role Labeller and the Afazio RTE system.

4.1 Systems

Nutcracker Nutcracker is a system for recognising textual entailment which uses deep semantic processing and automated reasoning. Deep semantic processing associates each sentence with a Discourse Representation Structure (DRS (Kamp and Reyle, 1993)) by first, using a statistical parser to build the syntactic parse of the sentence and second, using a symbolic semantic construction module to associate a DRS with the syntactic parse. Entailment between two DRSs is then checked by translating this DRS into a first-order logical (FOL) formula and first trying to find a proof. If a proof is found then the entailment is set to true. Otherwise, Nutcracker backs off with a word overlap module computed over an abstract representation of the input sentences and taking into account WordNet related information. Nutcracker was entered in the first RTE challenge and scored an accuraccy (percentage of correct judgments) of 0.562 when used as is and 0.612 when combined with machine learning techniques. For our experiment, we use the online version of Nutcracker and the given default parameters.

Afazio Like Nutcracker, the Afazio system combines a statistical parser (the Stanford parser) with a symbolic semantic component. This component pipelines several rewrite modules which translate the parser output into a first order logic formula intended to abstract away from surface differences and assign syntactic paraphrases the same representation (Bedaride and Gardent, 2009). Special emphasis is placed on capturing syntax based equivalences such as syntactic (e.g., active/passive) variations, redistributions and noun/verb variants. Once the parser output has been normalised into predicate/argument representations capturing these equivalences, the resulting structures are rewritten into first order logic formulae. Like Nutcracker, Afazio checks entailment using first order automated reasoners namely, *Equinox* and *Paradox* [5].

SRL (Johansson and Nugues, 2008)'s semantic role labeller achieved the top score in the closed CoNLL 2008 challenge reaching a labeled semantic F1 of 81.65. To allow for comparison with Nutcracker and Afazio, we adapted the

a clause or to the embedded verb if the sentence is a complex sentence.

[5] http://www.cs.chalmers.se/~koen/folkung/

rewrite module used in Afazio to rewrite Predicate/Argument structures into FOL formula in such a way as to fit (Johansson and Nugues, 2008)'s SRL output. We then use FOL automated reasoner to check entailment.

4.2 Evaluation scheme and results

The results obtained by the three systems are summarised in Table 1. TP (true positives) is the number of entailments recognised as such by the system and TN (true negatives) of non entailments. Conversely, FN and FP indicate how often the systems get it wrong: FP is the number of non entailments labelled as entailments by the system and FN, the number of entailments labelled as non entailments. 'ERROR' refers to cases where the CCG parser used by Nutcracker fails to find a parse. The last three columns indicate the overall ability of the systems to recognise false entailments (TN/N with N the number of false entailment in the benchmark), true entailments (TP/P) and all true and false entailment (Precision).

Overall, Afazio outperforms both Nutcracker and the SRL system. This is unsurprising since contrary to these other two systems, Afazio was specifically designed to handle syntax based sentential entailment. Its strength is that it combines a full SRL system with a semantic construction module designed for entailment detection. More surprisingly, the CCG parser used by Nutcracker often fails to find a parse.

The SRL system has a high rate of false negatives. Using the error mining technique presented in the next section, we found that the most suspicious syntactic constructs all included a relativised argument. A closer look at the analyses showed that this was due to the fact that SRL systems fail to identify the antecedent of a relative pronoun, an identification that is necessary for entailment checking. Another important difference with Afazio is that the SRL system produces a single output. In contrast, Afazio checks entailment for any of the pairs of semantic representations derived from the first 9 parses of the Stanford parser. The number 9 was determined empirically and proved to yield the best results overall although as we shall see in the error mining section, taking such a high number of parses into account often leads to incorrect results when the hypothesis (H) is short.

Nutcracker, on the other hand, produces many false positives. This is in part due to cases where the time bound is reached and the word overlap backoff triggered. Since the overall word overlap of the SSI suite is high, the backoff often predicts an entailment where in fact there is none (for instance, the pair *'John gave flowers to Mary/Mary gave flowers to John* has a perfect word overlap but entailment does not hold). When removing the backoff results i.e., when assigning all backoff cases a negative entailment value, overall precision approximates 60%. In other words, on cases such as those present in the SSI benchmark where word overlap is generally high but the correlation between word overlap and entailment value is neutral, Nutcracker should be used without backoff.

5 Finding the source of errors

The annotations contained in the automatically constructed testsuite can help identify the most likely sources of failures. We use (Sagot and de La Clergerie, 2006)'s suspicion rate to compute the probability that a given pair of sets of syntactic tags is responsible for an RTE detection failure. The tag set pairs with highest suspicion rate indicate which syntactic phenomena often cooccurs with failure.

More specifically, we store for each testsuite item (T,H), all tag pairs (t_j, h_k) such that the syntactic tags t_j and h_k are associated with the same predicate P_i but t_j occurs in T and h_k in H. That is, we collect the tag pairs formed by taking the tags that label the occurrence of the same predicate on both sides of the implication. If a predicate occurs only in H then for each syntactic tag h_k labelling this predicate, the pair (nil, h_k) is created. Conversely, if a predicate occurs only in T, the pair (t_j, nil) is added. Furthermore, the tags describing the subcategorisation type and the form of the verb are grouped into a single tag so as to reduce the tagset and limit data sparseness. For instance, given the pair of sentences in Figure (1), the following tag pairs are produced:
(n0Va1:active:relSubj, nil)
(n0Va1:active:canAdj, nil)

system	ERROR	TN	FN	TP	FP	TN/N	TP/P	Prec
afazio	0	360	147	353	140	0.7200	0.7060	71.3%
nutcracker	155	22	62	312	449	0.0467	0.8342	39.5% (60% w/o B.O.)
srl	0	487	437	63	13	0.9740	0.1260	55.0%

Table 1: Results of the three systems on the SSI-testsuite (TN = true negatives, FN = false negatives, TP = true positives, FP = false positives, N = TN + FP, P = TP + FN, Prec = Precision, ERROR: no parse tree found)

(n0Vn2n1:active:canSubj,n0Vn1Pn2:shortPassive:canSubj)
(n0Vn2n1:active:canSubj,n0Vn1Pn2:shortPassive:canIObj)
(n0Vn2n1:active:canObj,n0Vn1Pn2:shortPassive:canSubj)
(n0Vn2n1:active:canObj,n0Vn1Pn2:shortPassive:canIObj)
(n0Vn2n1:active:canIObj,n0Vn1Pn2:shortPassive:canSubj)
(n0Vn2n1:active:canIObj,n0Vn1Pn2:shortPassive:canIObj)

For each tag pair, we then compute the suspicion rate of that pair using (Sagot and de La Clergerie, 2006)'s fix point algorithm. To also take into account pairs of sets of tags (rather than just pairs of single tags), we furthermore preprocess the data according to (de Kok et al., 2009)'s proposal for handling n-grams.

Computing the suspicion rate of a tag pair. The error mining's suspicion rate algorithm of (Sagot and de La Clergerie, 2006) is a fix point algorithm used to detect the possible cause of parsing failures. We apply this algorithm to the pair of annotated sentences resulting from running the three systems on the automatically created testsuite as follows. Each such pair consists of a pair of sentences, a set of tag pairs, an entailment value (true or false) and a result value namely FP (false positive), FN (false negative), TP (true positive) or TN (true negative). To search for the most likely causes of failure, we consider separately entailments from non entailments. If entailment holds, the suspicion rate of a sentence pair is 0 for true positive and 1 for false positives. Conversely, if entailment does not hold, the suspicion rate of the sentence pair is 0 for true negatives and 1 for false negatives.

The aim is to detect the tag pair most likely to make entailment detection fail[6]. The algorithm iterates between tag pair occurrences and tag pair forms, redistributing probabilities with each iteration as follows. Initially, all tag pair occurrences in a given sentence have the same suspicion rate namely, the suspicion rate of the sentence (1 if the entailment could not be recognised, 0 otherwise) divided by the number of tag pair occurrences in that sentence. Next, the suspicion rate of a tag pair form is defined as the average suspicion rate of all occurrences of that tag pair. The suspicion rate of a tag pair occurrence within each particular sentence is then recalculated as the suspicion rate of that tag pair form normalised by the suspicion rates of the other tag pair forms occurring within the same sentence. The iteration stops when the process reaches a fixed point where the suspicion rates have stabilised.

Extending the approach to pairs of tag sets. To account for entailment recognition due to more than one tag pair, we follow (de Kok et al., 2009) and introduce a preprocessing step which first, expands tag pair unigrams to tag pair n-grams when there is evidence that it is useful that is, when an n-gram has a higher suspicion rate than each of its sub n-grams. For this preprocessing, the suspicion of a tag pair t is defined as the ratio of t occurrences in unrecognised entailments and the total number of t occurrences in the corpus. To compensate for data sparseness, an additional expansion factor is used which depends on the frequency of an n-gram and approaches one for higher frequency. In this way, long n-grams that have low frequency are not favoured. The longer the n-gram is, the more frequent or the more suspicious it needs to be in order to be selected by the preprocessing step.

We apply this extension to the SSI setting. We first extend the set of available tag pairs with tag set pairs such that the suspicion rate of these pairs is higher that the suspicion rate of each of the smaller tagset pairs that can be constructed from these sets. We then apply (Sagot and de La Clerg-

[6]We make the simplifying hypothesis that for each entailment not recognised, a single tag pair or tag pair n-gram is the cause of the failure.

Table 3: The first 3 suspects for false negatives

erie, 2006)'s fix point algorithm to compute the suspicion rate of the resulting tag pairs and tag sets pairs.

Results and discussion. We now show how error mining can help shed some light on the most probable sources of error when using Afazio.

For false positives (non entailment labelled as entailment by Afazio), the 3 most suspect tag pairs are given in Table 2. The first pair (n0Vs1:act:CanSubj,nil) points out to cases such as *Bill sees the woman give the flower to the man / The man gives the flower to the woman.* where T contains a verb with a sentential argument not present in H. In such cases, we found that the sentential argument in T is usually incorrectly analysed, the analyses produced are fragmented and entailment goes through. Similarly, the second suspect (n0Vn1:act:CanObj,nil) points to cases such as *a man sees Lisa dancing / a man dances*, where the transitive verb in T has no counterpart in H. Here the high number of analyses relied on by Afazio together with the small size of H leads to entailment detection: because we consider many possible analyses for T and H and because H is very short, one pair of analyses is found to match. Finally, the third suspect (n0V:betaVn,nil) points to cases such as *Bill insists for the singing man to dance / Bill dances* where the gerund is wrongly analysed and a relation is incorrectly established by the parser between *Bill* and *dance* (in H).

For false negatives, the first suspect indicates incorrect analyses for cases where an intransitive with canonical subject in H is matched by an intransitive with covert relative subject (e.g., *Bill sees the woman give the flower to the man / the man gives the flower to the woman.*). The second suspect points to cases such as *Bill insists for the man who sings to dance / Bill insists that the singing man dances.* where an embedded verb with relative overt subject in T (sings) is matched in H by an embedded gerund. Similarly, the third suspect points to embedded verbs with canonical subject matched by gerund verbs as in *the man who Bill insists that dances sings / Bill insists that the singing man dances*.

6 Conclusion

The development of a linguistically principled treatment of the RTE task requires a clear understanding of the strength and weaknesses of RTE systems w.r.t. to the various types of reasoning involved. The main contribution of this paper is the specification of an evaluation methodology which permits a focused evaluation of syntax based reasoning on arbitrarily many inputs. As the results show, there is room for improvment even on that most basic level. In future work, we plan to extend the approach to other types of inferences required for textual entailment recognition. A more sophisticated compositional semantics in the grammar used by the sentence generator would allow for entailments involving more complex semantic phenomena such as the interplay between implicative verbs, polarity and downward/upward monotonicity discussed in (Nairn et al., 2006). For instance, it would allow for sentence pairs such as *Ed did not forget to force Dave to leave / Dave left* to be assigned the correct entailment value.

Query Expansion based on Pseudo Relevance Feedback from Definition Clusters

Delphine Bernhard
LIMSI-CNRS
Delphine.Bernhard@limsi.fr

Abstract

Query expansion consists in extending user queries with related terms in order to solve the lexical gap problem in Information Retrieval and Question Answering. The main difficulty lies in identifying relevant expansion terms in order to prevent query drift. We propose to use definition clusters built from a combination of English lexical resources for query expansion. We apply the technique of pseudo relevance feedback to obtain expansion terms from definition clusters. We show that this expansion method outperforms both local feedback, based on the document collection, and expansion with WordNet synonyms, for the task of document retrieval in Question Answering.

1 Introduction

Question Answering (QA) systems aim at providing precise answers to user questions. Most QA systems integrate a document retrieval component, which is in charge of retrieving the most relevant documents or passages for a given user question. Since document retrieval is performed in early stages of QA, it is of the uttermost importance that all relevant documents be retrieved, to limit the loss of relevant answers for further processing. However, document retrieval systems have to solve the lexical gap problem, which arises from alternative ways of conveying the same piece of information in questions and answers. One of the solutions proposed to deal with this issue is query expansion (QE), which consists in extending user queries with related terms.

This paper describes a new method for using lexical-semantic resources in query expansion with a focus on QA applications. While some research has been devoted to using explicit semantic relationships for QE, such as synonymy or hypernymy, with rather disappointing results (Voorhees, 1994), we focus on the usefulness of textual and unstructured dictionary definitions for question expansion. Definitions extracted from seven English lexical resources are first grouped to obtain definition clusters, which capture redundancies and sense mappings across resources. Expansion terms are extracted from these definition clusters using pseudo relevance feedback: we first retrieve the definition clusters which are most related to the user query, and then extract the most relevant terms from these definition clusters to expand the query.

The contributions of this work are as follows: (i) we build definition clusters across seven different lexical resources for English, (ii) we thoroughly compare different question expansion methods using local and global feedback, and (iii) we address both the lexical gap and question ambiguity problems by integrating expansion and disambiguation in one and the same step.

In the next section, we describe related work. In Section 3, we describe our method for acquiring definition clusters from seven English lexical resources. In Section 4, we detail query expansion methods. We present experimental results in Section 5 and conclude in Section 6.

2 Related Work

Query expansion attempts to solve the vocabulary mismatch problem by adding new semantically related terms to the query. The goal is to increase recall by retrieving more relevant documents. Two types of query expansion methods are usually distinguished (Manning et al., 2008): *global* techniques, which do not take the results obtained for the original query into account, and

Coling 2008: Poster Volume, pages 54–62,
Beijing, August 2010

local techniques, which expand the query based on an analysis of the documents returned. Local methods are also known as *relevance feedback*.

A first type of global QE methods relies on external hand-crafted lexical-semantic resources such as WordNet. While expansion based on external resources is deemed more efficient than expansion relying on relevance feedback, it also has to tackle problems of semantic ambiguity, which explains why local analysis has been shown to be generally more effective than global analysis (Xu and Croft, 1996). However, recent work by Fang (2008) has demonstrated that global expansion based on WordNet and co-occurrence based resources can lead to performance improvement in an axiomatic model of information retrieval.

Corpus-derived co-occurrence relationships are also exploited for query expansion. Qiu and Frei (1993) build a corpus-based similarity thesaurus using the method described in Schütze (1998) and expand a query with terms which are similar to the query concept based on the similarity thesaurus. Song and Bruza (2003) construct vector representations for terms from the target document collection using the Hyperspace Analogue to Language (HAL) model (Lund and Burgess, 1996). The representations for all the terms in the query are then combined by a restricted form of vector addition. Finally, expansion terms are derived from this combined vector by information flow.

Quasi-parallel monolingual corpora have been recently employed for query expansion, using statistical machine translation techniques. Expansion terms are acquired by training a translation model on question-answer pairs (Riezler et al., 2007) or query-snippets pairs (Riezler et al., 2008) and by extracting paraphrases from bilingual phrase tables (Riezler et al., 2007).

The main difficulty of QE methods lies in selecting the most relevant expansion terms, especially when the query contains ambiguous words. Moreover, even if the original query is not ambiguous, it might become so after expansion. Recent attempts at integrating word sense disambiguation (WSD) in IR within the CLEF Robust WSD track[1] have led to mixed results which show that in most cases WSD does not improve performance of monolingual and cross-lingual IR systems (Agirre et al., 2009). For query expansion based on translation models, ambiguity problems are solved by a language model trained on queries (Riezler et al., 2008), in order to select the most likely expansion terms in the context of a given query.

In this article, we propose to integrate disambiguation and expansion in one and the same step by retrieving expansion terms from definition clusters acquired by combining several English lexical resources.

3 Acquisition of Definition Clusters

Dictionary definitions constitute a formidable resource for Natural Language Processing. In contrast to explicit structural and semantic relations between word senses such as synonymy or hypernymy, definitions are readily available, even for less-resourced languages. Moreover, they can be used for a wide variety of tasks, ranging from word sense disambiguation (Lesk, 1986), to producing multiple-choice questions for educational applications (Kulkarni et al., 2007) or synonym discovery (Wang and Hirst, 2009). However, all resources differ in coverage and word sense granularity, which may lead to several shortcomings when using a single resource. For instance, the sense inventory in WordNet has been shown to be too fine-grained for efficient word sense disambiguation (Navigli, 2006; Snow et al., 2007). Moreover, gloss and definition-based measures of semantic relatedness which rely on the overlap between the definition of a target word and its distributional context (Lesk, 1986) or the definition of another concept (Banerjee and Pedersen, 2003) yield low results when the definitions provided are short and do not overlap sufficiently.

As a consequence, we propose combining lexical resources to alleviate the coverage and granularity problems. To this aim, we automatically build cross-resource sense clusters. The goal of our approach is to capture redundancy in several resources, while improving coverage over the use of a single resource.

3.1 Resources

In order to build definition clusters, we used the following seven English resources:

WordNet We used WordNet 3.0, which contains 117,659 synset definitions.[2]

GCIDE The GCIDE is the GNU version of the Collaborative International Dictionary of English, derived from Webster's 1913 Revised Unabridged Dictionary. We used a recent XML version of this resource,[3] from which we extracted 196,266 definitions.

English Wiktionary and Simple English Wiktionary Wiktionary is a collaborative online dictionary, which is also available in a simpler English version targeted at children or non-native speakers. We used the English Wiktionary dump dated August 16, 2009 and the Simple English Wiktionary dump dated December 9, 2009. The English Wiktionary comprises 245,078 definitions, while the Simple English Wiktionary totals 11,535 definitions.

English Wikipedia and Simple English Wikipedia Wikipedia is a collaborative online encyclopedia. As Wiktionary, it provides a Simple English version. We used the Mediawiki API to extract 152,923 definitions from the English Wikipedia[4] and 53,993 definitions from the Simple English Wikipedia. Since full Wikipedia articles can be very long in comparison to the other resources, we only retrieved the first sentence of each page to constitute the definition database, following (Kazama and Torisawa, 2007).

OmegaWiki OmegaWiki is a collaborative multilingual dictionary based on a relational database. We used the SQL database dated December 17, 2009,[5] comprising 29,179 definitions.

[2]Statistics obtained from `http://wordnet.princeton.edu/wordnet/man/wnstats.7WN.html`

[3]Retrieved from `http://rali.iro.umontreal.ca/GCIDE/`

[4]As we mainly aimed at capturing the redundancy across resources, we only extracted definitions for the Wikipedia terms which were also found in the GCIDE, Omegawiki, Wiktionary or Simple English Wikipedia.

[5]Retrieved from `http://omegawiki.org/`

3.2 Definition Clustering

In order to cluster definitions, we first build a definition graph: each node in the graph corresponds to a definition in one of our input resources and two definition nodes are linked if they define the same term and their definitions are similar enough. Links are weighted by the cosine similarity of the definition nodes. To compute the cosine similarity, we stem the definition words with the Porter Stemmer and remove stop words. Moreover, we weigh words with their *tf.idf* value in the definitions. Document frequency (*df*) counts are derived from the definitions contained in all our resources.

Definition clusters are identified with a community detection algorithm applied to the definition graph. Communities correspond to groups of nodes with dense interconnections: in our case, we aim at retrieving groups of related definitions. We used the algorithm proposed by Blondel et al. (2008), based on modularity optimisation.[6] The modularity function measures the quality of a division of a graph into communities (Newman and Girvan, 2004).

In order to increase the precision of clustering, we remove edges from the graph whose cosine value is lower than a given threshold.

3.3 Evaluation of Definition Clusters

We built a gold-standard by manually grouping the definitions contained in our source resources for 20 terms from the Basic English Word List,[7] totalling 726 definitions, grouped in 321 classes. We evaluated the definition clusters in terms of clustering purity (Manning et al., 2008), which is a classical evaluation measure to measure clustering quality. Purity is defined as follows:

$$purity(\Omega, C) = \frac{1}{N} \sum_{k} \max_{j} |\omega_k \cap c_j| \qquad (1)$$

where N is the number of clustered definitions, $\Omega = \{\omega_1, \omega_2, \ldots, \omega_K\}$ is the set of definition

[6]We used its Python implementation by Thomas Aynaud, available at `http://perso.crans.org/aynaud/communities/community.py` [Visited on October 26, 2009].

[7]`http://en.wiktionary.org/wiki/Appendix:Basic_English_word_list`

Resource	Definition
WordNet	an arc of colored light in the sky caused by refraction of the sun's rays by rain
Gcide	A bow or arch exhibiting, in concentric bands, the several colors of the spectrum, and formed in the part of the hemisphere opposite to the sun by the refraction and reflection of the sun's rays in drops of falling rain.
Simple Wikipedia	A rainbow is an arc of color in the sky that you can see when the sun shines through falling rain.
Simple Wiktionary	The arch of colours in the sky you can see in the rain when the sun is at your back.

Table 1: Excerpt from a definition cluster.

clusters obtained, w_k is the set of definitions in cluster k, $C = \{c_1, c_2, \ldots, c_J\}$ is the set of definition families expected and c_j is the set of definitions in family j.

We also report the amount of clusters obtained for each cosine threshold value. The evaluation results are detailed in Table 2.

Cosine threshold	Purity	# Clusters
0.0	0.363	73
0.1	0.464	135
0.2	0.644	234
0.3	0.848	384
0.4	0.923	458
0.5	0.957	515

Table 2: Evaluation results for definition clustering.

Overall, the results which account for the best compromise between purity and cluster count are obtained for a threshold of 0.3: for this threshold, we obtain 384 clusters, which is closest to the expected value of 321 classes. The purity obtained for this cosine threshold is very close to the values obtained by Kulkarni et al. (2007), who clustered definitions extracted from only two source dictionaries and report a purity of 0.88 for their best results. In total we obtain 307,570 definition clusters. Table 1 displays an excerpt from one of the definition clusters obtained.

4 Query Expansion Methods

In this section, we describe the methods used for performing query expansion. We first describe two simple baseline methods, one based on local feedback, the other based on WordNet. Then, we detail our method relying on the definition clusters previously described.

4.1 Query Expansion based on Local Feedback

In order to perform local feedback based on the document collection, we used the pseudo relevance feedback methods implemented in the Terrier information retrieval platform (Ounis et al., 2007): Bo1 (Bose-Einstein 1), Bo2 (Bose-Einstein 2) and KL (Kullback-Leibler). These methods extract informative terms from the top-ranked documents retrieved using the original query and use them for query expansion.

4.2 Query Expansion based on WordNet Synonyms

As a second baseline for query expansion, we expand the query terms with their synonyms extracted from WordNet. For each query term t, we retrieve its WordNet synsets and keep the corresponding synset members as expansion terms.[8] We weigh the expansion terms in each synset by the frequency score provided in WordNet, which indicates how often the query term t occurs with the corresponding sense. In the rest of the paper, this method is referred to as **WN-synonyms**.

The expansion terms obtained using WN-synonyms are further reweighted using Rocchio's *beta* formula which computes the weight qtw of

[8] We use NLTK (`http://www.nltk.org/`) to access WordNet.

query term t as follows (Rocchio, 1971; Macdonald et al., 2005):

$$qtw = \frac{qtf}{qtf_{max}} + \beta \frac{w(t)}{w_{max}(t)} \quad (2)$$

where qtf is the frequency of term t in the query, qtf_{max} is the maximum query term frequency among the query terms, $w(t)$ is the expansion weight of t, detailed in Equation 3, and $w_{max}(t)$ is the maximum $w(t)$ of the expansion terms. In all our experiments, β is set to 0.4, which is the default value used in Terrier.

Given this formula, if an original query term occurs among the expansion terms, its weight in the expanded query increases. For expansion terms which do not occur in the original query, $qtf = 0$.

This formula has been proposed in the setting of pseudo relevance feedback, where expansion terms are chosen based on the top documents retrieved for the original query. However, in our WN-synonyms setting, one and the same expansion term might be obtained from different original query terms with different weights. It is therefore necessary to obtain a global similarity weight for one expansion term with respect to the whole query. Following Qiu and Frei (1993), we define $w(t)$ as:

$$w(t) = \frac{\sum_{t_i \in q} qtf_i \cdot s(t, t_i)}{\sum_{t_i \in q} qtf_i} \quad (3)$$

where q is the original query and $s(t, t_i)$ is the similarity between expansion term t and query term t_i, i.e., the frequency score in WordNet.

For final expansion, we keep the top T terms with the highest expansion weight.

4.3 Query Expansion Based on Definition Clusters

In order to use definition clusters (DC) for query expansion, we first use Terrier to index the clusters which obtained the best overall results in our evaluation of definition clustering, corresponding to a cosine threshold of 0.3.[9] For each cluster, we index both the definitions and the list of terms they define, which makes it possible to include synonyms or Wikipedia redirects in the index.

For a given question, we retrieve the top D definition clusters: the retrieval of definition clusters is based on all the question terms, and thus enables indirect contextual word sense disambiguation. Then, we extract expansion terms from these clusters using pseudo relevance feedback (PRF) as implemented in Terrier. The top T most informative terms are retrieved from the top D definition clusters retrieved and used for expansion. The expansion terms are weighted using the KL (Kullback-Leibler) term weighting model in Terrier. We chose this particular weighting model, as it yielded the best results for local feedback (see Table 3).

We name this method **DC-PRF**.

5 Experiments

In this section, we describe the experimental results obtained for the query expansion methods presented in the previous section. We used the Microsoft Research Question-Answering Corpus[10] (MSRQA) as our evaluation dataset.

5.1 Microsoft Research Question-Answering Corpus (MSRQA)

MSRQA provides a fully annotated set of questions and answers retrieved from the Encarta 98 encyclopedia. The Encarta corpus contains 32,715 articles, ranging from very short (3 tokens) to very long (59,798 tokens). QA systems usually split documents into smaller passages. We have therefore segmented the Encarta articles into smaller parts representing subsections of the original article, using a regular expression for identifying section headers in the text. As a result, the dataset comprises 61,604 documents, with a maximum of 2,730 tokens. The relevance judgements provided comprise the document id as well as the sentences (usually one) containing the answer. We processed these sentence level relevance judgements to obtain judgements for documents: a document is considered as relevant if it contains an exact answer sentence. Overall, we obtained relevance judgements for 1,098 questions.

[9] We used the 2.2.1 version of Terrier, downloadable from `http://terrier.org/`

[10] Downloadable from `http://research.microsoft.com/en-us/downloads/88c0021c-328a-4148-a158-a42d7331c6cf/`

	All questions		Easy questions		Medium questions		Hard questions

	+7.6%	+9.2%	+5.0%	+7.5%	+16.5%	+16.7%	+6.0%	+5.7%
DC-PRF + Terrier KL	0.2361	0.2796	0.2625	0.3184	0.1928	0.2213	**0.1389**	**0.1484**

Table 3: Experimental results. The performance gaps between the DC-PRF and the baseline retrieval models without expansion (none), Terrier-KL and WN-synonyms are statistically significant (two-tailed paired t-test, $p < 0.05$), except for hard questions and for the MAP comparison with Terrier-KL for easy questions. We also report the improvement percentage.

Based on the annotations available in the MSRQA dataset, we further distinguish three question types:

- *easy* questions, which have at least one answer with a strong match (two or more query terms in the answer).
- *medium* questions, which have no strong match answer, but at least an answer with a weak match (one query term in the answer).
- *hard* questions, which have neither a strong nor a weak match answer, but only answers which contain no query terms, and at the best synonyms and derivational morphological variants for query terms.

Overall, the evaluation dataset comprises 651 easy questions, 397 medium questions and 64 hard questions (some of these questions have no exact answer).

5.2 Results

As our baseline, we use the BB2 (Bose-Einstein model for randomness) retrieval model in Terrier. We varied the values for the parameters T (number of expansion terms) and D (number of expansion documents) and used the settings yielding the best evaluation results. For the PRF methods implemented in Terrier, the default settings (T=10, D=3) worked best; for DC-PRF, we used T=20 and D=40. Finally, for WN-synonyms we used T=10. We also combined both DC-PRF and Terrier-KL by first applying DC-PRF expansion and then using local Terrier-KL feedback on the retrieved documents (DC-PRF + Terrier KL). Prior to retrieval, all questions are tokenised and part-of-speech tagged using Xerox's Incremental Parser XIP (Aït-Mokhtar et al., 2002). Moreover, we retrieve 100 documents for each question and stem the Encarta document collection. The results shown in Table 3 are evaluated in terms of Mean-Average Precision (MAP) and Mean Reciprocal Rank (MRR). Table 4 provides examples of the top 5 expansion terms obtained for each expansion method.

The DC-PRF expansion method performs best overall, as well as for easy and medium question types. For medium questions, DC-PRF leads to an increase of 16.5% in MAP and 16.7% in MRR, with respect to the 'none' baseline. Local feedback methods, such as Terrier-KL, only bring minor improvements for easy questions, but lead to slightly lower results for medium and hard questions. This might be due to the small size of the document collection, which therefore lacks redundancy. The simple baseline expansion method based on WordNet leads to very slight improvements for medium questions over the setting without expansion. The combination of DC-PRF and Terrier-KL leads to lower results than using only

Terrier-KL	WN-synonyms	DC-PRF
12: *Are there UFOs?*		
sight – unidentifi – report – object – fly	flying – unidentified – object – UFO – saucer	unidentified – ufo – flying – ufology – objects
104: *What is the most deadly insect in the world?*		
speci – plant – feed – anim – liv	cosmos – creation – existence – macrocosm – universe	nightshade – belladonna – mortal – death – lethal
107: *When was the little ice age*		
drift – glacial – ago – sheet – million	small – slight – historic – period – water	floe – period – glacial – cold – interglacial
449: *How does a TV screen get a picture from the air waves?*		
light – beam – televi – electron – signal	moving – ridge – image – icon – ikon	television – movie – image – motion – door
810: *Do aliens really exist?*		
sedition – act – govern – deport – see	live – subsist – survive – alienate – extraterrestrial	alien – extraterrestrial – monsters – dreamworks – animation

Table 4: Expansion examples. The expansion terms produced by Terrier-KL are actually stemmed, as they are retrieved from a stemmed index.

DC-PRF, except for hard questions, for which the combination brings a very slight improvement.

The expansion samples provided in Table 4 exemplify the query drift problem of local feedback methods (Terrier-KL): for question 810, expansion terms focus on the "foreigner" sense of *alien* rather than on the "extraterrestrial" sense. The WN-synonyms method suffers from the problem of weighting synonyms, and mainly focuses on synonyms for the most frequent term of the question, e.g. "world" in question 104. Interestingly, the DC-PRF method accounts for neologisms, such as "ufology" which can be found in new collaboratively constructed resources such as Wikipedia or Wiktionary, but not in WordNet. This is made possible by the combination of diversified resources. It is also able to provide encyclopedic knowledge, such as "dreamworks" and "animation" in question 810, referring to the feature film "Monsters vs. Aliens".

The DC-PRF method also has some limitations. Even though the expansion terms "dreamworks" and "animation" correspond to the intended meaning of the word "alien" in question 810, they nevertheless might introduce some noise in the retrieval. Some other cases exemplify slight drifts in meaning from the query: in question 104, the expansion terms "nightshade" and "belladonna" refer to poisonous plants and not insects; "*deadly* nightshade" is actually the other name of the "belladonna". Similarly, in question 449, the expansion term "door" is obtained, in relation to the word "screen" in the question (as in "screen door"). This might be due to the fact that the terms defined by the definition clusters are indexed as well, leading to a high likelihood of retrieving syntagmatically related terms for multiword expressions. In future work, it might be relevant to experiment with different indexing schemes for definition clusters, e.g. indexing only the definitions, or adding the defined terms to the index only if they are not present in the definitions.

6 Conclusions and Future Work

In this paper, we presented a novel method for query expansion based on pseudo relevance feedback from definition clusters. The definition clusters are built across seven different English lexical resources, in order to capture redundancy while improving coverage over the use of a single resource. The expansions provided by feedback from definition clusters lead to a significant im-

provement of the retrieval results over a retrieval setting without expansion.

In the future, we would like to further ameliorate definition clustering and incorporate other resources, e.g. resources for specialised domains. Moreover, we have shown that query expansion based on definition clusters is most useful when applied to medium difficulty questions. We therefore consider integrating automatic prediction of query difficulty to select the best retrieval method. Finally, we would like to evaluate the method presented in this paper for larger datasets.

A Formal Scheme for Multimodal Grammars

Philippe Blache & Laurent Prévot
LPL-CNRS, Université de Provence
blache@lpl-aix.fr

Abstract

We present in this paper a formal approach for the representation of multimodal information. This approach, thanks to the to use of *typed feature structures* and *hypergraphs*, generalizes existing ones (typically annotation graphs) in several ways. It first proposes an homogenous representation of different types of information (nodes and relations) coming from different domains (speech, gestures). Second, it makes it possible to specify constraints representing the interaction between the different modalities, in the perspective of developing *multimodal grammars*.

1 Introduction

Multimodality became in the last decade an important challenge for natural language processing. Among the problems we are faced with in this domain, one important is the understanding of how does the different modalities interact in order to produce meaning. Addressing this question requires to collect data (building corpora), to describe them (enriching corpora with annotations) and to organize systematically this information into a homogeneous framework in order to produce, ideally, multimodal grammars.

Many international projects address this question from different perspectives: data representation and coding schemes (cf. ISLE (Dybkjaer, 2001), MUMIN (Allwood, 2005), etc.), corpus annotation (cf. LUNA (Rodriguez, 2007) or DIME (Pineda, 2000), etc.), annotation and editing tools (such as NITE NXT (Carletta, 2003), Anvil (Kipp, 2001), Elan (Wittenburg, 2006), Praat (Boersma, 2009), etc.).

We propose in this paper a generic approach addressing both formal representation and concrete annotation of multimodal data, that relies on *typed-feature structure* (TFS), used as a description language on graphs. This approach is generic in the sense that it answers to different needs: it provides at the same time a formalism directly usable for corpus annotation and a description language making it possible to specify constraints that constitute the core of a *multimodal grammar*.

In the first section, we motivate the use of TFS and present how to concretely implement them for multimodal annotation. We address in the second section one of the most problematic question for multimodal studies: how to represent and implement the relations between the different domains and modalities (a simple answer in terms of time alignment being not powerful enough). In the last section, we describe how to make use of this representation in order to specify multimodal grammars.

2 Typed-feature structures modeling

Information representation is organized in two dimensions: type hierarchies and constituency relations (typically, a prosodic unit is a set of syllables, which in turn are sets of phonemes). The former corresponds to an *is-a* relation, the latter to a *part-of* one. For example *intonational phrase* is a subtype of *prosodic phrase*, and *phonemes* are constituents of *syllables*.

Such an organization is directly represented by means of typed feature structures. They can be considered as a formal annotation schema, used as

Coling 2008: Poster Volume, pages 63–71,
Beijing, August 2010

a preliminary step before the definition of the concrete coding scheme[1]. This step is necessary when bringing together information (and experts) from different fields: it constitutes a common representation framework, homogenizing information representation. Moreover, it allows to clearly distinguish between knowledge representation and annotation. The coding scheme, at the annotation level (labels, features, values), is deduced from this formal level.

The remaining of the section illustrates how to represent objects from different domains by means of TFS. The Figure 1 presents the type hierarchy and the constituency structure of objects taken here as example.

2.1 Phonetics

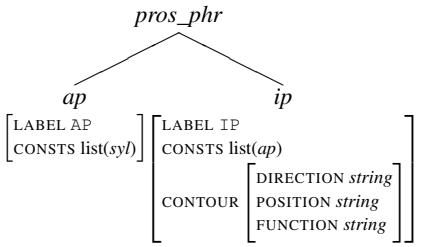
The phoneme is used as primary data: this object is at the lowest level of the constituent hierarchy (most of the objects are set of phonemes). The following feature structure proposes a precise encoding of the main properties describing a phoneme, including articulatory gestures.

$$
\textit{phon}\left[\begin{array}{l}
\text{SAMPA\_LABEL } \textit{sampa\_unit} \\
\text{CAT}\left\{\textit{vowel, consonant}\right\} \\
\text{TYPE}\left\{\textit{occlusive, fricative, nasal, etc.}\right\} \\
\text{ARTICULATION}\left[\begin{array}{l}
\text{LIP}\left[\begin{array}{l}\text{PROTUSION } \textit{string} \\ \text{APERTURE } \textit{aperture}\end{array}\right] \\
\text{TONGUE}\left[\begin{array}{l}\text{TIP}\left[\begin{array}{l}\text{LOCATION } \textit{string} \\ \text{DEGREE } \textit{string}\end{array}\right] \\ \text{BODY}\left[\begin{array}{l}\text{LOCATION } \textit{string} \\ \text{DEGREE } \textit{string}\end{array}\right]\end{array}\right] \\
\text{VELUM } \textit{aperture} \\
\text{GLOTTIS } \textit{aperture}
\end{array}\right] \\
\text{ROLE}\left[\begin{array}{l}\text{EPENTHETIC } \textit{boolean} \\ \text{LIAISON } \textit{boolean}\end{array}\right]
\end{array}\right]
$$

Phonemes being at the lowest level, they do not have any constituents. They are not organized into precise subtypes. The feature structure represent then the total information associated with this type.

2.2 Prosody

As seen above, prosodic phrases are of two different subtypes: *ap* (accentual phrases) and *ip* (intonational phrases). The prosodic type hierarchy is represented as follows:



Accentual phrases have two appropriate features: the label which is simply the name of the corresponding type, and the list of constituents, in this case a list of syllables. The objects of type *ip* contain the list of its constituents (a set of *ap*s) as well as the description of its contour. A contour is a prosodic event, situated at the end of the *ip* and is usually associated to an *ap*.

The prosodic phrases are defined as set of syllables. They are described by several appropriate features: the syllable structure, its position in the word, its possibility to be accented or prominent:

$$
\textit{syl}\left[\begin{array}{l}
\text{STRUCT } \textit{syl\_struct} \\
\text{POSITION}\left[\begin{array}{l}\text{RANK}\left\{\textit{integer}\right\} \\ \text{SYL\_NUMBER}\left\{\textit{integer}\right\}\end{array}\right] \\
\text{ACCENTUABLE } \textit{boolean} \\
\text{PROMINENCE } \textit{boolean} \\
\text{CONSTITUENTS list}(\textit{const\_syl})
\end{array}\right]
$$

Syllable constituents (objects of type *const_syl*) are described by two different features: the set of phonemes (syllable constituents), and the type of the constituent (onset, nucleus and coda). Note that each syllable constituent can contain a set of phonemes.

$$
\textit{const\_syl}\left[\begin{array}{l}
\text{PHON list}(\textit{phon}) \\
\text{CONST\_TYPE}\left\{\textit{onset, nucleus, coda}\right\}
\end{array}\right]
$$

2.3 Disfluencies

We can distinguish two kinds of disfluencies: *non lexicalized* (without any lexical material, such as lengthening, silent pauses or filled pauses) and *lexicalized* (non-voluntary break in the phrasal flow, generating a word or a phrase fragment). Lexicalized disfluencies have a particular organization with three subparts (or constituents):

- *Reparandum*: the word or phrase fragment, in which the break occurs
- *Break*: a point or an interval that can eventually be filled by a fragment repetition, parenthetical elements, etc.

[1]This approach has been first defined and experimented in the XXXX project, not cited for anonymity reasons.

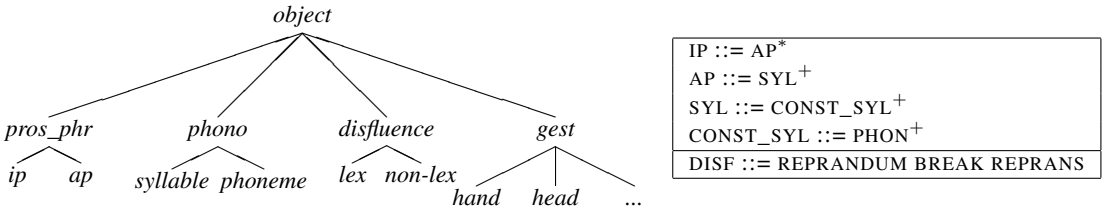


Figure 1: *Type and constituent hierarchies*

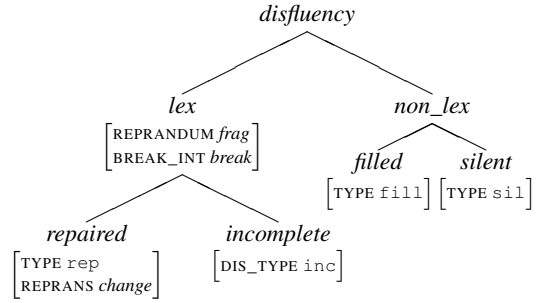
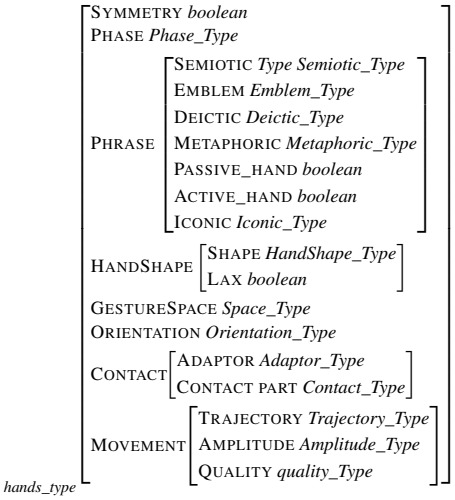
- *Reparans*: all that follow the break and recovers the reparandum (in modifying or completing it) or simply left it uncompleted.

The general disfluency type hierarchy, with the appropriate features at each level is given in the following figure:





2.4 Gestures

Besides verbal communication, gestures constitute the main aspect of multimodality. In multimodal annotation, this is probably the most difficult and time-consuming task. Moreover, only few works really focus on a precise description of all the different domains of verbal and non verbal modalities. The TFS-based approach proposed here answers to the first need in such a perspective: a common representation framework.

We give in this section a brief illustration of the representation of one gesture (hands). It relies on adaptation of different proposals, especially (Kipp03) or MUMIN (Allwood, 2005), both integrating McNeill's gesture description (McNeill05).

The following structure encodes the description of gesture phases, phrases (representing different semiotic types), the hand shape as well as its orientation, the gesture space, and the possible contact with bodies or objects. A last feature also describes the movement itself: trajectory, quality (fast, normal or slow) and amplitude (small, medium and large).

2.5 Application

We have experimented this modeling in the complete annotation of a multimodal corpus (see (Blache, 2010)). In this project, a complete TFS model has been first designed, covering all the different domains (prosody, syntax, gestures, discourse, etc.). From this model, the annotations have been created, leading to a 3-hours corpus of narrative dialogs, fully transcribed. The corpus is fully annotated for some domains (phonetics, prosody and syntax) and partly for others (gestures, discourse, disfluencies, specific phenomena). The result is one of the first large annotated multimodal corpus.

3 Graphs for Multimodal Annotation

Graphs are frequently used in the representation of complex information, which is the case with multimodality. As for linguistic annotation, one of the most popular representations is *Annotation Graphs* (Bird, 2001). They have been proposed in particular in the perspective of anchoring different kinds of information in the same reference,

making it possible to align them[2]. In AGs, nodes represent positions in the signal while edges bear linguistic information. Two edges connecting the same nodes are aligned: they specify different information on the same part of the input. Implicitly, this means that these edges bear different features of the same object.

Such a representation constitutes the basis of different approaches aiming at elaborating generic annotation formats, for example LAF (and its extension GrAF (Ide, 2007)). In this proposal, edge labels can be considered as nodes in order to build higher level information. One can consider the result as an *hypergraph*, in which nodes can be subgraphs.

We propose in this section a more generalized representation in which nodes are not positions in the signal, but represent directly objects (or set of objects). All nodes have here the same structure, being them nodes or hypernodes. The main interest of this proposal, on top of having an homogeneous representation, is the possibility to anchor information in different references (temporal, spatial or semantic).

3.1 Nodes

As seen above, multimodal annotation requires the representation of different kinds of information (speech signal, video input, word strings, images, etc.). The *objects*[3] that will be used in the description (or the annotation) of the input are of different nature: temporal or spatial, concrete or abstract, visual or acoustic, etc. A generic description requires first a unique way of locating (or indexing) all objects, whatever their domain. In this perspective, an index (in the HPSG sense) can be specified, relying on different information:

- LOCATION: objects can in most of the cases be localized in reference to a temporal or a spatial situation. For example, phonemes have a temporal reference into the speech signal, physical objects have spatial localization that can be absolute (spatial coordinates), or relative (with respect to other objects).
- REALIZATION: data can either refer to *concrete* or physical objects (phonemes, gestures, referential elements, etc.) as well as *abstract* ones (concepts, emotions, etc.).
- MEDIUM: specification of the different modalities: *acoustic, tactile* and *visual*.[4]
- ACCESSIBILITY: some data are directly accessible from the signal or the discourse, they have a physical existence or have already been mentioned. In this case, they are said to be "*given*" (e.g. gestures, sounds, physical objects). Some other kinds of data are deduced from the context, typically the abstract ones. They are considered as "*accessible*".

A generic structure node can be given, gathering the index and the some other object properties.

$$
\begin{bmatrix}
\text{ID} \\
\text{DOMAIN} \left\{ \textit{prosody, syntax, pragmatics, ...} \right\} \\
\text{INDEX} \begin{bmatrix}
\text{LOCATION} \left\{ \begin{array}{l} \text{TEMPORAL} \begin{bmatrix} \text{START } \textit{value} \\ \text{END } \textit{value} \end{bmatrix} \\ \text{SPATIAL } \textit{coord} \end{array} \right\} \\
\text{REALIZATION} \left\{ \textit{concrete, abstract} \right\} \\
\text{MEDIUM} \left\{ \textit{acoustic, tactile, visual} \right\} \\
\text{ACCESSIBILITY} \left\{ \textit{given, accessible} \right\}
\end{bmatrix} \\
\text{FEATURES } \textit{object\_type}
\end{bmatrix}_{node}
$$

This structure relies on the different information. Besides INDEX, some other features complete the description:

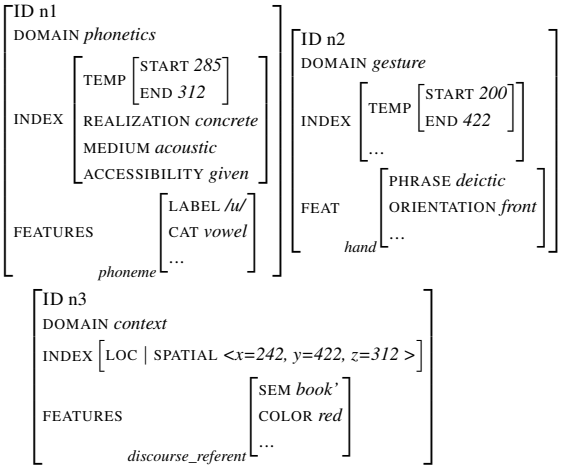
- ID: using an absolute ID is useful in the perspective of graph representation, in which nodes can encode any kind of information (atomic or complex, including subgraphs).
- DOMAIN: specification of the domain to which the information belongs. This feature is useful in the specification of generic interaction constraints between domains.
- FEATURES: nodes have to bear specific linguistic indications, describing object properties. This field encodes the type of information presented in the first section.

[2] Another important interest of AGs is that they can constitute the basis for an exchange format, when thinking on annotation tools interoperability (a proposal is currently elaborated under auspices of the MITRE program, see `http://www.mitre.org/`).

[3] We call *object* any annotation that participates to the description: phoneme, words, gestures, but also phrases, emotions, etc.

[4] See the W3C EMMA recommendation (*Extensible Multi-Modal Annotations*, `http://www.w3.org/2002/mmi/`.

The following examples illustrate the representation of atomic nodes from different domains: a phoneme (node *n1*) and a gesture (node *n2*), that are temporally anchored, and a physical object (node *n3*) which is spatially situated. This last object can be used as a referent, for example by a deictic gesture.

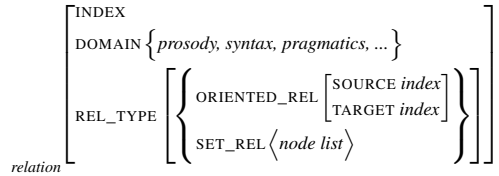


3.2 Relations

Linguistic information is usually defined in terms of relations between (sets of) objects, which can be atomic or complex. For example, a phrase is defined by syntactic relations (government, agreement, linearity, etc.) between its constituents. In some cases, these relations can concern objects from the same domain (e.g. syntax in the previous example). In other cases, different domains can be involved. For example, a long break (greater than 200ms) usually precedes a left corner of a new phrase.

The nature of the relation can also be different according to the kind of information to be encoded. Many relations are binary and oriented (precedence, dependency, etc.). Some others only consists in gathering different objects. A construction (in the sense of *Construction Grammars*, see (Fillmore96)) is precisely that: a set of object or properties that, put together, form a specific phenomenon. It is then useful in our representation to distinguish between *oriented relations* and *set relations*. Oriented relations (for example precedence) connect a source and a target, that can be eventually formed with set of objects. Set relations are used to gather a set of objects, without orientation or order (e.g. the constituency relation).

On top of this distinction, it is also necessary to give an index to the relations, in order to make their reference possible by other objects. As for nodes, an index is used, even though its form is simple and does not need a complex anchor. Finally, for the same reasons as for nodes, the specification of the domain is necessary. The following feature structure gives a first view of this organization:



Besides these information, a relation description has to be completed with other information:

- TYPE: different types of relations can be implemented in such representation, such as dependency, precedence, constituency, anaphore, etc.
- SCOPE: a relation can be specific to a construction or at the opposite valid whatever the context. For example, the precedence relation $[V \prec Clit_{[nom]}]$ is only valid in the context of interrogative constructions whereas the relation exluding the realization of a backchannel[5] after a connective is valid whatever the context. We distinguish then between *local* and *global* scopes.
- POLARITY: a relation can be negated, implementing the impossibility of a relation in a given context.
- CONSTRUCTION: in the case of a local relation, it is necessary to specify the construction to which it belongs.
- STRENGTH: some relation are mandatory, some other optional. As for constraints, we distinguish then between *hard* and *soft* relations, depending on their status.

Finally, a last property has to be precisely defined: the synchronization between two objects

[5] A backchannel is a reaction, verbal or gestual, of the adressee during a conversation.

coming from different domains (for example gestures and words). In some cases, both objects have to be strictly aligned, with same boundaries. For example, a syllable has to be strictly aligned with its set of phonemes: the left syllable boundary (resp. the right) has to be the same as that of the first syllable phoneme (resp. the last). In other cases, the synchronization must not be strict. For example, a deictic gesture is not necessarily strictly aligned with a referential pronoun. In this case, boundaries of both objects only have to be roughly in the same part of the signal.

We propose the definition of alignment operators adapted from (Allen, 1985) as follows:

$=$	*same*	boundaries have to be equal
$<_\Delta$	*before*	$b_1 <_\Delta b_2$ means b_1 value is lower than b_2, with $b_2 - b_1 < \Delta$
$>_\Delta$	*after*	$b_1 >_\Delta b_2$ means that the boundary b_1 follows b_2, with $b_1 - b_2 < \Delta$
$\approx_\Delta$	*almost*	boundaries are neighbors, without order relation, with $\mid b_1 - b_2 \mid \leq \Delta$

This set of operators allow to specify *alignment equations* between different objects. The advantage of this mechanism is that an equation system can describe complex cases of synchronization. For example, a construction can involve several objects from different domains. Some of these objects can be strictly aligned, some others not.

The final TFS representation is as follows:

$$\text{relation}\begin{bmatrix}\text{INDEX}\\ \text{DOMAIN}\{\textit{prosody, syntax, pragmatics, ...}\}\\ \text{REL\_TYPE}\begin{bmatrix}\{\text{ORIENTED\_REL}\begin{bmatrix}\text{SOURCE } \textit{index}\\ \text{TARGET } \textit{index}\end{bmatrix}\\ \{\text{SET\_REL}\langle \textit{node list}\rangle\}\end{bmatrix}\\ \text{TYPE}\{\textit{dependency, precedence, etc.}\}\\ \text{SCOPE}\{\textit{global, local}\}\\ \text{POLARITY}\{\textit{plus, minus}\}\\ \text{CONSTRUCTION } \textit{contruction\_type}\\ \text{STRENGTH}\{\textit{hard, soft}\}\\ \text{ALIGNMENT}\langle \textit{alignment\_equations}\rangle\end{bmatrix}$$

The following feature structure shows an example of a global relation indicating that a verbal nucleus usually comes with a minor raising of the intonation (only main features are indicated here). This information is represented by an implication relation, which is oriented from the syntactic category to the prosodic phenomenon. Alignment equations stipulate a strict synchronization between object.

$$\text{relation}\begin{bmatrix}\text{INDEX}\\ \text{REL\_TYPE} \mid \text{ORIENTED\_REL}\begin{bmatrix}\text{SOURCE } VN_1\\ \text{TARGET } mr_2\end{bmatrix}\\ \text{TYPE}\{\textit{implication}\}\\ \text{STRENGTH}\{\textit{soft}\}\\ \text{ALIGNMENT}\langle lb_1{=}lb_2;\ rb_1{=}rb_2\rangle\end{bmatrix}$$

4 Representation with Hypergraphs

Nodes and relations can be combined and form higher level nodes, representing constructions which are a set of objects (the constituents) plus a set of relations between them. Such nodes are in fact *hypernodes* and bear two kinds of information: the properties characterizing the object plus a set of relations between the constituents (representing a subgraph). In the syntactic domain, for example, they represent phrases, as follows:

$$\begin{bmatrix}\text{DOMAIN } \textit{syntax}\\ \text{INDEX} \mid \text{LOCATION} \mid \text{TEMPORAL}\begin{bmatrix}\text{START } 122\\ \text{END } 584\end{bmatrix}\\ \text{FEATURES}\begin{bmatrix}\text{CAT } VP\end{bmatrix}\\ \text{RELATIONS}\left\{\begin{bmatrix}\text{INDEX } r_1\\ \text{REL\_TYPE} \mid \text{SET\_REL}\langle V, NP, Adv\rangle\\ \text{TYPE } \textit{constituency}\\ \text{STRENGTH } \textit{hard}\end{bmatrix};\right.\\ \left.\begin{bmatrix}\text{INDEX } r_2\\ \text{REL\_TYPE} \mid \text{ORIENTED\_REL}\begin{bmatrix}\text{SOURCE } NP\\ \text{TARGET } V\end{bmatrix}\\ \text{TYPE } \textit{dependency}\\ \text{STRENGTH } \textit{hard}\end{bmatrix}\right\}\end{bmatrix}$$

In the same way, the interaction between different objects from different domains can involve several relations. For example, a deictic construction can be made of the conjunction of an anaphoric pronoun, a deictic gesture and a physical object (for example a book on a shelf). Such a construction can be described by the following structure:

$$\begin{bmatrix}\text{INDEX} \mid \text{LOCATION} \mid \text{TEMPORAL}\begin{bmatrix}\text{START } 841\\ \text{END } 1520\end{bmatrix}\\ \text{FEATURES}\begin{bmatrix}\text{SEM } book'\end{bmatrix}\\ \text{RELATIONS}\left\{\begin{bmatrix}\text{INDEX } r_3\\ \text{SET\_REL}\langle Pro_1, Dx\_gest_2, Ph\_object_3\rangle\\ \text{TYPE } \textit{constituency}\\ \text{ALIGNMENT}\langle lb_1 \approx_\Delta lb_2;\ rb_1 \approx_\Delta rb_2\rangle\end{bmatrix};\right.\\ \left.\begin{bmatrix}\text{INDEX } r_4\\ \text{ORIENTED\_REL}\begin{bmatrix}\text{SOURCE } Pro_1\\ \text{TARGET } Ph\_object_3\end{bmatrix}\\ \text{TYPE } \textit{reference}\end{bmatrix}\right\}\end{bmatrix}$$

This construction indicates some properties (limited here to the semantic value) and two re-

lations between the different objects: one constituency, indicating the different objects involved in the construction and their (fuzzy) alignment and a reference relation between the pronoun and a physical object (here, a book).

This structure represents an hypergraph: it is a graph connecting different nodes, each of them being to its turn described by another graph, as shown above. The main interest of such a representation is its flexibility: all kinds of information can be described, at any level. Graphs being less constrained than trees, and edges (or relations) being typed, we can gather different levels, different domains and different granularities. For example, an agreement relation can be specified thanks to the deictic construction, besides the constituency one, making it possible to instanciate the agreement value of the pronoun.

Note that hypergraphs are also investigated in other knowledge representation, their properties are well known (Hayes, 2004) and the implementation of specific hypergraphs as the one presented here could be done in RDF graphs for example as suggested in (Cassidy, 2010).

5 Constraints for Multimodal Grammars

In the same way as typed feature structures can implement constraints and constitute a description language on linguistic structures (cf. HPSG,), the same approach can be generalized to multimodal information. SOme recent works have been done in this direction (see (Alahverdzhieva, 2010; **?**)). The representation we propose can implement generic information about multimodal constructions. We illustrate in the following this aspect with two phenomena: *backchannels* and *dislocation*.

Several studies on conversational data (see for example (Bertrand09)) have described backchannels (that can be vocal or gestual) and their context. They have in particular underline some regularities on the left context:

- backchannels usually follow: major intonative phrases (IP), flat contours, end of conversational turn (i.e. saturated from a semantic, syntactic and pragmatic point of view)
- backchannels never appear after connectives

These constraints can be implemented by means of a feature structure (representing an hypernode) with a set of precedence relations. The different objects involved in the description of the phenomenon (IP, flat contour, conversational turn, connective) are indicated with an indexed ID, referring to their complete feature structure, not presented here.

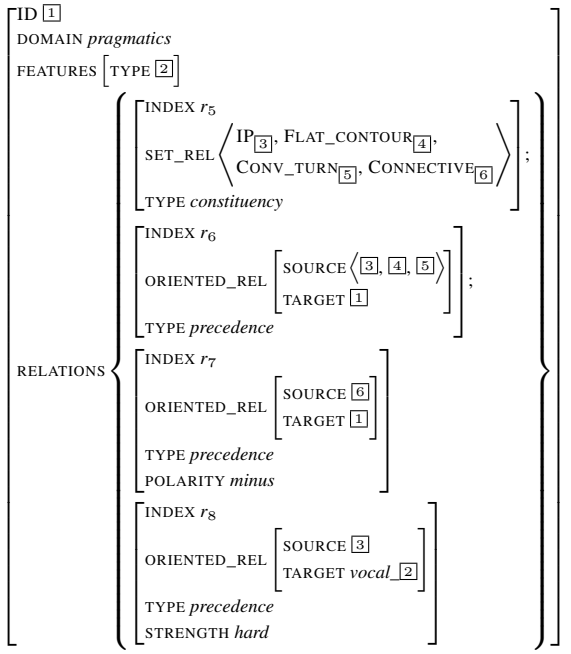


Figure 2: *Backchannel Constraint*

This structure (cf. Figure 2) represents a constraint that backchannels have to satisfy. The first relation specifies the constituents and their indexes, with which the different precedence constraints are represented. The relation *r6* indicates all kinds of object that should precede a backchannel. This constraint subsumes the most specific relation *r8* stipulating that a vocal backchannel is always preceded with an *IP* (this is a *hard* constraint). The relation *r7* excludes the possibility for a backchannel to be preceded with a connective.

The second example (cf. Figure 3) proposes a constraint system describing dislocated structures. We propose in this description to distinguish two syntactic constituents that form the two parts of the dislocation: the dislocated phrase (called *S1*) and the sentence from which the phrase has been

extracted (called *S2*). Usually (even if not always), *S2* contains a clitic referring to *S1*. We note in the following this clitic with the notation *S2//Clit*. For readability reasons, we only present in this structure the relations.

This structure describes the case of a left dislocation (with *S1* preceding *S2*, the constraint being hard). In such cases, *S1* is usually realized with a minor raising contour. The constraint *r13* implements the anaphoric relation between the clitic and the dislocated element. Finally, the relation *r14* indicates an agreement relation between the clitic and *S1* and in particular the fact that the case has to be the same for both objects.

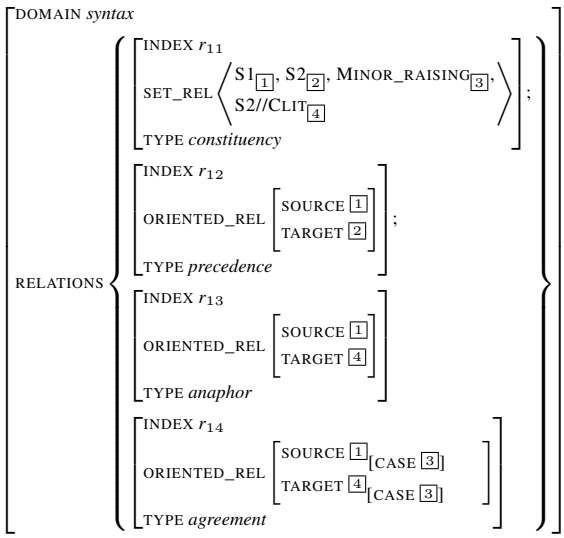

Figure 3: *Dislocation Constraint*

6 Conclusion

Linguistic annotation in general, and multimodality in particular, requires high level annotation schemes making it possible to represent in an homogeneous way information coming from the different domains and modalities involved in human communication.

The approach presented in this paper generalizes previous methods (in particular annotation graphs) thanks to two proposals: first in providing a way to index objects without strict order relation between nodes and second in specifying a precise and homogeneous representation of the objects and their relations. This approach has been developed into a formal scheme, *typed feature structures*, in which all the different domains can be represented, and making it possible to implement directly hypergraphs. TFS and hypergraphs are particularly well adapted for the specification of interaction constraints, describing interaction relations between modalities. Such constraints constitute the core of the definition of future multimodal grammars.

From a practical point of view, the proposal described in this paper is currently under experimentation within the OTIM project (see (Blache, 2010)). An XML scheme has been automatically generated starting from TFS formal scheme. The existing multimodal annotations, created with ad hoc annotation schemes, are to their turn automatically translated following this format. We obtain then, for the first time, a large annotated multimodal corpus, using an XML schema based on a formal specification.

Abstract

This paper presents a framework for combining semantic relations extracted from text to reveal even more semantics that otherwise would be missed. A set of 26 relations is introduced, with their arguments defined on an ontology of sorts. A semantic parser is used to extract these relations from noun phrases and verb argument structures. The method was successfully used in two applications: rapid customization of semantic relations to arbitrary domains and recognizing entailments.

1 Introduction

Semantic representation of text facilitates inferences, reasoning, and greatly improves the performance of Question Answering, Information Extraction, Machine Translation and other NLP applications. Broadly speaking, semantic relations are unidirectional underlying connections between concepts. For example, the noun phrase *the car engine* encodes a PART-WHOLE relation: the engine is a part of the car.

Semantic relations are the building blocks for creating a semantic structure of a sentence. There is a growing interest in text semantics fueled by the new wave of semantic technologies and ontologies that aim at transforming unstructured text into structured knowledge. More and more enterprises and academic organizations have adopted the World Wide Web Consortium (W3C) Resource Description Framework (RDF) specification as a standard representation of text knowledge. This is based on semantic triples, which can be used to represent semantic relations.

The work reported in this paper aims at extracting as many semantic relations from text as possible. Semantic parsers (SP) extract semantic relations from text. Typically they detect relations between adjacent concepts or verb argument structures, leaving considerable semantics unrevealed. For example, given *John is a rich man*, a typical SP extracts *John is a man* and *man is rich*, but not *John is rich*. The third relation can be extracted by combining the two relations detected by the parser. The observation that combining elementary semantic relations yields more relations is the starting point and the motivation for this work.

2 Related Work

In Computational Linguistics, WordNet (Miller, 1995), FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005) are probably the most used semantic resources. Like our approach and unlike PropBank, FrameNet annotates semantics between concepts regardless of their position in a parse tree. Unlike us, they use a predefined set of frames to be filled. PropBank adds semantic annotation on top of the Penn TreeBank and it contains only annotations between a verb and its arguments. Moreover, the semantics of a given label depends on the verb. For example, ARG2 is used for INSTRUMENT and VALUE.

Copious work has been done lately on semantic roles (Màrquez et al., 2008). Approaches to detect semantic relations usually focus on particular lexical and syntactic patterns or kind of arguments. There are both unsupervised (Turney, 2006) and supervised approaches. The SemEval-2007 Task 4 (Girju et al., 2007) focused on relations between nominals. Work has been done on detecting relations between noun phrases (Davidov and Rappoport, 2008; Moldovan et al., 2004), named entities (Hirano et al., 2007), and clauses (Szpakowicz et al., 1995). There have been pro-

Coling 2008: Poster Volume, pages 72–80,
Beijing, August 2010

posals to detect a particular relation, e.g., CAUSE (Chang and Choi, 2006), INTENT (Tatu, 2005) and PART-WHOLE (Girju et al., 2006).

Researchers have also worked on combining semantic relations. Harabagiu and Moldovan (1998) combine WordNet relations and Helbig (2005) transforms chains of relations into theoretical axioms. Some use logic as the underlying formalism (Lakoff, 1970; Sánchez Valencia, 1991), more ideas can be found in (Copestake et al., 2001).

3 Approach

In contrast to First Order Logic used in AI to represent text knowledge, we believe text semantics should be represented using a fixed set of relations. This facilitates a more standard representation and extraction automation which in turn allows reasoning. The fewer the relation types, the easier it is to reason and perform inferences. Thus, a compromise has to be made between having enough relation types to adequately represent text knowledge and yet keeping the number small for making the extraction and manipulation feasible.

The main contributions of this paper are: (i) an extended definition of a set of 26 semantic relations resulted after many iterations and pragmatic considerations; (ii) definition of a semantic calculus, a framework to manipulate and compose semantic relations (CSR); (iii) use of CSR to rapidly customize a set of semantic relations; and (iv) use of CSR to detect entailments. The adoption of CSR to other semantic projects does not require any modification of existing tools while being able to detect relations ignored by such tools.

4 Semantic Relations

Formally, a semantic relation is represented as R(x, y), where R is the relation type and x and y the first and second argument. R(x, y) should be read as *x is* R *of y*. The sentence *"John painted his truck"* yields AGENT(*John*, *painted*), THEME(*his truck*, *painted*) and POSSESSION(*truck*, *John*).

Extended definition Given a semantic relation R, DOMAIN(R) and RANGE(R) are defined as the set of sorts of concepts that can be part of the first and second argument. A semantic relation R(x, y) is defined by its: (i) relation type R; (ii) DOMAIN(R); and (iii) RANGE(R). Stating restrictions for DOMAIN and RANGE has several advantages: it (i) helps distinguishing between relations, e.g., $[\text{tall}]_{ql}$ and $[\text{John}]_{aco}$ can be linked through VALUE, but not POSSESSION; (ii) helps discarding potential relations that do not hold, e.g., abstract objects do not have INTENT; and (iii) helps combining semantic relations (Section 5).

Ontology of Sorts In order to define DOMAIN(R) and RANGE(R), we use a customized ontology of sorts (Figure 1) modified from (Helbig, 2005). The root corresponds to entities, which refers to *all things about which something can be said*.

Objects can be either concrete or abstract. The former occupy space, are touchable and tangible. The latter are intangible; they are somehow a product of human reasoning. Concrete objects are further divided into animate or inanimate. The former have life, vigor or spirit; the later are dull, without life. Abstract objects are divided into temporal or non temporal. The first corresponds to abstractions regarding points or periods of time (e.g. *July*, *last week*); the second to any other abstraction (e.g. *disease*, *justice*). Abstract objects can be sensually perceived, e.g., *pain*, *odor*.

Situations are anything that happens at a time and place. Simply put, if one can think of the time and location of an entity, it is a situation. Events (e.g. *mix*, *grow*) imply a change in the status of other entities, states (e.g. *standing next to the door*) do not. Situations can be expressed by verbs (e.g. *move*, *print*) or nouns (e.g. *party*, *hurricane*).

Descriptors complement entities by stating properties about their spatial or temporal context. They are composed of an optional non-content word signaling the local or temporal context and another entity. Local descriptors are further composed of a concrete object or situation, e.g., $[\textit{above}]_{prep}$ $[\textit{the roof}]_{co}$; temporal descriptors by a temporal abstract object or situation, e.g., $[\textit{during}]_{prep}$ $[\textit{the party}]_{ev}$. The non-content word signaling the local or temporal context is usually present, but not always, e.g., *"The* $[\textit{birthplace}]_{ev}$ *of his mother is* $[\textit{Ankara}]_{loc}$*"*.

Qualities represent characteristics than can be assigned to entities. They can be quantifiable like *tall* and *heavy*, or unquantifiable like *difficult* and *sleepy*. Quantities represent quantitative characteristics of concepts, e.g., *a few pounds*, *22 yards*.

Table 1: The set of 26 relations clustered and classified with their properties (reflexive, symmetric, transitive) and examples. An asterisk indicates that the property holds under certain conditions.

4.1 Semantic Relation Types

This work focuses on the set of 26 semantic relations depicted in Table 1. We found this set specific enough to capture the most frequent semantics of text without bringing unnecessary overspecialization. The set is inspired by several previous proposals. Fillmore introduced the notion of *case frames* and proposed a set of nine roles: AGENT, EXPERIENCER, INSTRUMENT, OBJECT, SOURCE, GOAL, LOCATION, TIME and PATH (Fillmore, 1971). Fillmore's work was extended to FrameNet (Baker et al., 1998). PropBank (Palmer et al., 2005) annotates a set of 17 semantic roles in a per-verb basis.

We aim to encode relations not only between a verb and its arguments, but also between and within noun phrases and adjective phrases. Therefore, more relations are added to the set. It includes relations present in WordNet (Miller, 1995), such as IS-A, PART-WHOLE and CAUSE. Szpakowicz et al. (1995) proposed a set of nine relations and Turney (2006) a set of five. Rosario and Hearst (2004) proposed a set of 38 relations including standard case roles and a set of specific relations for medical domain. Helbig (2005) proposed a set of 89 relations, including ANTONYMY and several TEMPORAL relations, e.g. SUCCESSION, EXTENSION, END.

Our set clusters some of the previous proposals (e.g. we only consider AT-TIME) and discards relations proposed elsewhere when they did not occur frequently enough in our experiments. For example, even though ANTONYMY and ENTAILMENT are semantically grounded, they are very infrequent and we do not deal with them. Our pragmatic goal is to capture as many semantics as possible with as few relations as possible. How-

ever, we show (Section 7.1) that our set can be easily customized to a specific domain.

The 26 relations are clustered such that relations belonging to the same cluster are close in meaning. Working with clusters is useful because it allows us to: (i) map to other proposed relations, justifying the chosen set of relations; (ii) work with different levels of specificity; and (iii) reason with the relations in a per cluster basis.

The reason cluster includes relations between a concept having a direct impact on another. CAU(*x*, *y*) holds if *y* would not hold if *x* did not happen. JST(*x*, *y*) encodes a moral cause, motive or socially convened norm. If IFL(*x*, *y*), *x* affects the intensity of *y*, but it does not affect its occurrence.

The goal cluster includes INT and PRP. INT(*x*, *y*) encodes intended consequences, which are volitional. PRP(*x*, *y*) is a broader relation and can be defined for inanimate objects.

The object modifiers cluster encodes descriptions of objects and situations: SRC(*x*, *y*) holds if *x* expresses the origin of *y*. VAL(*x*, *y*) holds for any other attribute, e.g. *heavy*, *handsome*.

The syntactic subjects cluster includes relations linking a syntactic subject and a situation. The differences rely on the characteristics of the subject and the connection per se. AGT(*x*, *y*) encodes an intentional doer, *x* must be volitional. If EXP(*x*, *y*), *x* does not change the situation, it only experiences *y*; it does not participate intentionally in *y* either. If INS(*x*, *y*), *x* is used to perform *y*, *x* is a tool or device that facilitates *y*.

The direct objects cluster includes relations encoding syntactic direct objects. THM(*x*, *y*) holds if *x* is affected or directly involved by *y*. TPC(*x*, *y*) holds if *y* is a communication verb, like *talk* and *argue*. STI(*x*, *y*) holds if *y* is a perception verb and *x* a stimulus that makes *y* happen.

The association cluster includes ASO and KIN. ASO is a broad relation between any pair of entities; KIN encodes a relation between relatives.

The rest of the relations do not fall into any cluster. ISA, PW, SYN, AT-L and AT-T have been widely studied in the literature. MAK(*x*, *y*) holds if *y* makes or produces *x*; POS(*x*, *y*) holds if *y* owns *x*; MNR encodes the way a situation occurs. RCP captures the connection between an event and an object which is the receiver of the event. PRO describes links between a situation or object and its characteristics, e.g., *height*, *age*. Values to the characteristics are given through VAL. QNT(*x*, *y*) holds if *y* is quantitatively determined by *x*.

Relations can also be classified depending on the kind of concepts they describe and their *intra* or *inter* nature into: (i) Intra-Object; (ii) Inter-Objects; (iii) Intra-Situation; (iv) Inter-Situations; and (v) for Object and Situation description.

4.2 Detection of Semantic Relations

Relations are extracted by an in-house SP from a wide variety of syntactic realizations. For example, the compound nominal *steel knife* contains PW(*steel*, *knife*), whereas *carving knife* contains PRP(*carving*, *knife*); the genitive *Mary's toy* contains POS(*toy*, *Mary*), whereas *Mary's brother* contains KIN(*brother*, *Mary*), and *eyes of the baby* contains a PW(*eyes*, *baby*). Relations are also extracted from a verb and its arguments (NP verb, verb NP, verb PP, verb ADVP and verb S), adjective phrases and adjective clauses.

The SP first uses a combination of state-of-the-art text processing tools, namely, part-of-speech tagging, named entity recognition, syntactic parsing and word sense disambiguation. After a candidate syntactic pattern has been found, a series of machine learning classifiers are applied to decide if a relation holds. Four different algorithms are used: decision trees, Naive Bayes, SVM and Semantic Scattering combined in a hybrid approach. Some algorithms use a per-relation approach (i.e., decide whether or not a given relation holds) and others a per-pattern approach (i.e., which relation, if any, holds for a particular pattern). Additionally, human-coded rules are used for a few unambiguous cases. The SP participated in the SemEval 2007 Task 4 (Badulescu and Srikanth, 2007).

5 Composition of Semantic Relations

The goal of semantic calculus (SC) is to provide a formal framework for manipulating semantic relations. CSR is a part of this, its goal is to apply *inference axioms* over already identified relations in text in order to infer more relations.

Semantic Calculus: Operators and Properties The *composition operator* is represented by the

$(\mathrm{R}^{-1})^{-1} = \mathrm{R}$
$\mathrm{R}_i \circ \mathrm{R}_j = (\mathrm{R}_j{}^{-1} \circ \mathrm{R}_i{}^{-1})^{-1}$
R^{-1} inherits all the properties of R
$\perp^{-1} = \perp$
$\forall i$: $\perp \bowtie \mathrm{R}_i$
R is reflexive iff $\forall x$: $\mathrm{R}(x, x)$
R is symmetric iff $\mathrm{R}(x, y) = \mathrm{R}(y, x)$
R is transitive iff $\mathrm{R}(x, y) \circ \mathrm{R}(y, z) \rightarrow \mathrm{R}(x, z)$
$\mathrm{R}_i \triangleright \mathrm{R}_j \leftrightarrow \mathrm{R}_i{}^{-1} \triangleleft \mathrm{R}_j{}^{-1}$
$\mathrm{R}_i \bowtie \mathrm{R}_j \leftrightarrow \mathrm{R}_i{}^{-1} \bowtie \mathrm{R}_j{}^{-1}$
If R_i is symmetric and $\mathrm{R}_i \bowtie \mathrm{R}_j$, $\mathrm{R}_i{}^{-1} \bowtie \mathrm{R}_j$
If R_j is symmetric and $\mathrm{R}_i \bowtie \mathrm{R}_j$, $\mathrm{R}_i \bowtie \mathrm{R}_j{}^{-1}$

Table 2: Semantic calculus properties

symbol $\circ$. It combines two relations and yields a third one. Formally, we denote $\mathrm{R}_1 \circ \mathrm{R}_2 \rightarrow \mathrm{R}_3$.

The *inverse* of R is denoted R^{-1} and can be obtained by simply switching its arguments. Given $\mathrm{R}(x, y)$, $\mathrm{R}^{-1}(y, x)$ always holds. The easiest way to read $\mathrm{R}^{-1}(y, x)$ is *x is* R *of y*.

R_1 *left dominates* R_2, denoted by $\mathrm{R}_1 \triangleright \mathrm{R}_2$, iff the composition of R_1 and R_2 yields R_1, i.e., $\mathrm{R}_1 \triangleright \mathrm{R}_2$ iff $\mathrm{R}_1 \circ \mathrm{R}_2 \rightarrow \mathrm{R}_1$. R_1 *right dominates* R_2, denoted by $\mathrm{R}_1 \triangleleft \mathrm{R}_2$, iff the composition of R_2 and R_1 yields R_1, i.e., $\mathrm{R}_1 \triangleleft \mathrm{R}_2$ iff $\mathrm{R}_2 \circ \mathrm{R}_1 \rightarrow \mathrm{R}_1$. R_1 *completely dominates* R_2, denoted by $\mathrm{R}_1 \bowtie \mathrm{R}_2$, iff $\mathrm{R}_1 \triangleright \mathrm{R}_2$ and $\mathrm{R}_1 \triangleleft \mathrm{R}_2$, i.e., $\mathrm{R}_1 \bowtie \mathrm{R}_2$ iff $\mathrm{R}_1 \circ \mathrm{R}_2 \rightarrow \mathrm{R}_1$ and $\mathrm{R}_2 \circ \mathrm{R}_1 \rightarrow \mathrm{R}_1$.

An OTHER ($\perp$) relation holds between *x* and *y* if no relation from the given set holds. Formally, $\perp(x, y)$ iff $\neg\exists \mathrm{R}_i$ such that $\mathrm{R}_i(x, y)$.

Using the notation above, the properties depicted in Table 2 follow.

Necessary conditions for Combining Relations Axioms can be defined only for compatible relations as premises. R_1 and R_2 are *compatible* if it is possible, from a theoretical point of view, to apply the composition operator to them. Formally, $\mathrm{RANGE}(\mathrm{R}_1) \cap \mathrm{DOMAIN}(\mathrm{R}_2) \neq \emptyset$

If R_1 and R_2 are compatible but not equal a *restriction* occurs. Let us denote $\mathrm{RANGE}(\mathrm{R}_1) \cap \mathrm{DOMAIN}(\mathrm{R}_2) = I$. A *backward* restriction takes place if $\mathrm{RANGE}(\mathrm{R}_1) \neq I$ and a *forward* restriction if $\mathrm{DOMAIN}(\mathrm{R}_2) \neq I$. In the former case $\mathrm{RANGE}(\mathrm{R}_1)$ is reduced; in the later $\mathrm{DOMAIN}(\mathrm{R}_2)$ is reduced. A forward and backward restriction can be found with the same pair of relations.

It is important to note that two compatible relations may not be the premises for a valid axiom. For example, KIN and AT-L are compatible but do not yield any valid inference.

Another necessary condition for combining two relations $\mathrm{R}_1(x, y)$ and $\mathrm{R}_2(y, z)$ is that they have to have a common argument, *y*.

5.1 Unique axioms

An axiom is defined as a set of relations called premises and a conclusion. Given the premises it unequivocally yields a relation that holds as conclusion. The composition operator is the basic way of combining two relations to form an axiom.

In general, for n relations there are $\binom{n}{2} = \frac{n(n-1)}{2}$ different pairs. For each pair, taking into account the two relations and their inverses, there are $4 \times 4 = 16$ different possible combinations. Applying property $\mathrm{R}_i \circ \mathrm{R}_j = (\mathrm{R}_j{}^{-1} \circ \mathrm{R}_i{}^{-1})^{-1}$, only 10 combinations are unique: (i) 4 combine R_1, R_2 and their inverses; (ii) 3 combine R_1 and $\mathrm{R}_1{}^{-1}$; and (iii) 3 combine R_2 and $\mathrm{R}_2{}^{-1}$. The most interesting axioms fall into category (i), since the other two can be resolved by the transitivity property of a relation and its inverse.

For n relations there are $2n^2 + n$ potential axioms: $\binom{n}{2} \times 4 + 3n = 2 \times n(n-1) + 3n = 2n^2 + n$. For $n = 26$, there are 1300 potential axioms in (i), 820 of which are compatible.

The number can be further reduced. After manual examination of combinations of ASO and KIN with other relations, we conclude that they do not yield any valid inferences, invalidating 150 potential axioms. This is due to the broad meaning of these relations. QNT can be discarded as well, invalidating 45 more potential axioms.

Some axioms can be easily validated. Because synonymous concepts are interchangeable, SYN is easily combined with any other relation: $\mathrm{SYN}(x, y) \circ \mathrm{R}(y, z) \rightarrow \mathrm{R}(x, z)$ and $\mathrm{R}(x, y) \circ \mathrm{SYN}(y, z) \rightarrow \mathrm{R}(x, z)$. Because hyponyms inherit relations from their hypernyms, $\mathrm{ISA}(x, y) \circ \mathrm{R}(y, z) \rightarrow \mathrm{R}(x, z)$ and $\mathrm{R}(x, y) \circ \mathrm{ISA}^{-1}(y, z) \rightarrow \mathrm{R}(x, z)$ hold. These observations allow us to validate 138 of the 625 potential axioms left, still leaving 487.

As noted before, relations belonging to the same cluster tend to behave similarly. This is especially true for the reason and goal clusters due to their semantic motivation. Working with these two clusters instead of the relations brings the

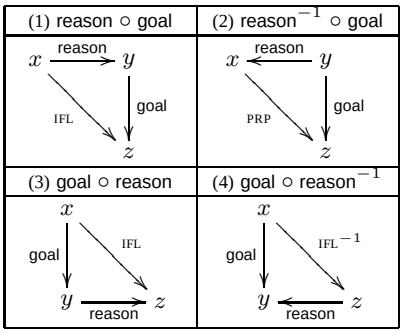

Table 3: The four axioms taking as premises reason and goal clusters. Diagonal arrows indicate inferred relations.

number of axioms to be examined down to 370.

Out of the 370 axioms left, we have extensively analyzed and defined the 35 involving AT-L, the 43 involving reason and the 58 involving goal. Because of space constraints, in this paper we only fully introduce the axioms for reason and goal (Section 6), as well as a variety of axioms useful to recognize textual entailments (Section 7.2).

6 Case Study: Reason and Goal

In this section, we present the four unique axioms for reason and goal relations (Table 3).

(1) **REA(*x, y*) ∘ GOA(*y, z*) → IFL(*x, z*)**: an event is influenced by the reason of its goal.

For example: Bill saves money because he is unemployed; he spends far less than he used to. Therefore, being unemployed can lead to spend far less.

P REA(*be unemployed, save money*)
GOA(*save money, spend far less*)
C IFL(*be unemployed, spend far less*)

(2) **REA^{-1}(*x, y*) ∘ GOA(*y, z*) → PRP(*x, z*)**: events have as their purpose the effects of their goals. This is a strong relation.

For example: Since they have a better view, they can see the mountain range. They cut the tree to have a better view. Therefore, they cut the tree to see the mountain range.

P REA^{-1}(*see the mountain range, better view*)
GOA(*better view, cut the tree*)
C PRP(*see the mountain range, cut the tree*)

Note that possible unintended effects of cutting the tree (e.g. homeowners' association complains) are caused by the event *cut the tree*, not by its effect *get a better view*.

(3) **GOA(*x, y*) ∘ REA(*y, z*) → IFL(*x, z*)**: the goal of an action influences its effects.

For example: John crossed the street carelessly to get there faster. He got run over by a propane truck. Therefore, John got run over by a propane truck influenced by (having the goal of) getting there faster.

P GOA(*get there faster, crossed carelessly*)
REA(*crossed carelessly, got run over*)
C IFL(*get there faster, got run over*)

(4) **GOA(*x, y*) ∘ REA^{-1}(*y, z*) → IFL^{-1}(*x, z*)**. Events influence the goals of its effects.

For example: Jane exercises to lose weight. She exercised because of the good weather. Therefore, good weather helps to lose weight.

P GOA(*lose weight, exercise*)
REA^{-1}(*exercise, good weather*)
C IFL^{-1}(*lose weight, good weather*)

The axioms have been evaluated using manually annotated data. PropBank CAU and PNC are used as reason and goal. Reason annotation is further collected from a corpus which adds causal annotation to the Penn TreeBank (Bethard et al., 2008). A total of 5 and 29 instances for axioms 3 and 4 were found. For all of them, the axioms yield a valid inference. For example, *Buick [approached]$_y$ American express about [a joint promotion]$_x$ because [its card holders generally have a good credit history]$_z$*. PropBank annotation states GOA(x, y) and REA^{-1}(y, z), axiom 4 makes the implicit relation IFL^{-1}(x, z) explicit.

7 Applications and Results

7.1 Customization of Semantic Relations

Problem There is no agreement on a set of relations that best represent text semantics. This is rightfully so since different applications and domains call for different relations. CSR can be used to rapidly customize a set of relations without having to train a new SP or modify any other tool. Given a text, the SP extracts 26 elementary semantic relations. Axioms within the framework of CSR yield n new relations, resulting in a richer semantic representation (Figure 2).

CSR axioms Two ways to get new relations are:

(i) Direct mapping. This is the easiest case and it is equivalent to rename a relation. For example, we can map POS to BELONG or IS-OWNER-OF.

Axiom	Rest. on y	Example
AGT(x, y) ∘ THM^{-1}(y, z) → ARRESTED(x, z)	*arrested* concept	[Police]$_x$ [apprehended]$_y$ 51 [football fans]$_z$.
THM(x, y) ∘ AT-L(y, z) → ARRESTED-AT(x, z)	*arrested* concept	Police [apprehended]$_y$ 51 [fans]$_x$ [near the Dome]$_z$.
AGT(x, y) ∘ AT-L(y, z) → BANKS-AT(x, z)	*banking* activity	[John]$_x$ [withdrew]$_y$ $20 [at the nearest Chase]$_z$.
POS(x, y) ∘ AT-L(y, z) → BANKS-AT(x, z)	*account* concept	[John]$_x$ got a [checkbook]$_y$ at [Chase]$_z$.

Table 4: Examples of semantic relation customization using CSR.

Pair	Text T		Hypothesis H

Table 5: RTE3 examples and their elementary semantic relations (i.e., the ones the SP detects). Only relevant semantic relations for entailment detection are shown for T.

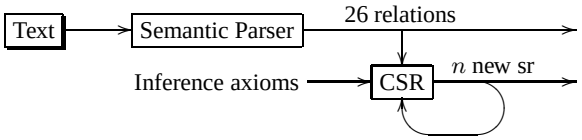

Figure 2: Flowchart for obtaining customized semantic relations using CSR.

(ii) Combinations of two elementary relations yield new specialized relations. In this case, restrictions on the arguments must be fulfilled.

Consider we need the new relation ARRESTED(x, y), which encodes the relation between two animate concrete objects x and y, where x arrested y. We can infer this relation by using the following axiom: AGENT(x, y) ∘ THEME^{-1}(y, z) → ARRESTED(x, z) provided that y is an *arrested* concept. A simple way of checking if a given concept is of a certain kind is to check WordNet. Collecting all the words belonging the the synset arrest.v.1, we get the following list of *arrested* concepts: *collar*, *nail*, *apprehend*, *pick up*, *nab* and *cop*. Using lexical chains the list could be further improved.

More examples of axioms for generating customized semantic relations are shown in Table 4.

Results Virtually any domain could be covered by applying customization over the set of 26 relations. The set has been successfully customized to a law enforcement domain. Ax-

ioms for a total of 37 new relations were defined and implemented. Among others, axioms to infer IS-EMPLOYER, IS-COWORKER, IS-PARAMOUR, IS-INTERPRETER, WAS-ASSASSIN, ATTENDS-SCHOOL-AT, JAILED-AT, COHABITS-WITH, AFFILIATED-TO, MARRIED-TO, RENTED-BY, KIDNAPPED-BY and the relations in Table 4 were defined. Note that a relation can be inferred by several axioms. This customization effort to add 37 new specialized relations took a person only a few days and without modifying the SP.

7.2 Textual Entailment

Problem An application of CSR is recognizing entailments. Given text T and hypothesis H, the task consists on determining whether or not H can be inferred by T (Giampiccolo et al., 2007).

CSR axioms Several examples of the RTE3 challenge can be solved by applying CSR (Table 5). The rest of this section depicts the axioms involved in detecting entailment for each pair.

Pair 113 is a simple one. A perfect match for H in T can be obtained by an axiom reading *all concepts inherit the semantic relations of their hypernyms*. Formally, ISA(x, y) $\circ$ THM(y, z) $\rightarrow$ THM(x, z), $T2$ and $T4$ are the premises and the conclusion matches $H2$. $T1$ matches $H1$.

Pair 429 can be solved by an axiom reading *agents are values for their themes*. Formally, AGT(x, y) $\circ$ THM^{-1}(y, z) $\rightarrow$ VAL(x, z); $T1$ and $T2$ yield VAL(*Hindu, Ganga*), which combined with $T3$ results in a match between T and H.

Pair 445 follows a similar pattern, but the way an EXP combines with its THM differs from the way an AGT does. The *theme is a value of the experiencer*, THM(x, y) $\circ$ EXP^{-1}(y, z) $\rightarrow$ VAL(x, z). Given $T2$ and $T3$, the axiom yields $T4$: VAL(*video, site*). Assuming that SYN(*site, website*), $T1$ and $T4$ match H.

Pair 716 also requires only one inference step. Using $T3$ and $T2$, an axiom reading *situations have as their purpose the purpose of its theme* infers $H2$, yielding a perfect match between T and H. Formally, PRP(x, y) $\circ$ THM(y, z) $\rightarrow$ PRP(x, z).

Pair 771 Using as premises $T1$ and $T2$, an axiom reading *an agent performs the purposes of its actions* infers $H1$. Using $T3$ and $T5$, and $T4$ and $T5$ as premises, an axiom reading *synonymous concepts are interchangeable* infers $H2$ and $H3$, resulting in a perfect match between T and H. Formally, AGT(x, y) $\circ$ PRP^{-1}(y, z) $\rightarrow$ AGT(x, z), RCP^{-1}(x, y) $\circ$ SYN(y, z) $\rightarrow$ RCP^{-1}(x, z) and QNT(x, y) $\circ$ SYN(y, z) $\rightarrow$ QNT(x, z).

Results We conducted two experiments to quantify the impact of CSR in detecting entailments.

First, 60 pairs were randomly selected from the RTE3 challenge and parsed with the SP. 14 of them (23%) could be solved by simply matching the elementary relations in T and H. After applying CSR, 21 more pairs (35%) were solved. Thus, adding CSR on top of the SP clearly improves entailment detection. Out of the 25 pairs not solved, 5 (8%) need coreference resolution and 20 (34%) require commonsense knowledge or fairly complicated reasoning methods (e.g. *a shipwreck is a ship that sank*).

CSR has also been added to a state of the art system for detecting textual entailment (Tatu and Moldovan, 2007). Prior to the addition, the system made 222 errors consisting of 46 false negatives (examples in Table 5) and 176 false positives. CSR was able to correctly solve 18 (39%) of the 46 false negatives.

8 Conclusions

Although the idea of chaining semantic relations has been proposed before, this paper provides a formal framework establishing necessary conditions for composition of semantic relations. The CSR presented here can be used to rapidly customize a set of relations to any arbitrary domain. In addition to the customization of an information extraction tool and recognizing textual entailments, CSR has the potential to contribute to other applications. For example, it can help improve a semantic parser, it can be used to acquire commonsense knowledge axioms and more.

When an axiom that results from combining two relations does not always hold, it may be possible to add constraints that limit the arguments of the premises to only some concepts.

This work stems from the need to automate the extraction of deep semantics from text and representing text as semantic triples. The paper demonstrates that CSR is able to extract more relations than a normal semantic parser would.

Improved Unsupervised Sentence Alignment for Symmetrical and Asymmetrical Parallel Corpora

Fabienne Braune **Alexander Fraser**
Institute for Natural Language Processing
Universität Stuttgart
{braunefe,fraser}@ims.uni-stuttgart.de

Abstract

We address the problem of unsupervised and language-pair independent alignment of symmetrical and asymmetrical parallel corpora. Asymmetrical parallel corpora contain a large proportion of 1-to-0/0-to-1 and 1-to-many/many-to-1 sentence correspondences. We have developed a novel approach which is fast and allows us to achieve high accuracy in terms of F_1 for the alignment of both asymmetrical and symmetrical parallel corpora. The source code of our aligner and the test sets are freely available.

1 Introduction

Sentence alignment is the problem of, given a parallel text, finding a bipartite graph matching minimal groups of sentences in one language to their translated counterparts. Because sentences do not always align 1-to-1, the sentence alignment task is non-trivial.

The achievement of high accuracy with minimal consumption of computational resources is a common requirement for sentence alignment approaches. However, in order to be applicable to parallel corpora in any language without requiring a separate training set, a method for sentence-alignment should also work in an unsupervised fashion and be language pair independent. By "unsupervised", we denote methods that infer the alignment model directly from the data set to be aligned. Language pair independence refers to approaches that require no specific knowledge about the languages of the parallel texts to align.

We have developed an approach to unsupervised and language-pair independent sentence alignment which allows us to achieve high accuracy in terms of F_1 for the alignment of both symmetrical and asymmetrical parallel corpora. Due to the incorporation of a novel two-pass search procedure with pruning, our approach is acceptably fast. Compared with Moore's bilingual sentence aligner (Moore, 2002), we obtain an average F_1 of 98.38 on symmetrical parallel documents, while Moore's aligner achieves 94.06. On asymmetrical documents, our approach achieves 97.67 F_1 while Moore's aligner obtains 88.70. On average, our sentence aligner is only about 4 times slower than Moore's aligner.

This paper is organized as follows: previous work is described in section 2. In section 3, we present our approach. Finally, in section 4, we conduct an extensive evaluation, including a brief insight into the impact of our aligner on the overall performance of an MT system.

2 Related Work

Among approaches that are unsupervised and language independent, (Brown et al., 1991) and (Gale and Church, 1993) use sentence-length statistics in order to model the relationship between groups of sentences that are translations of each other. As shown in (Chen, 1993) the accuracy of sentence-length based methods decreases drastically when aligning texts containing small deletions or free translations. In contrast, our approach augments a sentence-length based model with lexical statistics and hence constantly provides high quality alignments.

(Moore, 2002) proposes a multi-pass search

Coling 2008: Poster Volume, pages 81–89,
Beijing, August 2010

procedure where sentence-length based statistics are used in order to extract the training data for the IBM Model-1 translation tables. The acquired lexical statistics are then combined with the sentence-length based model in order to extract 1-to-1 correspondences with high accuracy[1]. Moore's approach constantly achieves high precision, is robust to sequences of inserted and deleted text, and is fast. However, the obtained recall is at most equal to the proportion of 1-to-1 correspondences contained in the parallel text to align. This point is especially problematic when aligning asymmetrical parallel corpora. In contrast, our approach allows to extract 1-to-many/many-to-1 correspondences. Hence, we achieve high accuracy in terms of precision and recall on both symmetrical and asymmetrical documents. Moreover, because we use, in the last pass of our multi-pass method, a novel two-stage search procedure, our aligner also requires acceptably low computational resources.

(Deng et al., 2006) have developed a multi-pass method similar to (Moore, 2002) but where the last pass is composed of two alignment procedures: a standard dynamic programming (DP) search that allows one to find many-to-many alignments containing a large amount of sentences in each language and a divisive clustering algorithm that optimally refines those alignments through iterative binary splitting. This alignment method allows one to find, in addition to 1-to-1 correspondences, high quality 1-to-many/many-to-1 alignments. However, 1-to-0 and 0-to-1 correspondences are not modeled in this approach[2]. This leads to poor performance on parallel texts containing that type of correspondence. Furthermore performing an exhaustive DP search in order to find large size many-to-many alignments involves high computational costs. In comparison to (Deng et al., 2006), our approach works in the opposite way. Our two-step search procedure first finds a model-optimal alignment composed of the smallest possible correspondences, namely 1-to-0/0-to-1 and 1-to-1, and then merges those correspondences into larger alignments. This allows the finding of 1-to-0/0-to-1 alignments as well as high quality 1-to-many/many-to-1 alignments, leading to high accuracy on parallel texts but also on corpora containing large blocs of inserted or deleted text. Furthermore, our approach keeps the computational costs of the alignment procedure low: our aligner is, on average, about 550 times faster than our implementation[3] of (Deng et al., 2006).

Many other approaches to sentence-alignment are either supervised or language dependent. The approaches by (Chen, 1993), (Ceausu et al., 2006) or (Fattah et al., 2007) need manually aligned pairs of sentences in order to train the used alignment models. The approaches by (Wu, 1994), (Haruno and Yamazaki, 1996), (Ma, 2006) and (Gautam and Sinha, 2007) require an externally supplied bilingual lexicon. Similarly, the approaches by (Simard and Plamondon, 1998) or (Melamed, 2000) are language pair dependent insofar as they are based on cognates.

3 Two-Step Clustering Approach

We present here our two-step clustering approach to sentence alignment[4] which is the main contribution of this paper. We begin by giving the main ideas of our approach using an introductory example (section 3.1). Then we show to which extent computational costs are reduced in comparison to a standard DP search (section 3.2) before presenting the theoretical background of our approach (section 3.3). We further discuss a novel pruning strategy used within our approach (section 3.4). This pruning technique is another important contribution of this paper. Next, we present the alignment model (section 3.5) which is a slightly modified version of the alignment model used in (Moore, 2002). Finally, we describe the overall

[1] The used search heuristic is a forward-backward computation with a pruned dynamic programming procedure as the forward pass.

[2] In (Deng et al., 2006), p. 5, the $p(a_k) = p(x, y)$ which determines the prior probability of having an alignment containing x source and y target sentences, is equal to 0 if $x < 1$ or $y < 1$. As $p(a_k)$ is a multiplicative factor of the model, the probability of having an insertion or a deletion is always equal to 0.

[3] In order to provide a precise comparison between our aligner and (Deng et al., 2006), we have implemented their model into our optimized framework.

[4] Note that our approach does not aim to find many-to-many alignments. None of the unsupervised sentence alignment approaches discussed in section 2 are able to correctly find that type of correspondence.

procedure required to align a parallel text with our method (section 3.6).

3.1 Sketch of Approach

Consider a parallel text composed of six source language sentences F_i and four target language sentences E_j. Further assume that the correct alignment between the given texts is composed of four correspondences: three 1-to-1 alignments between F1, E1; F2, E2 and F6, E4 as well as a 3-to-1 alignment between F3, F4, F5 and E3. Figure 1 illustrates this alignment.

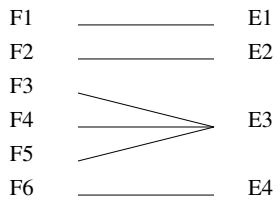

Figure 1: *Correct Alignment between F_i and E_j*

In the perspective of a statistical approach to sentence alignment, the alignment in figure 1 is found by computing the model-optimal alignment A^* for the bitext considered:

$$A^* = \underset{A}{\operatorname{argmax}} \prod_{a_k \in A} SCORE(a_k) \qquad (1)$$

where $SCORE(a_k)$ denotes the score attributed by the alignment model[5] to a minimal alignment a_k composing A^*. The optimization given in equation 1 relies on two commonly made assumptions: (c_1) a model-optimal alignment A^* can be decomposed into k minimal and independent alignments a_k; (c_2) each alignment a_k depends only on local portions of text in both languages.

The search for A^* is generally performed using a dynamic programming (DP) procedure over the space formed by the l source and m target sentences. The computation of A^* using a DP search relies on the assumption (c_3) that sentence alignment is a monotonic and continuous process. The DP procedure recursively computes the optimal score $D(l,m)^*$ for a sequence of alignments covering the whole parallel corpus. The optimal score $D(l,m)^*$ is given by the following recursion:

$$D(l,m)^* = \min_{0 \leq x,y \leq R \ , \ x=1 \vee y=1} D(l-x, m-y)^* - \log SCORE(a_k) \qquad (2)$$

where x denotes the number of sentences on the source language side of a_k and y the number of sentences on the target language side of a_k.

The constant R constitutes an upper bound to the number of sentences that are allowed on each side of a minimal alignment a_k. This constant has an important impact on the computational costs of the DP procedure insofar as it determines the number of minimal alignments that have to be compared and scored at each step of the recursion given in equation 2. As will be shown in section 3.2, the number of comparisons increases depending on R.

The solution we propose to the combinatorial growth of the number of performed operations consists of dividing the search for A^* into two steps. First, a model-optimal alignment A_1^*, in which the value of R is fixed to 1, is found. Second, the alignments a'_k composing A_1^* are merged into clusters m_r containing up to R sentences on either the source or target language side. The alignment composed of these clusters is A_R^*.

The search for the first alignment A_1^* is performed using a standard DP procedure as given in equation 2 but with $R = 1$. This first alignment is, hence, only composed of 0-to-1, 1-to-0 and 1-to-1 correspondences. Using our example, we show, in figure 2, the alignment A_1^* found in the first step of our approach. The neighbors of F4, that is F3 and F5, are aligned as 1-to-0 correspondences.

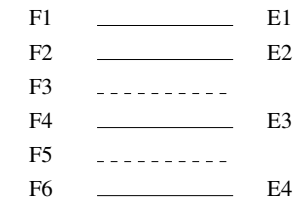

Figure 2: *A_1^* in our Approach (first step)*

The search for A_R^* is performed using a DP search over the alignments a'_k composing A_1^*. The score $D(A_R)^*$ obtained when all alignments $a'_k \in A_1^*$ have been optimally clustered can be written

[5]The alignment model will be presented in section 3.5.

recursively as:

$$D(A_R)^* = \min_{0 \leq r \leq R} D(A_R - r)^* - \log SCORE(m_r) \quad (3)$$

where $D(A_R - r)^*$ denotes the best score obtained for the prefix covering all minimal alignments in A_1^* except the last r minimal alignments considered for composing the last cluster m_r.

The application of the second step of our approach is illustrated in figure 3. The first alignment, between F1 and E1, cannot be merged to be part of a 1-to-many or many-to-1 cluster because the following alignment in A_1^* is also 1-to-1. So it must be retained as given in A_1^*. The five last alignments are, however, candidates for composing clusters. For instance, the alignment F2-E2 and F3-ϵ, where ϵ denotes the empty string, could be merged in order to compose the 2-to-1 cluster F2,F3-E2. However, in our example, the alignment model chooses to merge the alignments F3-ϵ, F4-E3 and F5-ϵ in order to compose the 3-to-1 cluster F3,F4,F5-E3.

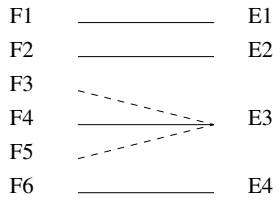

Figure 3: A_R^* *in our Approach (second step)*

3.2 Computational Gains

The aim of this section is to give an idea about why our method is faster than the standard DP approach. Let C denote the number of comparisons performed at each step of the recursion of the standard DP procedure, as given in equation 2. This amount is equivalent to the number of possible combinations of x source sentences with y target sentences. Hence, for an approach finding all types of correspondences except many-to-many, we have:

$$C = 2R + 1 \quad (4)$$

In terms of lookups in the word-correspondence tables of a model including lexical statistics, the number of operations C_l performed at each step of the recursion is given by:

$$C_l = R' * w^2 \quad (5)$$

where R' denotes the number of scored sentences[6]. w denotes the average length of each sentence in terms of words. The total number of lookups performed in order to align a parallel text containing l source and m target sentences using a standard DP procedure is hence given by:

$$L = R' * w^2 * l * m \quad (6)$$

In the perspective of our two-step search procedure, the computational costs of the search for the initial alignment A_1^* is given by:

$$L'_1 = w^2 * l * m \quad (7)$$

For the second step of our approach, because A_R^* is a cluster of A_1^*, the dynamic programming procedure used to find this alignment is no longer over the $l * m$ space formed by the source and target sentences but instead over the space formed by the minimal alignments a'_k in A_1^*. The average number of those alignments is approximately $\frac{l+m}{2}$.[7] The number of lookups performed at each step of our DP procedure is given by:

$$L'_2 = R' * w^2 * \frac{l+m}{2} \quad (8)$$

where R' and w are defined as in equation 6. The total number of lookups for our clustering approach is hence given by:

$$L'_{1+2} = (w^2 * l * m) + (R' * w^2 * \frac{l+m}{2}) \quad (9)$$

In order to compare the costs of our approach and a standard DP search over the $l * m$ space formed by the source and target sentences, we re-write equation 6 as:

$$L = (w^2 * l * m) + ((R' - 1) * w^2 * l * m) \quad (10)$$

The comparison of equation 9 with equation 10 shows that the computational gains obtained using our two-step approach reside in the reduction of the search space from $l * m$ to $\frac{l+m}{2}$.[8]

[6] In a framework where no caching of scores is performed, we have $R' = R^2 + R + 1$ compared sentences while score-caching allows one to reduce R' to R.

[7] Note that this amount tends to $l + m$ when A_1^* contains a large number of 0-to-1/1-to-0 correspondences.

[8] It should be noted that through efficient pruning, the search space of the standard (DP) procedure can be further reduced, see section 3.4.

3.3 Theoretical Background

We now present the theoretical foundation of our approach. First, we rewrite equation 1 in a more detailed fashion as:

$$A_R^* = \underset{A}{\operatorname{argmax}} \prod_{a_k(x_k,y_k)\in A_R} P(a_k(x_k,y_k), s_i^q, t_j^r) \tag{11}$$

with $0 \leq x_k, y_k \leq R$, where R denotes the maximal amounts x and y of source and target language sentences composing a minimal alignment $a_k(x_k, y_k)$. The distribution $P(a_k(x_k, y_k), s_i^q, t_j^r)$ specifies the alignment model presented in section 3.5.

As seen in section 3.1, the formulation of the alignment problem as given in equation 11 and the use of a DP search in order to solve this equation rely on the assumptions (c_1) to (c_3). Following these assumptions, a model-optimal alignment A_1^* can be defined as an ordered set of minimal alignments $a'_k(x_k, y_k)$, with $0 \leq x_k, y_k \leq 1$, where the aligned portions of text are sequential. In other words, if the $k-th$ alignment $a'_k(x_k, y_k)$ contains the sequences s_i^q and t_j^r of source and target language sentences, then the next alignment $a'_{k+1}(x_{k+1}, y_{k+1})$ is composed of the sequences s_{q+1}^u and t_{r+1}^v. Hence, each alignment composing A_R, with $R > 1$, can be obtained through sequential merging of a series of alignments $a'_k(x_k, y_k) \in A_1^*$.[9] Accordingly, the sequences of sentences s_1^u and t_1^v are obtained by merging s_1^q and t_1^r with s_{q+1}^u and t_{r+1}^v. It can then be assumed that (c_4) the ordered set of minimal alignments composing A_R^* under equation 11 is equivalent to the set of clusters obtained by sequentially merging the minimal alignments composing A_1^*. Following assumption (c_4), the optimization over $a_k(x_k, y_k) \in A_R$ is equivalent to an optimization over the merged alignments $m_r(x_r, y_r) \in A_R$. Hence, equation 11 is equivalent to:

$$A_R^* = \underset{A_R}{\operatorname{argmax}} \prod_{m_r(x_r,y_r)\in A_R} P(m_r(x_r,y_r), s_i^u, t_j^v) \tag{12}$$

where each $m_r(x_r, y_r)$ is obtained by merging r minimal alignments $a'_k(x_k, y_k) \in A_1^*$.

The computation of A_R^* is done in two steps. First, a model-optimal alignment A_1^* is found using a standard DP procedure as defined in equation 2 but with $R = 1$ and where $SCORE(a_k)$ is given by the alignment model $-\log P(a_k, s_{l-x+1}^l, t_{m-y+1}^m)$. In the second step, the search procedure used to find the optimal clusters is defined as in equation 3 but where $SCORE(m_r)$ is given by the alignment model $-\log P(m_r, s_i^u, t_j^v)$.

3.4 Search Space Pruning

In order to further reduce the costs of finding A_1^*, we initially pruned the search space in the same fashion as (Moore, 2002). We explored a narrow band around the main diagonal of the bitext to align. Each time the approximated alignment came close to the boundaries of the band, the search was reiterated with a larger band size. However, the computational costs for alignments that were not along the diagonal quickly increased with this pruning strategy. A high loss of efficiency was hence observed when aligning asymmetrical documents with this technique. Incidentally, Moore reports, in his experiments, that for the alignment of a parallel text containing 300 deleted sentences, the computational costs of his pruned DP procedure is 40 times higher than for a corpus containing no deletions.

In order to overcome this problem, we developed a pruning strategy that allows us to avoid the loss of efficiency occurring when aligning asymmetrical documents. Instead of exploring a narrow band around the main diagonal of the text to align, we use sentence-length statistics in order to compute an approximate path through the considered bitext. Our search procedure then explores the groups of sentences that are around this path. If the approximated alignment comes close to the boundaries of the band, the search is re-iterated.

The path initially provided using a sentence-length model[10] and then iteratively refined is closer to the correct alignment than the main diagonal of the bitext to align. Hence, the approximated alignment does not come close to the band

[9] Alignments of type 1-to-0/0-to-1 and 1-to-1 are assumed to be clusters where a minimal alignment $a'_k(x_k, y_k) \in A_1^*$ has been merged with the empty alignment $e_0(0,0)(\epsilon, \epsilon)$.

[10] The used model is the sentence-length based component of (Moore, 2002), which is able to find 1-to-0/0-to-1 correspondences.

as often as when searching around the main diagonal. This results in relatively high computational gains, especially for asymmetrical parallel texts (see section 4).

3.5 Moore's Alignment Model

The model we use is basically the same as in (Moore, 2002) but minor modifications have been made in order to integrate this model in our two-step clustering approach. The three component distributions of the model are given by[11]:

$$P(a_k, s_i^q, t_j^r) = P(a_k)P(s_i^q|a_k)P(t_j^r|a_k, s_i^q) \quad (13)$$

The first component, $P(a_k)$, specifies the generation of a minimal alignment a_k. The second component, $P(s_i^q|a_k)$, specifies the generation of a sequence s_i^q of source language sentences in a minimal alignment a_k. The last component, i.e. $P(t_j^r|a_k, s_i^q)$, specifies the generation of a sequence of target language sentences depending on a sequence of generated source sentences.

Our first modification to Moore's model concerns the component distribution $P(a_k)$. In the second pass of our two-step approach, which is the computation of the model-optimal clustered alignment A_R^*, we estimate $P(a_k)$ by computing the relative frequency of sequences of alignments a_k' in the initial alignment A_1^* that are candidates for composing a cluster m_r of specific size.[12] A second minimal modification to Moore's model concerns the lexical constituent of $P(t_j^r|a_k, s_i^q)$, which we denote here by $P(f_b|e_n, a_k)$. In contrast with Moore, we use the best alignment (Viterbi alignment) of each target word f_b with all source words e_n, according to IBM Model-1:

$$P(f_b|e_n, a_k) = \frac{\arg\max_{n=1}^{l_e} P_t(f_b|e_n)}{l_e + 1} \quad (14)$$

where l_e denotes the number of words in the source sentence(s) of a_k. Our experimental results have shown that this variant performed slightly better than Moore's summing over all alignments.

[11] In order to simplify the presentation of the model, we use the short notation a_k for denoting $a_k(x_k, y_k)$

[12] For the computation of A_1^*, the distribution $P(a_k)$ is defined as in Moore's work.

3.6 Alignment Procedure

In order to align a parallel text (s_1^l, t_1^m) we use a multi-pass procedure similar to (Moore, 2002) but where the last pass is replaced by our two-step clustering approach. In the first pass, an approximate alignment is computed using sentence-length based statistics and the one-to-one correspondences with likelihood higher than a given threshold are selected for the training of the IBM Model-1 translation tables[13]. Furthermore, each found alignment is cached in order to be used as the initial diagonal determining the search space for the next pass. In the second pass, the corpus is re-aligned according to our two-step approach: (i) a model-optimal[14] alignment containing at most one sentence on each side of the minimal alignments $a_k(x_k, y_k)$ is found; (ii) those alignments are model-optimally merged in order to obtain an alignment containing up to R sentences on each side of the clusters $m_r(x_r, y_r)$. In our experiments, a maximum number of 4 sentences is allowed on each side of a cluster.

4 Experiments

We evaluate our approach (CA) using three baselines against which we compare alignment quality and computational costs.[15] The first (Mo) is the method by (Moore, 2002). As a second baseline (Std), we have implemented an aligner that finds the same type of correspondences as our approach but performs a standard DP search instead of our two-pass clustering procedure and implements Moore's pruning strategy. Our third baseline (Std P.) is similar to (Std) but integrates our pruning technique.[16] We also evaluate the impact

[13] Words with frequency < 3 in the corpus have been dropped.

[14] This is optimal according to the alignment model which will be presented in section 3.5.

[15] We do not evaluate sentence-length based methods in our experiments because these methods obtain an F_1 which is generally about 10% lower than for our approach on symmetrical documents. For asymmetrical documents the performance is even worse. For example, when using Gale&Church F_1 sinks to 13.8 on documents which are not aligned at paragraph level and contain small deletions.

[16] We do not include (Deng et al., 2006) in our experiments because our implementation of this aligner is 550 times slower than our proposed method and the inability to find 1-to-0/0-to-1 correspondences makes it inappropriate for asymmetrical documents.

S	1-1	1-N/N-1	0-1/1-0	Oth.	Tot.
1	88.2%	10.9 %	0.005%	0.85%	3,877
2	91.9%	7.5%	0.007%	0.53%	2,646
3	91.6%	2.7%	4.3%	1.4%	23,715
4	44.8%	6.2%	49%	0.01%	2,606

Table 1: *Test Set for Evaluation with $2 \leq N \leq 4$*

of our aligner on the overall performance of an MT system.

Evaluation. We evaluate the alignment accuracy of our approach using four test sets annotated at sentence-level. The two first are composed of hand aligned documents from the Europarl corpus for the language-pairs German-to-English and French-to-English. The third is composed of an asymmetric document from the German-to-English part of the Europarl corpus. Our fourth test set is a version of the BAF corpus (Simard, 1998), where we corrected the tokenization. BAF is an interesting heterogeneous French-to-English test set composed of 11 texts belonging to four different genres. The types of correspondences composing our test sets are given in table 1. The metrics used are precision, recall and F_1[17]. Only alignments that correspond exactly to reference alignments count as correct. The computational costs required for each approach are measured in seconds. The time required to train IBM Model-1 is not included in our calculations[18].

Summary of Results. Regarding alignment accuracy, the results in table 2 show that (CA) obtains, on average, an F_1 that is 4.30 better than for (Mo) on symmetrical documents. The results in table 3 show that, on asymmetrical texts, (CA) achieves an F_1 which is 8.97 better than (Mo). The accuracy obtained using (CA), (Std) and (Std P.) is approximately the same. We have further compared the accuracy of (CA) with (Std) for finding 1-to-many/many-to-1 alignments. The obtained results show that (CA) achieves an F_1 that is 5.0 better than (Std).

Regarding computational costs, the time required by (CA) is on average 4 times larger than for (Mo) when aligning symmetrical documents. On asymmetrical documents, (Mo) is, however, only 1.5 times faster than (CA). Compared to (Std), (CA) is approximately 6 times faster on symmetrical and 80 times faster on asymmetrical documents. The time of (Std P.) is 3 times higher than for (CA) on symmetrical documents and 22 times higher on asymmetrical documents. This shows that, first, our pruning technique is more efficient than Moore's and, second, that the main increase in speed is due to the two step clustering approach.

Discussion. On the two first test sets, (Mo) achieves high precision while the obtained recall is limited by the number of correspondences that are not 1-to-1 (see table 1). Regarding (Std), (Std P.) and (CA), all aligners achieve high precision as well as high recall, leading to an F_1 which is over 98% for both documents. The computational costs of (CA) for the alignment of symmetrical documents are, on average, 4 times higher than (Mo), 6 times lower than (Std) and 3.5 times lower than (Std P.). On our third test set (Mo) achieves, with an F_1 of 88.70, relatively poor recall while the other aligners reach precision and recall values that are over 98%. Regarding the computational costs, (CA) is only 1.5 times slower than (Mo) on asymmetrical documents while it is 80 times faster than (Std) and about 22 times faster than (Std P.). On our fourth test set all evaluated aligners perform approximately the same than on Europarl. While (Mo) obtains, with 94.46, an F_1 which is the same as for Europarl, (CA) performs, with an F_1 of 97.67, about 1% worse than on Europarl. A slightly larger decrease of 1.6% is observed for (Std) which obtains 96.81 F_1. Note, however, that (CA), (Std) and (Std P.) still perform about 3% better than (Mo). Regarding computational costs, (CA) is 4 times slower than (Mo) and 40 times faster than (Std). The high difference in speed between our approach and (Std) is due to the fact that the BAF corpus contains texts of variable symmetry while (Std) shows a great speed decrease when aligning asymmetrical documents. Finally, we have compared the accuracy of (Std) and (CA) for the finding of 1-to-many/many-to-1 alignments containing at least 3 sentences on the "many"

[17] We measure precision, recall and F_1 on the 1-to-N/N-to-1 alignments, $N >= 1$, which means that we view insertions and deletions as "negative" decisions, like Moore.

[18] The reason for this decision is that our optimized framework trains the Model-1 translation tables far faster than Moore's bilingual sentence aligner.

Appr.	Lang.	Prec.	Rec.	F1	Speed

Std	F-E	98.45	98.83	98.64	35,041s
Std P.	D-E	98.37	98.49	98.43	13,387s
Std P.	F-E	98.41	98.78	98.60	21,848s
CA	D-E	98.25	98.70	98.47	3,461s
CA	F-E	98.00	98.60	98.30	6,978s

Table 2: *Performance on Europarl*

Appr.	Prec.	Rec.	F1	Speed
Mo	97.90	81.08	88.70	552s
Std	97.66	97.74	97.70	71,475s
Std P.	97.74	97.81	97.77	17,502s
CA	97.38	97.97	97.67	800s

Table 3: *Performance on asym. documents*

Appr.	Prec.	Rec.	F1	Speed
Mo	96.58	92.43	94.46	563s
Std	96.82	96.80	96.81	84,988s
CA	97.05	97.63	97.34	2,137s

Table 4: *Performance on BAF*

side. This experiment has shown that (Std) finds a larger amount of those alignments while making numerous wrong conjectures. On the other hand, (CA) finds less 1-to-many/many-to-1 correspondences but makes only few incorrect hypotheses. Hence, F_1 is about 5% better for (CA).

MT evaluation We also measured the impact of 1-to-N/N-to-1 alignments (which are not extracted by Moore) on MT. We used standard settings of the Moses toolkit, and the Europarl devtest2006 set as our test set. We ran MERT separately for each system. System (s1) was trained just on the 1-to-1 alignments extracted from the Europarl v3 corpus by our system while system (s2) was trained with all correspondences found. (s1) obtains a BLEU score of 0.2670 while (s2) obtains a BLEU score of 0.2703. Application of the pairwise bootstrap test (Koehn, 2004) shows that (s2) is significantly better than (s1).

5 Conclusion

We have addressed the problem of unsupervised and language-pair independent alignment of symmetrical and asymmetrical parallel corpora. We have developed a novel approach which is fast and allows us to achieve high accuracy in terms of F_1 for the alignment of bilingual corpora. Our method achieved high accuracy on symmetrical and asymmetrical parallel corpora, and we have shown that the 1-to-N/N-to-1 alignments extracted by our approach are useful. The source code of the aligner and the test sets are available at http://sourceforge.net/projects/gargantua .

Automatic Acquisition of Lexical Formality

Julian Brooke, Tong Wang, and Graeme Hirst

University of Toronto
{jbrooke,tong,gh}@cs.toronto.edu

Abstract

There has been relatively little work focused on determining the formality level of individual lexical items. This study applies information from large mixed-genre corpora, demonstrating that significant improvement is possible over simple word-length metrics, particularly when multiple sources of information, i.e. word length, word counts, and word association, are integrated. Our best hybrid system reaches 86% accuracy on an English near-synonym formality identification task, and near perfect accuracy when comparing words with extreme formality differences. We also test our word association method in Chinese, a language where word length is not an appropriate metric for formality.

1 Introduction

The derivation of lexical resources for use in computational applications has been focused primarily on the denotational relationships among words, e.g. the synonym and hyponym relationships encapsulated in WordNet (Fellbaum, 1998). Largely missing from popular lexical resources such as WordNet and the General Inquirer (Stone et al., 1966) is stylistic information; there are, for instance, no resources which provide comprehensive information about the formality level of words, which relates to the appropriateness of a word in a given context. Consider, for example, the problem of choice among near-synonyms: there are only minor denotational differences among synonyms such as *get*, *acquire*, *obtain*, and *snag*, but it is difficult to construct a situation where any choice would be equally suitable. The key difference between these words is their formality, with *acquire* the most formal and *snag* the most informal.

In this work, we conceive of formality as a continuous property. This approach is inspired by resources such as *Choose The Right Word* (Hayakawa, 1994), in which differences between synonyms are generally described in relative rather than absolute terms, as well as linguistic literature in which the quantification of stylistic differences among genres is framed in terms of dimensions rather than discrete properties (Biber, 1995). We begin by defining the *formality score* for a word as a real number value in the range 1 to -1, with 1 representing an extremely formal word, and -1 an extremely informal word. A formality lexicon, then, gives a FS score to every word within its coverage.

The core of our approach to the problem of classifying lexical formality is the automated creation of formality lexicons from large corpora. In this paper, we focus on the somewhat low-level task of identifying the relative formality of word pairs; we believe, however, that a better understanding of lexical formality is relevant to a number of problems in computational linguistics, including sub-fields such as text generation, error correction of (ESL) writing, machine translation, text classification, text simplification, word-sense disambiguation, and sentiment analysis. One conclusion of our research is that formality variation is omnipresent in natural corpora, but it does not follow that the identification of these differences on the lexical level is a trivial one; nevertheless,

Coling 2008: Poster Volume, pages 90–98,
Beijing, August 2010

we are able to make significant progress using the methods presented here, in particular the application of latent semantic analysis to blog corpora.

2 Related Work

As far as we are aware, there are only a few lines of research explicitly focused on the question of linguistic formality. In linguistics proper, the study of register and genre usually involves a number of dimensions or clines, sometimes explicitly identified as formality (Leckie-Tarry, 1995; Carter, 1998), or decomposed into notions such as informational versus interpersonal content (Biber, 1995). Heyligen and Dewaele (1998) provide a part-of-speech based quantification of textual contextuality (which they argue is fundamental to the notion of formality); their metric has been used, for instance, in a computational investigation of the formality of online encyclopedias (Emigh and Herring, 2005). In this kind of quantification, however, there is little, if any, focus on individual elements of the lexicon. In computational linguistics, formality has received attention in the context of text generation (Hovy, 1990); of particular note relevant to our research is the work of Inkpen and Hirst (2006), who derive boolean formality tags from *Choose the Right Word* (Hayakawa, 1994). Like us, their focus was improved word choice, though the approach was much broader, also including dimensions such as polarity. An intriguing example of formality relevant to text classification is the use of informal language (slang) to help distinguish true news from satire (Burfoot and Baldwin, 2009).

Our approach to this task is inspired and informed by automatic lexical acquisition research within the field of sentiment analysis (Turney and Littman, 2003; Esuli and Sebastiani, 2006; Taboada and Voll, 2006; Rao and Ravichandra, 2009). Turney and Littman (2003) apply latent semantic analysis (LSA) (Landauer and Dumais, 1997) and pointwise mutual information (PMI) to derive semantic orientation ratings for words using large corpora; like us, they found that LSA was a powerful technique for deriving this lexical information. The lexical database SentiWordNet (Esuli and Sebastiani, 2006) provides 0–1 rankings for positive, negative, and neutral polarity, derived automatically using relationships between words in WordNet (Fellbaum, 1998). Unfortunately, WordNet synsets tend to cut across the formal/informal distinction, and so the resource is not obviously useful for our task.

The work presented here builds directly on a pilot study (Brooke et al., 2010), the focus of which was the construction of formality score (FS) lexicons. In that work, we employed less sophisticated forms of some of the methods used here in a relatively small dataset (the Brown Corpus), providing a proof of concept, but with poor coverage, and with no attempt to combine the methods to maximize performance. However, the small dataset allowed us to do a thorough test of certain options associated with our task. In particular we found that using a similarity metric based on LSA gave good performance across our test sets, especially when the term-document matrix was binary (unweighted), the k-value used for LSA was small, and the method used to derive a formality score was cosine similarity to our seed terms. A metric using total word counts in corpora with divergent formality also showed promise, with both methods performing above our word-length baseline for words within their coverage. PMI, by comparison, proved less effective, and we do not pursue it further here.

3 Data and Resources

3.1 Word Lists

All the word lists discussed here are publicly available.[1] We begin with two, one formal and one informal, that we use both as seeds for our lexicon construction methods and as test sets for evaluation (our gold standard). We assume that all slang terms are by their very nature informal and so our 138 informal seeds were taken primarily from an online slang dictionary[2] (e.g. *wuss*, *grubby*) and also include some contractions and interjections (e.g. *cuz*, *yikes*). The 105 formal seeds were selected from a list of discourse markers (e.g. *moreover*, *hence*) and adverbs from a sentiment lexicon (e.g. *preposterously*, *inscrutably*); these sources were chosen to avoid words with

[1] http://www.cs.toronto.edu/~jbrooke/FormalityLists.zip

[2] http://onlineslangdictionary.com/

overt topic, and to ensure that there was some balance of sentiment across formal and informal seed sets. Part of speech, however, is not balanced across our seed sets.

Another test set we use to evaluate our methods is a collection of 399 pairs of near-synonyms from *Choose the Right Word* (CTRW), a manual for assisting writers with synonym word choice; each pair was either explicitly or implicitly compared for formality in the book. Implicit comparison included statements such as *this is the most formal of these words*; in those cases, and more generally, we avoided words appearing in more than one comparison (there are no duplicate words in our CTRW set), as well as multiword expressions and words whose formality is strongly ambiguous (i.e. word-sense dependent). An example of this last phenomenon is the word *cool*, which is used colloquially in the sense of *good* but more formally as in the sense of *cold*. Partly as a result of this polysemy, which is clearly more common among informal words, our pairs are biased toward the formal end of the spectrum; although there are some informal comparisons, e.g. *belly-ache/whine*, *wisecrack/joke*, more typical pairs include *determine/ascertain* and *hefty/ponderous*. Despite this imbalance, one obvious advantage of using near-synonyms in our evaluation is that factors other than linguistic formality (e.g. topic, opinion) are less likely to influence performance. In general, the CTRW allows for a more objective, fine-grained evaluation of our methods, and is oriented towards our primary interest, near-synonym word choice.

To test the performance of our unsupervised method beyond English, one of the authors (a native speaker of Mandarin Chinese) created two sets of Chinese two-character words, one formal, one informal, based on but not limited to the words in the English sets. The Chinese seeds include 49 formal seeds and 43 informal seeds.

3.2 Corpora

Our corpora fall generally into three categories: formal (written) copora, informal (spoken) corpora, and mixed corpora. The Brown Corpus (Francis and Kučera, 1982), our development corpus, is used here both as a formal and mixed corpus. Although extremely small by modern corpus standards (only 1 million words), the Brown Corpus has the advantage of being compiled explicitly to represent a range of American English, though it is all of the published, written variety. The Switchboard (SW) Corpus is a collection of American telephone conversations (Godfrey et al., 1992), which contains roughly 2400 conversations with over 2.6 million word tokens; we use it as an informal counterpart to the Brown Corpus. Like the Brown Corpus, The British National Corpus (Burnard, 2000) is a manually-constructed mixed-genre corpus; it is, however, much larger (roughly 100 million words). It contains a written portion (90%), which we use as a formal corpus, and a spontaneous spoken portion (4.3%), which we use as an informal corpus. Our other mixed corpora are two blog collections available to us: the first, which we call our development blog corpus (DevBlog) contains a total of over 900,000 English blogs, with 216 million tokens.[3] The second is the 'first tier' English blogs included in the publicly available ICSWM 2009 Spinn3r Dataset (Burton et al., 2009), a total of about 1.3 billion word tokens in 7.5 million documents. For our investigations in Chinese, we use the Chinese portion of the ICSWM blogs, approximately 25.4 million character tokens in 86,000 documents.

4 Methods

4.1 Simple Formality Measures

The simplest kind of formality measure is based on word length, which is often used directly as an indicator of formality for applications such as genre classification (Karlgren and Cutting, 1994). Here, we use logarithmic scaling to derive a FS score based on word length. Given a maximum word length L[4] and a word w of length l, the formality score function, $FS(w)$, is given by:

$$FS(w) = -1 + 2\frac{\log l}{\log L}$$

[3] These blogs were gathered by the University of Toronto Blogscope project (www.blogscope.net) over a week in May 2008.

[4] We use an upper bound of 28 characters, which is the length of *antidisestablishmentarianism*, the prototypical longest word in English; this value of L provides an appropriate formality/informality threshold, between 5- and 6-letter words

For hyphenated terms, the length of each component is averaged. Though this metric works relatively well for English, we note that it is problematic in a language with significant word agglutination (e.g. German) or without an alphabet (e.g. Chinese, see below).

Another straightforward method is the assumption that Latinate prefixes and suffixes are indicators of formality in English (Kessler et al., 1997), i.e. informal words will not have Latinate affixes such as *-ation* and *intra-*. Here, we simply assign words that appear to have such a prefix or suffix an FS of 1, and all other words an FS of -1.

Our frequency methods derive FS from word counts in corpora. Our first, naive approach assumes a single corpus, where either formal words are common and informal words are rare, or vice versa. To smooth out the Zipfian distribution, we use the frequency rank of words as exponentials; for a corpus with R frequency ranks, the FS for a word of rank r under the *formal is rare* assumption is given by:

$$FS(w) = -1 + 2\frac{e^{(r-1)}}{e^{(R-1)}}$$

Under the *informal is rare* assumption:

$$FS(w) = 1 - 2\frac{e^{(r-1)}}{e^{(R-1)}}$$

We have previously shown that these methods are not particularly effective on their own (Brooke et al., 2010), but we note that they provide useful information for a hybrid system.

A more sophisticated method is to use two corpora that are known to vary with respect to formality and use the relative appearance of words in each corpus as the metric. If word appears n times in a (relatively) formal corpus and m times in an informal corpus (and one of m, n is not zero), we derive:

$$FS(w) = -1 + 2\frac{n}{m \times N + n}$$

Here, N is the ratio of the size (in tokens) of the informal corpus (IC) to the formal corpus (FC). We need the constant N so that an imbalance in the size of the corpora does not result in an equivalently skewed distribution of FS.

4.2 Latent Semantic Analysis

Next, we turn to LSA, a technique for extracting information from a large corpus of texts by (drastically) reducing the dimensionality of a term–document matrix, i.e. a matrix where the row vectors correspond to the appearance or (weighted) frequency of words in a set of texts. In essence, LSA simplifies the variation of words across a collection of texts, exploiting document–document correlation to produce information about the k most important dimensions of variation ($k <$ total number of documents), which are generally thought to represent semantic concepts, i.e. topic. The mathematical basis for this transformation is singular value decomposition[5]; for the details of the matrix transformations, we refer the reader to the discussion of Turney and Littman (2003). The factor k, the number of columns in the compacted matrix, is an important variable in any application of LSA, one is generally determined by trial and error (Turney and Littman, 2003).

LSA is computationally intensive; in order to apply it to extremely large blog corpora, we need to filter the documents and terms before building our term–document matrix. We adopt the following strategy: to limit the number of documents in our term–document matrix, we first remove documents less than 100 tokens in length, with the rationale that these documents provide less co-occurrence information. Second, we remove documents that either do not contain any target words (i.e. one of our seeds or CTRW test words), or contain only target words which are among the most common 20 in the corpus; these documents are less likely to provide us with useful information, and the very common target terms will be well represented regardless. We further shrink the set of terms by removing all hapax legomena; a single appearance in a corpus is not enough to provide reliable co-occurrence information, and roughly half the words in our blog corpora appear only once. Finally, we remove symbols and all words which are not entirely lower

[5] We use the implementation included in Matlab; we take the rows of the decomposed U matrix weighted by the singular values in Σ for our word vectors. Using no weights or Σ^{-1} generally resulted in worse performance, particularly with the CTRW sets.

case; we are not interested, for instance, in numbers, acronyms, and proper nouns. We can estimate the effect this filtering has on performance by testing it both ways in a development corpus.

Once a k-dimensional vector for each relevant word is derived using LSA, a standard method is to use the cosine of the angle between a word vector and the vectors of seed words to identify how similar the distribution of the word is to the distribution of the seeds. To begin, each formal seed is assigned a FS value of 1, each informal seed a FS value of -1, and then a raw seed similarity score (FS') is calculated for each word w:

$$FS'(w) = \sum_{s \in S, s \neq w} W_s \times FS(s) \times \cos(\theta(w,s))$$

S is the set of all seeds. Note that seed terms are excluded from their own FS calculation, this is equivalent to *leave-one-out* cross-validation. W_s is a weight that depends on whether s is a formal or informal seed, W_i (for informal seeds) is calculated as:

$$W_i = \frac{\sum_{f \in F} FS(f)}{|\sum_{i \in I} FS(i)| + \sum_{f \in F} FS(f)}$$

and W_f (for formal seeds) is:

$$W_f = \frac{|\sum_{i \in I} FS(i)|}{|\sum_{i \in I} FS(i)| + \sum_{f \in F} FS(f)}$$

Here, I is the set of all informal seeds, and F is the set of all formal seeds. These weights have the effect of countering any imbalance in the seed set, as formal and informal seeds ultimately have the same (potential) influence on each word, regardless of their count. This weighting is necessary for the iterative extension of this method discussed in the next section.

We calculate the final FS score as follows:

$$FS(w) = \frac{FS'(w) - FS'(r)}{N_w}$$

The word r is a reference term, a common function word that has no formality.[6] This has the effect of countering any (moderate) bias that might exist in the corpus; in the Brown Corpus, for instance, function words have positive formality before this step, simply because formal words occurred more often in the corpus. N_w is a normalization factor, either

$$N_w = \max_{w_i \in I'} |FS'(w_i) - FS'(r)|$$

for all $w_i \in I'$ or

$$N_w = \max_{w_f \in F'} |FS'(w_f) - FS'(r)|$$

for all $w_f \in F'$. I' contains all words w such that $FS'(w) - FS'(r) < 0$, and F' contains all words w such that $FS'(w) - FS'(r) > 0$. This ensures that the resulting lexicon has terms exactly in the range 1 to -1, with the reference word r at the midpoint.

We also tested the LSA method in Chinese. The only major relevant difference between Chinese and English is word segmentation: Chinese does not have spaces between words. To sidestep this problem, we simply included all character bigrams found in our corpus. The drawback of this approach in the inclusion of a huge number of nonsense 'words' (1.3 million terms in just 86,000 documents), however we are at least certain to identify all instances of our seeds.

4.3 Hybrid Methods

There are a number of ways to leverage the information we derive from our basic methods. One intriguing option is to use the basic FS measures as the starting point for an iterative process using the LSA cosine similarity. Under this paradigm, all words in the starting FS lexicon are potential seed words; we choose a cutoff value for inclusion in the seed word set (e.g. words which have at least .5 or $-.5$ FS), and then carry out the cosine calculations, as above, to derive new FS values (a new FS lexicon). We can repeat this process as many times as required, with the idea that the connections between various words (as reflected in their LSA-derived vectors) will cause the system to converge towards the true FS values.

A simple hybrid method that combines the two word count models uses the ratio of word counts in two corpora to define the center of the FS spectrum, but single corpus methods to define the extremes. Formally, if m and n (word counts for the

[6] The particular choice of this word is relatively unimportant; common function words all have essentially the same LSA vectors because they appear at least once in nearly every document of any size. For English, we chose r = *and*, and for Chinese, r = *yinwei* (*because*); there does not seem to be an obvious two-character, formality-neutral equivalent to *and* in Chinese.

informal corpus *IC* and formal corpus *FC*, respectively) are both non-zero, then FS is given by:

$$FS(w) = -0.5 + \frac{n}{m \times N + n}$$

However, if n is zero, FS is given by:

$$FS(w) = -1 + 0.5\frac{e^{\sqrt{r_{IC}-1}}}{e^{\sqrt{R_{IC}-1}}}$$

where r_{IC} is the frequency rank of the word in IC, and R_{IC} is the total number of ranks in IC. If m is zero, FS is given by:

$$FS(w) = 1 - 0.5\frac{e^{\sqrt{r_{FC}-1}}}{e^{\sqrt{R_{FC}-1}}}$$

where i is the rank of the word in IC, and R_{IC} is the total number of frequency ranks in IC). This function is undefined in the case where m and n are both zero. Intuitively, this is a kind of backoff, relying on the idea that words of extreme formality are rare even in a corpus of corresponding formality, whereas words in the *core vocabulary* (Carter, 1998), which are only moderately formal, will appear in all kinds of corpora, and thus are amenable to the ratio method.

Finally, we explore a number of ways to combine lexicons directly. The motivation for this is that the lexicons have different strengths and weaknesses, representing partially independent information. An obvious method is an averaging or other linear combination of the scores, but we also investigate vote-based methods (requiring agreement among n dictionaries). Beyond these simple options, we test support vector machines and naive Bayes classification using the WEKA software suite (Witten and Frank, 2005), applying 10-fold cross-validation using default WEKA settings for each classifier. The features here are task dependent (see Section 5); for the pairwise task, we use the difference between the FS value of the words in each lexicon, rather than their individual scores. Finally, we can use the weights from the SVM model of the CTRW (pairwise) task to interpolate an optimal formality lexicon.

5 Evaluation

We evaluate our methods using the gold standard judgments from the seed sets and CTRW word pairs. To differentiate the two, we continue to use the term *seed* for the former; in this context, however, these 'seed sets' are being viewed as a test set (recall that our LSA method is equivalent to *leave-one-out* cross-validation).

We derive the following measures: first, the coverage (Cov.) is the percentage of words in the set that are covered under the method. The class-based accuracy (C-Acc.) of our seed sets is the percentage of covered words which are correctly classified as formal (FS > 0) or informal (FS < 0). The pair-based accuracy (P-Acc.) is the result of exhaustively pairing words in the two seed sets and testing their relative formality; that is, for all $w_i \in I$ and $w_f \in F$, the percentage of w_i/w_f pairs where $FS(w_i) < FS(w_f)$. For the CTRW pairs there are only two metrics, the coverage and the pair-based accuracy; since the CTRW pairs represent relative formality of varying degrees, it is not possible to calculate a class-based accuracy.

The first section of Table 1 provides the results for the basic methods in various corpora. The word length (1) and morphology-based (2) methods provide good coverage, but poor accuracy, while the word count ratio methods (3–4) are fairly accurate, but suffer from low coverage. The LSA results in Table 1 are the best for each corpus across the k values we tested. When both coverage and accuracy are considered, there is a clear benefit associated with increasing the amount of data, though the difference between the Dev-Blog and ICWSM suggests diminishing returns. The performance of the filtered Dev-Blog is actually slightly better than the unfiltered versions (though there is a drop in coverage), suggesting that filtering is a good strategy.

In our previous work (Brooke et al., 2010), we noted that CTRW set performance in the Brown dropped for $k > 3$, while performance on the seed set was mostly steady as k increased. Figure 1 shows the pairwise performance of each test set for various corpora across various k. The results here are similar; all three corpora reach a CTRW maximum at a relatively low k values (though higher than Brown Corpus); however the seed set performance in each corpus continues to improve (though marginally) as k increases, while CTRW performance drops. An explanation for this is that

Table 1: Seed coverage, class-based accuracy, pairwise accuracy, CTRW coverage, and pairwise accuracy for various FS lexicons and hybrid methods (%).

Method	Seed set			CTRW set	
	Cov.	**C-Acc.**	**P-Acc.**	**Cov.**	**P-Acc.**

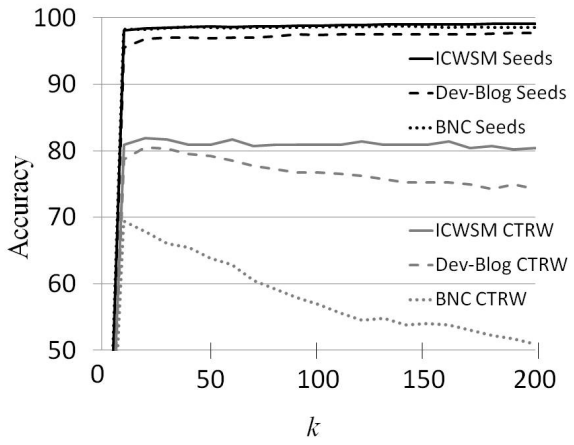

Figure 1: Seed and CTRW pairwise accuracy, LSA method for large corpora k, $10 \leq k \leq 200$.

the seed terms represent extreme examples of formality; thus there are numerous semantic dimensions to distinguish them. However, the CTRW set includes near-synonyms, many with only relatively subtle differences in formality; for these pairs, it is important to focus on the core dimensions relevant to formality, which are among the first discovered in a factor analysis of mixed-register texts (Biber, 1995).

With regards to hybrid methods, we first briefly summarize our testing with the iterative model, which included extensive experiments using basic lexicons and the LSA vectors derived from the Brown Corpus, and some targeted testing with the blog corpora (iteration on these corpora is extraordinarily time-consuming). In general, we found only that there were only small, inconsistent benefits to be gained from the iterative ap-

proach. More generally, the intuition behind the iterative method, i.e. that performance would increase with an drastic increase in the number of seeds, was found to be flawed: in other testing, we found that we could randomly remove most of the seeds without negatively affecting performance. Even at relatively high k values, it seems that a few seeds are enough to calibrate the model.

The ratio (with backoff) hybrid built from the BNC (10) provides CTRW performance that is comparable the best LSA models, though performance in the seed sets is somewhat poor; supplementing with word counts from the Brown Corpus and Switchboard Corpus provides a small improvement (11). The weighed hybrid dictionaries in (12,13) demonstrate that it is possible to effectively combine lexicons built using two different methods on the same corpus (12) or the same method on different corpora (13); the former, in particular, provides an impressive boost to CTRW accuracy, indicating that word count and word association methods are partially independent.

The remainder of Table 1 shows the best results using voting, averaging, and weighting. The voting results (14–16) indicate that it is possible to sacrifice some coverage for very high accuracy in both sets, including a near-perfect score in the seed sets and significant gains in CTRW performance. In general, the best accuracy without a significant loss of coverage came from 2 of 3 voting (15–16), using dictionaries that represented our three basic sources of information (word length, word count, and word association). The machine learning hybrids (17–18) also demonstrate a marked improvement over any single lexicon, though it is important to note that each accuracy score here reflects a different task-specific model. Hybrid FS lexicons built with the weights learned by the SVM models (19–20) provide superior performance on the task corresponding to the model used, though the simple averaging of the best dictionaries (21) also provides good performance across all evaluation metrics.

Finally, the LSA results for Chinese are modest but promising, given the relatively small scale of our experiments: we saw a pairwise accuracy of 82.2%, with 79.3% class-based accuracy ($k = 10$). We believe that the main reason for the generally lower performance in Chinese (as compared to English) is the modest size of the corpus, though our simplistic character bigram term extraction technique may also play a role. As mentioned, smaller seed sets do not seem to be an issue. Interestingly, the class-based accuracy is 10.8% lower if no reference word is used to calibrate the divide between formal and informal, suggesting a rather biased corpus (towards informality); in English, by comparison, the reference-word normalization had a slightly negative effect on the LSA results, though the effect mostly disappeared after hybridization. The obvious next step is to integrate a Chinese word segmenter, and use a larger corpus. We could also try word count methods, though finding appropriate (balanced) resouces similar to the BNC might be a challenge; (mixed) blog corpora, on the other hand, are easily collected.

6 Conclusion

In this work, we have experimented with a number of different methods and source corpora for determining the formality level of lexical items, with the implicit goal of distinguishing the formality of near-synonym pairs. Our methods show marked improvement over simple word-length metrics; when multiple sources of information, i.e. word length, word counts, and word association, are integrated, we are able to reach over 85% performance on the near-synonym task, and close to 100% accuracy when comparing words with extreme formality differences; our voting methods show that even higher precision is possible. We have also demonstrated that our LSA word association method can be applied to a language where word length is not an appropriate metric of formality, though the results here are preliminary. Other potential future work includes addressing a wider range of phenomena, for instance assigning formality scores to morphological elements, syntactic cues, and multi-word expressions, and demonstrating that a formality lexicon can be usefully applied to other NLP tasks.

Toward Qualitative Evaluation of Textual Entailment Systems

Abstract

This paper presents a methodology for a quantitative and qualitative evaluation of Textual Entailment systems. We take advantage of the decomposition of Text Hypothesis pairs into *monothematic pairs*, i.e. pairs where only one linguistic phenomenon at a time is responsible for entailment judgment, and propose to run TE systems over such datasets. We show that several behaviours of a system can be explained in terms of the correlation between the accuracy on monothematic pairs and the accuracy on the corresponding original pairs.

1 Introduction

Since 2005, Recognizing Textual Entailment (RTE) has been proposed as a task whose aim is to capture major semantic inference needs across applications in Computational Linguistics (Dagan et al., 2009). Systems are asked to automatically judge whether the meaning of a portion of text, referred as Text (*T*), entails the meaning of another text, referred as Hypothesis (*H*). This evaluation provides useful cues for researchers and developers aiming at the integration of TE components in larger applications (see, for instance, the use of a TE engine in the QALL-ME project system[1], the use in relation extraction (Romano et al., 2006), and in reading comprehension systems (Nielsen et al., 2009)).

Although the RTE evaluations showed progresses in TE technologies, we think that there is still large room for improving qualitative analysis of both the RTE datasets and the system results. In particular, we intend to focus this paper on the following aspects:

1. There is relatively poor analysis of the linguistic phenomena that are relevant for the RTE datasets, and very little is known about the distribution of such phenomena, and about the ability of participating systems to correctly detect and judge them in *T,H* pairs. Experiments like the ablation tests attempted in the last RTE-5 campaign on lexical and lexical-syntactic resources go in this direction, although the degree of comprehension is still far from being optimal.

2. We are interested in the correlations among the capability of a system to address single linguistic phenomena in a pair and the ability to correctly judge the pair itself. Despite the strong intuition about such correlation (i.e. the more the phenomena for which a system is trained, the better the final judgment), no empirical evidences support it.

3. Although the ability to detect and manage single phenomena seems to be a crucial feature of high performing systems, very little is known about how systems manage to combine such results in a global score for a pair. The mechanism underlying such composition may shed light on meaning composition related to TE tasks.

4. Finally, we are interested in the relation between the above mentioned items over the different kinds of pairs represented in RTE

[1] http://qallme.fbk.eu/

Coling 2008: Poster Volume, pages 99–107,
Beijing, August 2010

datasets, specifically *entailment*, *contradiction* and *unknown* pairs. In this case the intuition is that some phenomena are more relevant for a certain judgment rather than for another.

To address the issues above, we propose an evaluation methodology aiming at providing a number of quantitative and qualitative indicators about a TE system. The method is based on the decomposition of *T,H* pairs into *monothematic pairs*, each representing one single linguistic phenomenon relevant for entailment judgment. Evaluation is carried out both on the original *T,H* pair and on the monothematic pairs originated from it. We define a correlation index between the accuracy of the system on the original *T,H* pairs and the accuracy on the corresponding monothematic pairs. We investigate the use of such correlations on different subsets of the evaluation dataset (i.e. positive vs negative pairs) and we try to induce regular patterns of evaluation.

The method we propose has been tested on a sample of 60 pairs, each decomposed in the corresponding monothematic pairs, and using two systems that obtained similar performances in RTE-5. We show that the main features and differences of these systems come to light when evaluated using qualitative criteria. Futhermore, we compare such systems with two different baseline systems, the first one performing Word Overlap, while the second one is an ideal system that knows *a priori* the probability of a linguistic phenomenon to be associated with a certain entailment judgement.

The paper is structured as follows. Section 2 explains the procedure for the creation of monothematic pairs starting from RTE pairs. Section 3 presents the evaluation methodology we propose, while Section 4 describes our pilot study. Section 5 concludes the paper and proposes future developments.

2 Decomposing RTE pairs

Our proposal on qualitative evaluation takes advantage of previous work on specialized entailment engines and monothematic datasets. A *monothematic pair* is defined (Magnini and Cabrio, 2009) as a *T,H* pair in which a certain phenomenon relevant to the entailment relation is highlighted and isolated. The main idea is to create the monothematic pairs basing on the phenomena that are actually present in the original RTE pairs, so that the actual distribution of the linguistic phenomena involved in the entailment relation emerges.

For the decomposition procedure, we refer to the methodology described in (Bentivogli et al., 2010), consisting of a number of steps carried out manually. The starting point is a *[T,H]* pair taken from one of the RTE data sets, that should be decomposed in a number of monothematic pairs $[T, H_i]$, where T is the original Text and H_i are the Hypotheses created for each linguistic phenomenon relevant for judging the entailment relation in *[T,H]*. In details, the procedure for the creation of monothematic pairs is composed of the following steps:

1. Individuate the phenomena contributing to the entailment decision in *[T,H]*.

2. For each linguistic phenomenon *i*:

   (a) Detect a general entailment rule r_i for *i*, and instantiate it using the part of T expressing *i* as the left hand side (LHS) of the rule, and information from H on *i* as the right side (RHS).

   (b) substitute the portion of T that matches the LHS of r_i with the RHS of r_i.

   (c) consider the result of the previous step as H_i, and compose the monothematic pair $[T, H_i]$. Mark the pair with phenomenon *i*.

3. Assign an entailment judgment to each monothematic pair.

Relevant linguistic phenomena are grouped using both fine-grained categories and broader categories, defined referring to widely accepted classifications in the literature (e.g. (Garoufi, 2007)) and to the inference types typically addressed in RTE systems: *lexical*, *syntactic*, *lexical-syntactic*, *discourse* and *reasoning*. Each macro category includes fine-grained phenomena (Table 2 lists the phenomena detected in RTE-5 datasets).

Text snippet (pair 125)			Phenomena	Judg.

	H2	**The new president of Mexico**, Felipe Calderon, seems to be doing all the right things in cracking down on Mexico's drug traffickers. . [...]	syntactic:argument-realization	E
	H3	**Felipe Calderon is** Mexico's **new president**.	syntactic:apposition	E

Table 1: Application of the decomposition methodology to an original RTE pair

Table 1 shows an example of the decomposition of a RTE pair (marked as *contradiction*) into monothematic pairs. At step 1 of the methodology both the phenomena that preserve the entailment and those that break the entailment rules causing a contradiction in the pair are detected, i.e. argument realization, apposition and semantic opposition (column *phenomena* in the table). While the monothematic pairs created basing on the first two phenomena preserve the entailment, the semantic opposition generates a contradiction (column *judgment*). As an example, let's apply step by step the procedure to the phenomenon of semantic opposition. At step 2a of the methodology the general rule:

Pattern: x $\Leftarrow$ / $\Rightarrow$ y
Constraint: *semantic opposition(y,x)*

is instantiated (*new*$\Leftarrow$ / $\Rightarrow$*outgoing*), and at step 2b the substitution in T is carried out (*Mexico's outgoing president, Felipe Calderon [...]*). At step 2c a negative monothematic pair T, H_1 is composed (column *text snippet* in the table) and marked as *semantic opposition* (macro-category *lexical*), and the pair is judged as *contradiction*.

3 Evaluation methodology

Aim of the evaluation methodology we propose is to provide quantitative and qualitative indicators about the behaviours of actual TE systems.

3.1 General Method

The basic assumption of the evaluation methodology is that the more a system is able to correctly solve the linguistic phenomena underlying the entailment relation separately, the more the system should be able to correctly judge more complex pairs, in which different phenomena are present and interact in a complex way. Such assumption is motivated by the notion of meaning compositionality, according to which the meaning of a complex expression *e* in a language *L* is determined by the structure of *e* in *L* and the meaning of the constituents of *e* in *L* (Frege, 1892). In a parallel way, we assume that it is possible to understand the entailment relation of a *T,H* pair (i.e. to correctly judge the *entailment/contradiction* relation) only if all the phenomena contributing to such relation are solved.

According to such assumption, we expect that the higher the accuracy of a system on the monothematic pairs and the compositional strategy, the better its performances on the original RTE pairs. Furthermore, the precision a system gains on single phenomena should be maintained over the general dataset, thanks to suitable mechanisms of meaning combination.

Given a dataset composed of original RTE pairs $[T, H]$, a dataset composed of all the monothematic pairs derived from it $[T, H]_{mono}$, and a TE system *S*, the evaluation methodology we propose consists of the following steps:

1. Run *S* both on $[T, H]$ and on $[T, H]_{mono}$, to obtain the accuracies of *S* both on the RTE original and on monothematic pairs;

2. Extract data concerning the behaviour of *S* on each phenomenon or on categories of phenomena, and calculate separate accuracies. This way it is possible to evaluate how much a system is able to correctly deal with single or with categories of phenomena;

3. Calculate the correlation between the ability of the system to correctly judge the monothematic pairs of $[T, H]_{mono}$ with respect to the

ability to correctly judge the original ones in $[T, H]$. Such correlation is expressed through a *Correlation Index (CI)*, as defined in Section 3.2;

4. In order to check if the same *CI* is maintained over both entailment and contradiction pairs (i.e. to verify if the system has peculiar strategies to correctly assign both judgments, and if the high similarity of monothematic pairs does not bias its behaviour), we calculate a *Deviation Index (DI)* as the difference between the *CIs* on entailment and on contradiction pairs, as explained in more details in Section 3.3.

3.2 Correlation Index (CI)

As introduced before, we assume that the accuracy obtained on $[T, H]_{mono}$ should positively correlate with the accuracy obtained on $[T, H]$. We define a *Correlation Index* as the ratio between the accuracy of the system on the original RTE dataset and the accuracy obtained on the monothematic dataset, as follows:

$$CI = \frac{acc[T, H]}{acc[T, H]_{mono}} \quad (1)$$

We expect the correlation index of an optimal ideal system (or the human goldstandard) to be equal to 1, i.e. 100% accuracy on the monothematic dataset should correspond to 100% accuracy on the original RTE dataset. For this reason, we consider $CI = 1$ as the ideal correlation, and we calculate the difference between such ideal CI and the correlation obtained for a system *S*.

Given such expectations, CI_S can assume three different configurations with respect to the upperbound (i.e. the ideal correlation):

- $CI_S \cong 1$ (ideal correlation): When CI_S approaches to 1, the system shows high correlation with the ideal behaviour assumed by the compositionality principle. As a consequence, we can predict that improving single modules will correspondingly affect the global performance.

- $CI_S < 1$ (missing correlation): The system is not able to exploit the ability in solving single phenomena to correctly judge the original RTE pairs. This may be due to the fact that the system does not adopt suitable combination mechanisms and loses the potentiality shown by its performances on monothematic pairs.

- $CI_S > 1$ (over correlation): The system does not exploit the ability to solve single linguistic components to solve the whole pairs, and has different mechanisms to evaluate the entailment. Probably, such a system is not intended to be modularized.

Beside this "global" correlation index calculated on the complete RTE data and on all the monothematic pairs created from it, the *CI* can also be calculated *i)* on categories of phenomena, to verify which phenomena a system is more able to solve both when isolated and when interacting with other phenomena, e.g. :

$$CI_{lex} = \frac{acc[T, H]_{lex}}{acc[T, H]_{mono-lex}} \quad (2)$$

including in $[T, H]_{lex}$ all the pairs in which at least one lexical phenomenon is present and contribute to the entailment/contradiction judgments, and in $[T, H]_{mono-lex}$ all the monothematic pairs in which a lexical phenomenon is isolated; or *ii)* on kind of judgment (*entailment*, *contradiction*, *unknown*), allowing deeper qualitative analysis of the performances of a system.

3.3 Deviation Index (DI)

We explained that a low *CI* (i.e. < 1) of a system reflects the inability to correctly exploit the potentially promising results obtained on monothematic pairs to correctly judge RTE pairs. Actually, it could also be the case that the system does not perform a correct combination because even the results got on the monothematic pairs were due to chance (e.g. a word overlap system performs well on monothematic pairs because of the high similarity between *T* and *H*, and not because it has linguistic strategies).

We detect such cases by decomposing the evaluation datasets, separating positive (i.e. *entailment*) from negative (i.e. *contradiction*, *unknown*) examples both in $[T, H]$ and in $[T, H]_{mono}$, and

independently run *S* on the new datasets. Then, we have more fine grained evaluation patterns through which we can analyze the system behaviour.

In the ideal case, we expect to have good correlation between the accuracy obtained on the monothematic pairs and the accuracy obtained on the original ones ($0 < CI_{pos} \leq 1$ and $0 < CI_{neg} \leq 1$). On the contrary, we expect that systems either without a clear composition strategy or without strong components on specific linguistic phenomena (e.g. a word overlap system), would show a significant difference of correlation on the different datasets. More specifically, situations of *inverse correlation* on the entailment and contradiction pairs (e.g. over correlation on contradiction pairs and missing correlation on entailment pairs) may reveal that the system itself is affected by the nature of the dataset (i.e. its behaviour is biased by the high similarity of $[T, H]_{mono}$), and weaknesses in the ability of solving phenomena that more frequently contribute to the assignment of a contradiction (or an entailment) judgment come to light.

We formalize such intuition defining a *Deviation Index (DI)* as the difference between the correlation indexes, respectively, on entailment and contradiction/unknown pairs, as follows:

$$|DI| = CI_{pos} - CI_{neg} \quad (3)$$

For instance, an high Deviation Index due to a missing correlation on positive entailment pairs and an over correlation for negative pairs, is interpreted as an evidence that the system has low accuracy on $[T, H]_{mono}$ - *T* and *H* are very similar and the system has no strategies to understand that the phenomenon that is present has to be judged as contradictory -, and a higher accuracy on $[T, H]$, probably due to chance. In the ideal case $DI_S \cong 0$, since we assumed the ideal *CIs* on both positive and negative examples to be as close as possible to 1 (see Section 3.2).

4 Experiments and discussion

This Section describes the experimental setup of our pilot study, carried out using two systems that took part in RTE-5 i.e EDITS and VENSES. We show the results obtained and the qualitative analysis performed basing on the proposed evaluation methodology. Their respective *CIs* and *DIs* are compared with two baselines: a word overlap system, and a system biased by the knowledge of the probability that a linguistic phenomenon contributes to the assignment of a certain entailment judgment.

4.1 Dataset

The evaluation method has been tested on a dataset composed of 60 pairs from RTE-5 test set ($[T, H]_{RTE5-sample}$, composed of 30 *entailment*, and 30 *contradiction* randomly extracted examples), and a dataset composed of all the monothematic pairs derived by the first one following the procedure described in Section 2. The second dataset $[T, H]_{RTE5-mono}$ is composed of 167 pairs (135 *entailment*, 32 *contradiction* examples, considering 35 different linguistic phenomena)[2]. On average, 2.78 monothematic pairs have been created from the original pairs. In this pilot study we decided to limit our analysis to entailment and contradiction pairs since, as observed in (Bentivogli et al., 2010), in most of the unknown pairs no linguistic phenomena relating T to H could be detected.

4.2 TE systems

EDITS The EDITS system (Edit Distance Textual Entailment Suite)[3] (Negri et al., 2009) assumes that the distance between *T* and *H* is a characteristic that separates the positive pairs, for which entailment holds, from the negative pairs, for which entailment does not hold (two way task). It is based on edit distance algorithms, and computes the *[T,H]* distance as the overall cost of the edit operations (i.e. *insertion*, *deletion* and *substitution*) required to transform *T* into *H*. For our experiments we applied the model that produced EDITS best run at RTE-5 (acc. on test set: 60.2%). The main features are: Tree Edit Distance algorithm on the parsed trees of *T* and *H*, Wikipedia lexical entailment rules, and PSO optimized operation costs (Mehdad et al., 2009).

[2] http://hlt.fbk.eu/en/Technology/TE-_Specialized_Data

[3] Available as open source at http://edits.fbk.eu/

VENSES The other system used in our experiments is VENSES[4] (Delmonte et al., 2009), that obtained performances similar to EDITS at RTE-5 (acc. on test set: 61.5%). It applies a linguistically-based approach for semantic inference, and is composed of two main components: *i)* a grammatically-driven subsystem validates the well-formedness of the predicate-argument structure and works on the output of a deep parser producing augmented head-dependency structures; and *ii)* a subsystem detects allowed logical and lexical inferences basing on different kind of structural transformations intended to produce a semantically valid meaning correspondence. Also in this case, we applied the best configuration of the system used in RTE-5.

Baseline system 1: Word Overlap algorithm The first baseline applies a Word Overlap (WO) algorithm on tokenized text. The threshold to separate positive from negative pairs has been learnt on the whole RTE-5 training dataset.

Baseline system 2: Linguistic biased system The second baseline is produced by a more sophisticated but biased system. It exploits the probability of linguistic phenomena to contribute more to the assignment of a certain judgment than to another. Such probabilities are learnt on the $[T, H]_{RTE5-mono}$ goldstandard: given the list of the phenomena with their frequency in monothematic positive and negative pairs (columns 1,2,3 of Table 2), we calculate the probability *P* of phenomenon *i* to appear in a positive (or in a negative) pair as follows:

$$P(i|[T,H]_{positive}) = \frac{\#(i|[T,H]_{RTE5-positive-mono})}{\#(i|[T,H]_{RTE5-mono})} \quad (4)$$

For instance, if the phenomenon *apposition* appears in 11 monothematic positive pairs and in 6 negative pairs, it has a probability of 64.7% to appear in positive examples and 35.3% to appear in negative ones. Such knowledge is then stored in the system, and is used in the classification phase, assigning the most probable judgment associated to a certain phenomenon.

[4]http://project.cgm.unive.it/venses_en.html

When applied to $[T, H]_{RTE5-sample}$, this system uses a simple combination strategy: if phenomena associated with different judgments are present in a pair, and one phenomenon is associated with a contradiction judgment with a probability $> 50\%$, the pair is marked as *contradiction*, otherwise it is marked as *entailment*.

4.3 Results

Following the methodology described in Section 3, at step 1 we run EDITS and VENSES on $[T, H]_{RTE5-sample}$, and on $[T, H]_{RTE5-mono}$ (Table 3 reports the accuracies obtained).

At step 2, we calculate the accuracy of EDITS and VENSES on each single linguistic phenomenon, and on categories of phenomena. Table 2 shows the distribution of the phenomena on the dataset, reflected in the number of positive and negative monothematic pairs created for each phenomenon. As can be seen, some phenomena appear more frequently than others (e.g. *coreference*, *general inference*). Furthermore, some linguistic phenomena allow only the creation of positive or negative examples, while others can contribute to the assignment of both judgments. Due to the small datasets we used, some phenomena appear rarely; the accuracy on them cannot be considered completely reliable.

Nevertheless, from these data the main features of the systems can be identified. For instance, EDITS obtains the highest accuracy on positive monothematic pairs, while it seems it has no peculiar strategies to deal with phenomena causing contradiction (e.g. *semantic opposition*, and *quantity mismatching*). On the contrary, VENSES shows an opposite behaviour, obtaining the best results on the negative cases.

At step 3 of the proposed evaluation methodology, we calculate the correlation index between the ability of the system to correctly judge the monothematic pairs of $[T, H]_{RTE5-mono}$ with respect to the ability to correctly judge the original ones in $[T, H]_{RTE5-sample}$.

Table 3 compares EDITS and VENSES *CI* with the two baseline systems described before. As can be noticed, even if EDITS *CI* outperforms the WO system, they show a similar behaviour (high accuracy on monothematic pairs, and much lower

on the RTE sample). According to our definition, their *CIs* ($0 < CI < 1$) show a good ability of the systems to deal with linguistic phenomena when isolated, but a scarce ability in combining them to assign the final judgment. EDITS *CI* is not far from the *CI* of the linguistic biased baseline system, even if we were expecting a higher *CI* for the latter system. The reason is that beside the linguistic phenomena that allow only the creation of negative monothematic pairs, all the phenomena that allow both judgments have a higher probability to contribute to the creation of positive monothematic pairs.

Comparing the *CI* of the four analyzed systems with the ideal correlation ($CI_S \cong 1$, see Section 3.2), VENSES is the closest one ($\Delta = 0.15$), even if it shows a light over correlation (probably due to the nature of the dataset). The second closest

one is the linguistic biased system ($\Delta = 0.21$), showing that the knowledge of the most probable judgment assigned to a certain phenomenon can be a useful information.

Table 4 reports an evaluation of the four systems on categories of linguistic phenomena.

To check if the same *CI* is maintained over both entailment and contradiction pairs, we calculate a *Deviation Index* as the difference between the *CIs* on entailment and on contradiction pairs (step 4 of our methodology). As described in Section 3, we created four datasets dividing both $[T, H]_{RTE5-sample}$ and $[T, H]_{RTE5-mono}$ into positive (i.e. *entailment*) and negative (i.e. *contradiction*) examples. We run EDITS and VENSES on the datasets and we calculate the *CI* on positive and on negative examples separately. If we obtained missing correlation between the accuracy on the monothematic pairs and the accuracy on RTE original ones, it would mean that the potentiality that the systems show on monothematic pairs is not exploited to correctly judge more complex pairs, therefore compositional mechanisms should be improved.

Table 5 shows that the *DIs* of the linguistic biased system and of VENSES are close to the ideal case ($DI_S \cong 0$), indicating a good capacity to correctly differentiate entailment from contradiction cases. EDITS results demonstrate that the

shallow approach implemented by the system has no strategies to correctly judge negative examples (similarly to the WO system), therefore should be mainly improved with this respect.

We also calculated the CI for every pair of the dataset, putting into relation each original pair with all the monothematic pairs derived from it. Figure 1 shows EDITS and VENSES's *CI* on each pair of our sample.[5] Even if the systems obtained similar performances in the challenge, the second system seems to behave in an opposite way with respect to EDITS, showing higher *CI* for negative cases than for the positive ones.

[5]The ideal case CI=1 corresponds to 0 on the logarithmic scale.

5 Conclusion and Future work

We have proposed a methodology for the evaluation of TE systems based on the analysis of the system behaviour on monothematic pairs with respect to the behaviour on corresponding original pairs. Through the definition of two indicators, a Correlation Index and a Deviation Index, we infer evaluation patterns which indicate strength and weaknesses of the system. As a pilot study, we have compared two systems that took part in RTE-5. We discovered that, although the two systems have similar accuracy on RTE-5 datasets, they show significant differences in their respective abilities to manage different linguistic phenomena and to properly combine them. We hope that the analysis provided by our methodology may bring interesting elements both to TE system developers and for deep discussion on the nature of TE itself.

As future work, we plan to refine the evaluation methodology introducing the possibility to assign different relevance to the phenomena.

6 Acknowledgements

Thanks to Professor Rodolfo Delmonte and to Sara Tonelli for running the VENSES system on our data sets.

Abstract

We compare the performance of three statistical parsing architectures on the problem of deriving typed dependency structures for French. The architectures are based on PCFGs with latent variables, graph-based dependency parsing and transition-based dependency parsing, respectively. We also study the influence of three types of lexical information: lemmas, morphological features, and word clusters. The results show that all three systems achieve competitive performance, with a best labeled attachment score over 88%. All three parsers benefit from the use of automatically derived lemmas, while morphological features seem to be less important. Word clusters have a positive effect primarily on the latent variable parser.

1 Introduction

In this paper, we compare three statistical parsers that produce typed dependencies for French. A syntactic analysis in terms of typed grammatical relations, whether encoded as functional annotations in syntagmatic trees or in labeled dependency trees, appears to be useful for many NLP tasks including question answering, information extraction, and lexical acquisition tasks like collocation extraction.

This usefulness holds particularly for French, a language for which bare syntagmatic trees are often syntactically underspecified because of a rather free order of post-verbal complements/adjuncts and the possibility of subject inversion. Thus, the annotation scheme of the French Treebank (Abeillé and Barrier, 2004) makes use of flat syntagmatic trees without VP nodes, with no structural distinction between complements, adjuncts or post-verbal subjects, but with additional functional annotations on dependents of verbs.

Parsing is commonly enhanced by using more abstract lexical information, in the form of morphological features (Tsarfaty, 2006), lemmas (Seddah et al., 2010), or various forms of clusters (see (Candito and Seddah, 2010) for references). In this paper, we explore the integration of morphological features, lemmas, and linear context clusters.

Typed dependencies can be derived using many different parsing architectures. As far as statistical approaches are concerned, the dominant paradigm for English has been to use constituency-based parsers, the output of which can be converted to typed dependencies using well-proven conversion procedures, as in the Stanford parser (Klein and Manning, 2003). In recent years, it has also become popular to use statistical dependency parsers, which are trained directly on labeled dependency trees and output such trees directly, such as MSTParser (McDonald, 2006) and MaltParser (Nivre et al., 2006). Dependency parsing has been applied to a fairly broad range of languages, especially in the CoNLL shared tasks in 2006 and 2007 (Buchholz and Marsi, 2006; Nivre et al., 2007).

We present a comparison of three statistical parsing architectures that output typed dependencies for French: one constituency-based architecture featuring the Berkeley parser (Petrov et al., 2006), and two dependency-based systems using radically different parsing methods, MSTParser (McDonald et al., 2006) and MaltParser (Nivre et al., 2006). These three systems are compared both in terms of parsing accuracy and parsing times, in realistic settings that only use predicted information. By using freely available software packages that implement language-independent approaches

Coling 2008: Poster Volume, pages 108–116,
Beijing, August 2010

and applying them to a language different from English, we also hope to shed some light on the capacity of different methods to cope with the challenges posed by different languages.

Comparative evaluation of constituency-based and dependency-based parsers with respect to labeled accuracy is rare, despite the fact that parser evaluation on typed dependencies has been advocated for a long time (Lin, 1995; Carroll et al., 1998). Early work on statistical dependency parsing often compared constituency-based and dependency-based methods with respect to their *unlabeled* accuracy (Yamada and Matsumoto, 2003), but comparison of different approaches with respect to *labeled* accuracy is more recent.

Cer et al. (2010) present a thorough analysis of the best trade-off between speed and accuracy in deriving Stanford typed dependencies for English (de Marneffe et al., 2006), comparing a number of constituency-based and dependency-based parsers on data from the Wall Street Journal. They conclude that the highest accuracy is obtained using constituency-based parsers, although some of the dependency-based parsers are more efficient.

For German, the 2008 ACL workshop on parsing German (Kübler, 2008) featured a shared task with two different tracks, one for constituency-based parsing and one for dependency-based parsing. Both tracks had their own evaluation metrics, but the accuracy with which parsers identified subjects, direct objects and indirect objects was compared across the two tracks, and the results in this case showed an advantage for dependency-based parsing.

In this paper, we contribute results for a third language, French, by benchmarking both constituency-based and dependency-based methods for deriving typed dependencies. In addition, we investigate the usefulness of morphological features, lemmas and word clusters for each of the different parsing architectures. The rest of the paper is structured as follows. Section 2 describes the French Treebank, and Section 3 describes the three parsing systems. Section 4 presents the experimental evaluation, and Section 5 contains a comparative error analysis of the three systems. Section 6 concludes with suggestions for future research.

2 Treebanks

For training and testing the statistical parsers, we use treebanks that are automatically converted from the French Treebank (Abeillé and Barrier, 2004) (hereafter FTB), a constituency-based treebank made up of $12,531$ sentences from the *Le Monde* newspaper. Each sentence is annotated with a constituent structure and words bear the following features: gender, number, mood, tense, person, definiteness, wh-feature, and clitic case. Nodes representing dependents of a verb are labeled with one of 8 grammatical functions.[1]

We use two treebanks automatically obtained from FTB, both described in Candito et al. (2010). FTB-UC is a modified version of the original constituency-based treebank, where the rich morphological annotation has been mapped to a simple tagset of 28 part-of-speech tags, and where compounds with regular syntax are broken down into phrases containing several simple words while remaining sequences annotated as compounds in FTB are merged into a single token. Function labels are appended to syntactic category symbols and are either used or ignored, depending on the task.

FTB-UC-DEP is a dependency treebank derived from FTB-UC using the classic technique of head propagation rules, first proposed for English by Magerman (1995). Function labels that are present in the original treebank serve to label the corresponding dependencies. The remaining unlabeled dependencies are labeled using heuristics (for dependents of non-verbal heads). With this conversion technique, output dependency trees are necessarily projective, and extracted dependencies are necessarily local to a phrase, which means that the automatically converted trees can be regarded as pseudo-projective approximations to the correct dependency trees (Kahane et al., 1998). Candito et al. (2010) evaluated the converted trees for 120 sentences, and report a 98% labeled attachment score when comparing the automatically converted dependency trees to the manually corrected ones.

[1] These are `SUJ` (subject), `OBJ` (object), `A-OBJ`/`DE-OBJ` (indirect object with preposition *à* / *de*), `P-OBJ` (indirect object with another preposition / locatives), `MOD` (modifier), `ATS`/`ATO` (subject/object predicative complement).

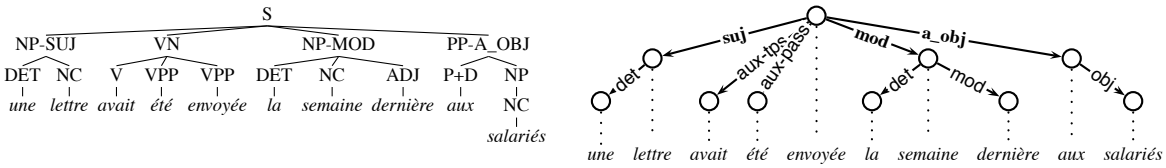

Figure 1: An example of constituency tree of the FTB-UC (left), and the corresponding dependency tree (right) for *A letter had been sent the week before to the employees.*

Figure 1 shows two parallel trees from FTB-UC and FTB-UC-DEP. In all reported experiments in this paper, we use the usual split of FTB-UC: first 10% as test set, next 10% as dev set, and the remaining sentences as training set.

3 Parsers

Although all three parsers compared are statistical, they are based on fairly different parsing methodologies. The Berkeley parser (Petrov et al., 2006) is a latent-variable PCFG parser, MSTParser (McDonald et al., 2006) is a graph-based dependency parser, and MaltParser (Nivre et al., 2006) is a transition-based dependency parser.

The choice to include two different dependency parsers but only one constituency-based parser is motivated by the study of Seddah et al. (2009), where a number of constituency-based statistical parsers were evaluated on French, including Dan Bikel's implementation of the Collins parser (Bikel, 2002) and the Charniak parser (Charniak, 2000). The evaluation showed that the Berkeley parser had significantly better performance for French than the other parsers, whether measured using a parseval-style labeled bracketing F-score or a CoNLL-style unlabeled attachment score. Contrary to most of the other parsers in that study, the Berkeley parser has the advantage of a strict separation of parsing model and linguistic constraints: linguistic information is encoded in the treebank only, except for a language-dependent suffix list used for handling unknown words.

In this study, we compare the Berkeley parser to MSTParser and MaltParser, which have the same separation of parsing model and linguistic representation, but which are trained directly on labeled dependency trees. The two dependency parsers use radically different parsing approaches but have achieved very similar performance for a wide range of languages (McDonald and Nivre, 2007). We describe below the three architectures in more detail.[2]

3.1 The Berkeley Parser

The Berkeley parser is a freely available implementation of the statistical training and parsing algorithms described in (Petrov et al., 2006) and (Petrov and Klein, 2007). It exploits the fact that PCFG learning can be improved by splitting symbols according to structural and/or lexical properties (Klein and Manning, 2003). Following Matsuzaki et al. (2005), the Berkeley learning algorithm uses EM to estimate probabilities on symbols that are automatically augmented with latent annotations, a process that can be viewed as symbol splitting. Petrov et al. (2006) proposed to score the splits in order to retain only the most beneficial ones, and keep the grammar size manageable: the splits that induce the smallest losses in the likelihood of the treebank are merged back. The algorithm starts with a very general treebank-induced binarized PCFG, with order h horizontal markovisation. created, where at each level a symbol appears without track of its original siblings. Then the Berkeley algorithm performs split/merge/smooth cycles that iteratively refine the binarized grammar: it adds two latent annotations on each symbol, learns probabilities for the refined grammar, merges back 50% of the splits, and smoothes the final probabilities to prevent overfitting. All our experiments are run using BerkeleyParser 1.0,[3] modified for handling

[2]For replicability, models, preprocessing tools and experimental settings are available at `http://alpage.inria.fr/statgram/frdep.html`.

[3]`http://www.eecs.berkeley.edu/\~petrov/berkeleyParser`

French unknown words by Crabbé and Candito (2008), with otherwise default settings (order 0 horizontal markovisation, order 1 vertical markovisation, 5 split/merge cycles).

The Berkeley parser could in principle be trained on functionally annotated phrase-structure trees (as shown in the left half of figure 1), but Crabbé and Candito (2008) have shown that this leads to very low performance, because the splitting of symbols according to grammatical functions renders the data too sparse. Therefore, the Berkeley parser was trained on FTB-UC without functional annotation. Labeled dependency trees were then derived from the phrase-structure trees output by the parser in two steps: *(1)* function labels are assigned to phrase structure nodes that have functional annotation in the FTB scheme; and *(2)* dependency trees are produced using the same procedure used to produce the pseudo-gold dependency treebank from the FTB (cf. Section 2).

The functional labeling relies on the Maximum Entropy labeler described in Candito et al. (2010), which encodes the problem of functional labeling as a multiclass classification problem. Specifically, each class is of the eight grammatical functions used in FTB, and each head-dependent pair is treated as an independent event. The feature set used in the labeler attempt to capture bilexical dependencies between the head and the dependent (using stemmed word forms, parts of speech, etc.) as well as more global sentence properties like mood, voice and inversion.

3.2 MSTParser

MSTParser is a freely available implementation of the parsing models described in McDonald (2006). These models are often described as *graph-based* because they reduce the problem of parsing a sentence to the problem of finding a directed maximum spanning tree in a dense graph representation of the sentence. Graph-based parsers typically use global training algorithms, where the goal is to learn to score correct trees higher than incorrect trees. At parsing time a global search is run to find the highest scoring dependency tree. However, unrestricted global inference for graph-based dependency parsing is NP-hard, and graph-based parsers like MSTParser therefore limit the scope of their features to a small number of adjacent arcs (usually two) and/or resort to approximate inference (McDonald and Pereira, 2006). For our experiments, we use MSTParser 0.4.3b[4] with 1-best projective decoding, using the algorithm of Eisner (1996), and second order features. The labeling of dependencies is performed as a separate sequence classification step, following McDonald et al. (2006).

To provide part-of-speech tags to MSTParser, we use the MElt tagger (Denis and Sagot, 2009), a Maximum Entropy Markov Model tagger enriched with information from a large-scale dictionary.[5] The tagger was trained on the training set to provide POS tags for the dev and test sets, and we used 10-way jackknifing to generate tags for the training set.

3.3 MaltParser

MaltParser[6] is a freely available implementation of the parsing models described in (Nivre, 2006) and (Nivre, 2008). These models are often characterized as *transition-based*, because they reduce the problem of parsing a sentence to the problem of finding an optimal path through an abstract transition system, or state machine. This is sometimes equated with shift-reduce parsing, but in fact includes a much broader range of transition systems (Nivre, 2008). Transition-based parsers learn models that predict the next state given the current state of the system, including features over the history of parsing decisions and the input sentence. At parsing time, the parser starts in an initial state and greedily moves to subsequent states – based on the predictions of the model – until a terminal state is reached. The greedy, deterministic parsing strategy results in highly efficient parsing, with run-times often linear in sentence length, and also facilitates the use of arbitrary non-local features, since the partially built dependency tree is fixed in any given state. However, greedy inference can also lead to error propagation if early predictions place the parser in incorrect states. For the experiments in this paper, we use MaltParser

[4] `http://mstparser.sourceforge.net`

[5] Denis and Sagot (2009) report a tagging accuracy of 97.7% (90.1% on unknown words) on the FTB-UC test set.

[6] `http://www.maltparser.org`

1.3.1 with the arc-eager algorithm (Nivre, 2008) and use linear classifiers from the LIBLINEAR package (Fan et al., 2008) to predict the next state transitions. As for MST, we used the MElt tagger to provide input part-of-speech tags to the parser.

4 Experiments

This section presents the parsing experiments that were carried out in order to assess the state of the art in labeled dependency parsing for French and at the same time investigate the impact of different types of lexical information on parsing accuracy. We present the features given to the parsers, discuss how they were extracted/computed and integrated within each parsing architecture, and then summarize the performance scores for the different parsers and feature configurations.

4.1 Experimental Space

Our experiments focus on three types of lexical features that are used either in addition to or as substitutes for word forms: morphological features, lemmas, and word clusters. In the case of MaltParser and MSTParser, these features are used in conjunction with POS tags. Motivations for these features are rooted in the fact that French has a rather rich inflectional morphology.

The intuition behind using morphological features like tense, mood, gender, number, and person is that some of these are likely to provide *additional cues* for syntactic attachment or function type. This is especially true given that the 29 tags used by the MElt tagger are rather coarse-grained.

The use of lemmas and word clusters, on the other hand, is motivated by *data sparseness* considerations: these provide various degrees of generalization over word forms. As suggested by Koo et al. (2008), the use of word clusters may also reduce the need for annotated data.

All our features are automatically produced: no features except word forms originate from the treebank. Our aim was to assess the performance currently available for French in a realistic setting.

Lemmas Lemmatized forms are extracted using Le*fff* (Sagot, 2010), a large-coverage morphosyntactic lexicon for French, and a set of heuristics for unknown words. More specifically, Le*fff* is queried for each $(word, pos)$, where pos is the tag predicted by the MElt tagger. If the pair is found, we use the longest lemma associated with it in Le*fff*. Otherwise, we rely on a set of simple stemming heuristics using the form and the predicted tag to produce the lemma. We use the form itself for all other remaining cases.[7]

Morphological Features Morphological features were extracted in a way similar to lemmas, again by querying Le*fff* and relying on heuristics for out-of-dictionary words. Here are the main morphological attributes that were extracted from the lexicon: mood and tense for verbs; person for verbs and pronouns; number and gender for nouns, past participles, adjectives and pronouns; whether an adverb is negative; whether an adjective, pronoun or determiner is cardinal, ordinal, definite, possessive or relative. Our goal was to predict all attributes found in FTB that are recoverable from the word form alone.

Word Form Clusters Koo et al. (2008) have proposed to use unsupervised word clusters as features in MSTParser, for parsing English and Czech. Candito and Crabbé (2009) showed that, for parsing French with the Berkeley parser, using the same kind of clusters as substitutes for word forms improves performance. We now extend their work by comparing the impact of such clusters on two additional parsers.

We use the word clusters computed by Candito and Crabbé (2009) using Percy Liang's implementation[8] of the Brown unsupervised clustering algorithm (Brown et al., 1992). It is a bottom-up hierarchical clustering algorithm that uses a bigram language model over clusters. The resulting cluster ids are bit-strings, and various levels of granularity can be obtained by retaining only the first x bits. Candito and Crabbé (2009) used the *L'Est Républicain* corpus, a 125 million word journalistic corpus.[9] To reduce lexi-

[7] Candito and Seddah (2010) report the following coverage for the Le*fff*: around 96% of the tokens, and 80.1% of the token types are present in the Le*fff* (leaving out punctuation and numeric tokens, and ignoring case differences).

[8] `http://www.eecs.berkeley.edu/~pliang/software`

[9] `http://www.cnrtl.fr/corpus/estrepublicain`

cal data sparseness caused by inflection, they ran a lexicon-based stemming process on the corpus that removes inflection marks without adding or removing lexical ambiguity. The Brown algorithm was then used to compute 1000 clusters of stemmed forms, limited to forms that appeared at least 20 times.

We tested the use of clusters with different values for two parameters: **nbbits** = the cluster prefix length in bits, to test varying granularities, and **minocc** = the minimum number of occurrences in the *L'Est Républicain* corpus for a form to be replaced by a cluster or for a cluster feature to be used for that form.

4.2 Parser-Specific Configurations

Since the three parsers are based on different machine learning algorithms and parsing algorithms (with different memory requirements and parsing times), we cannot integrate the different features described above in exactly the same way. For the Berkeley parser we use the setup of Candito and Seddah (2010), where additional information is encoded within symbols that are used as substitutes for word forms. For MaltParser and MSTParser, which are based on discriminative models that permit the inclusion of interdependent features, additional information may be used either in addition to or as substitutes for word forms. Below we summarize the configurations that have been explored for each parser:

- **Berkeley:**
  1. **Morphological features:** N/A.
  2. **Lemmas:** Concatenated with POS tags and substituted for word forms.
  3. **Clusters:** Concatenated with morphological suffixes and substituted for word forms; grid search for optimal values of **nbbits** and **minocc**.
- **MaltParser** and **MSTParser:**
  1. **Morphological features:** Added as features.
  2. **Lemmas:** Substituted for word forms or added as features.
  3. **Clusters:** Substituted for word forms or added as features; grid search for optimal values of **nbbits** and **minocc**.

4.3 Results

Table 1 summarizes the experimental results. For each parser we give results on the development set for the baseline (no additional features), the best configuration for each individual feature type, and the best configuration for any allowed combination of the three features types. For the final test set, we only evaluate the baseline and the best combination of features. Scores on the test set were compared using a χ^2-test to assess statistical significance: unless specified, all differences therein were significant at $p \leq 0.01$.

The MSTParser system achieves the best labeled accuracy on both the development set and the test set. When adding lemmas, the best configuration is to use them as substitutes for word forms, which slightly improves the UAS results. For the clusters, their use as substitutes for word forms tends to degrade results, whereas using them as features alone has almost no impact. This means that we could not replicate the positive effect[10] reported by Koo et al. (2008) for English and Czech. However, the best combined configuration is obtained using lemmas instead of words, a reduced set of morphological features,[11] and clusters as features, with minocc=$50,000$ and nbbits=10.

MaltParser has the second best labeled accuracy on both the development set and the test set, although the difference with Berkeley is not significant on the latter. MaltParser has the lowest unlabeled accuracy of all three parsers on both datasets. As opposed to MSTParser, all three feature types work best for MaltParser when used in addition to word forms, although the improvement is statistically significant only for lemmas and clusters. Again, the best model uses all three types of features, with cluster features minocc=600 and nbbits=7. MaltParser shows the smallest discrepancy from unlabeled to labeled scores. This might be because it is the only architecture where labeling is directly done as part of parsing.

[10] Note that the two experiments cannot be directly compared. Koo et al. (2008) use their own implementation of an MST parser, which includes extra second-order features (e.g. grand-parent features on top of sibling features).

[11] As MSTParser training is memory-intensive, we removed the features containing information already encoded part-of-speech tags.

	Development Set										Test Set			
	Baseline		**Morpho**		**Lemma**		**Cluster**		**Best**		**Baseline**		**Best**	
Parser	LAS	UAS	LAS	UAS	LAS	UAS	LAS	UAS	LAS	UAS	LAS	UAS	LAS	UAS
Berkeley	85.1	89.3	–	–	85.9	90.0	86.5	90.8	86.5	**90.8**	85.6	89.6	86.8	**91.0**
MSTParser	**87.2**	**90.0**	87.2	90.2	87.2	90.1	87.2	90.1	**87.5**	90.3	87.6	90.3	**88.2**	90.9
MaltParser	86.2	89.0	86.3	89.0	86.6	89.2	86.5	89.2	86.9	89.4	86.7	89.3	87.3	89.7

Table 1: Experimental results for the three parsing systems. LAS=labeled accuracy, UAS=unlabeled accuracy, for sentences of any length, ignoring punctuation tokens. Morpho/Lemma/Cluster=best configuration when using morphological features only (resp. lemmas only, clusters only), Best=best configuration using any combination of these.

For Berkeley, the lemmas improve the results over the baseline, and its performance reaches that of MSTParser for unlabeled accuracy (although the difference between the two parsers is not significant on the test set). The best setting is obtained with clusters instead of word forms, using the full bit strings. It also gives the best unlabeled accuracy of all three systems on both the development set and the test set. For the more important labeled accuracy, the point-wise labeler used is not effective enough.

Overall, MSTParser has the highest labeled accuracy and Berkeley the highest unlabeled accuracy. However, results for all three systems on the test set are roughly within one percentage point for both labeled and unlabeled accuracy, which means that we do not find the same discrepancy between constituency-based and dependency-based parser that was reported for English by Cer et al. (2010).

Table 2 gives parsing times for the best configuration of each parsing architecture. MaltParser runs approximately 9 times faster than the Berkeley system, and 10 times faster than MSTParser. The difference in efficiency is mainly due to the fact that MaltParser uses a linear-time parsing algorithm, while the other two parsers have cubic time complexity. Given the rather small difference in labeled accuracy, MaltParser seems to be a good choice for processing very large corpora.

	Bky	**Malt**	**MST**
Tagging	_	0:27	0:27
Parsing	12:19	0:58 (0:18)	14:12 (12:44)
Func. Lab.	0:23	_	_
Dep. Conv.	0:4	_	_
Total	12:46	1:25	14:39

Table 2: Parsing times (min:sec) for the dev set, for the three architectures, on an imac 2.66GHz. The figures within brackets show the pure parsing time without the model loading time, when available.

5 Error Analysis

We provide a brief analysis of the errors made by the best performing models for Berkeley, MSTParser and MaltParser on the development set, focusing on labeled and unlabeled attachment for nouns, prepositions and verbs. For nouns, Berkeley has the best unlabeled attachment, followed by MSTParser and then MaltParser, while for labeled attachment Berkeley and MSTParser are on a par with MaltParser a bit behind. For prepositions, MSTParser is by far the best for both labeled and unlabeled attachment, with Berkeley and MaltParser performing equally well on unlabeled attachment and MaltParser performing better than Berkeley on labeled attachment.[12] For verbs, Berkeley has the best performance on both labeled and unlabeled attachment, with MSTParser and MaltParser performing about equally well. Although Berkeley has the best unlabeled attachment overall, it also has the worst labeled attachment, and we found that this is largely due to the functional role labeler having trouble assigning the correct label when the dependent is a preposition or a clitic.

For errors in attachment as a function of word distance, we find that precision and recall on dependencies of length > 2 tend to degrade faster for MaltParser than for MSTParser and Berkeley,

[12] In the dev set, for MSTParser, 29% of the tokens that do not receive the correct governor are prepositions (883 out of 3051 errors), while these represent 34% for Berkeley (992 out of 2914), and 30% for MaltParser (1016 out of 3340).

with Berkeley being the most robust for dependencies of length > 6. In addition, Berkeley is best at finding the correct root of sentences, while MaltParser often predicts more than one root for a given sentence. The behavior of MSTParser and MaltParser in this respect is consistent with the results of McDonald and Nivre (2007).

6 Conclusion

We have evaluated three statistical parsing architectures for deriving typed dependencies for French. The best result obtained is a labeled attachment score of 88.2%, which is roughly on a par with the best performance reported by Cer et al. (2010) for parsing English to Stanford dependencies. Note two important differences between their results and ours: First, the Stanford dependencies are in a way deeper than the surface dependencies tested in our work. Secondly, we find that for French there is no consistent trend favoring either constituency-based or dependency-based methods, since they achieve comparable results both for labeled and unlabeled dependencies.

Indeed, the differences between parsing architectures are generally small. The best performance is achieved using MSTParser, enhanced with predicted part-of-speech tags, lemmas, morphological features, and unsupervised clusters of word forms. MaltParser achieves slightly lower labeled accuracy, but is probably the best option if speed is crucial. The Berkeley parser has high accuracy for unlabeled dependencies, but the current labeling method does not achieve a comparably high labeled accuracy.

Examining the use of lexical features, we find that predicted lemmas are useful in all three architectures, while morphological features have a marginal effect on the two dependency parsers (they are not used by the Berkeley parser). Unsupervised word clusters, finally, give a significant improvement for the Berkeley parser, but have a rather small effect for the dependency parsers.

Other results for statistical dependency parsing of French include the pilot study of Candito et al. (2010), and the work ofSchluter and van Genabith (2009), which resulted in an LFG statistical French parser. However, the latter's results are obtained on a modified subset of the FTB, and are expressed in terms of F-score on LFG f-structure features, which are not comparable to our attachment scores. There also exist a number of grammar-based parsers, evaluated on gold test sets annotated with chunks and dependencies (Paroubek et al., 2005; de la Clergerie et al., 2008). Their annotation scheme is different from that of the FTB, but we plan to evaluate the statistical parsers on the same data in order to compare the performance of grammar-based and statistical approaches.

Abstract

As unlexicalized parsing lacks word token information, it is important to investigate novel parsing features to improve the accuracy. This paper studies a set of tree topological (TT) features. They quantitatively describe the tree shape dominated by each non-terminal node. The features are useful in capturing linguistic notions such as grammatical weight and syntactic branching, which are factors important to syntactic processing but overlooked in the parsing literature. By using an ensemble classifier-based model, TT features can significantly improve the parsing accuracy of our unlexicalized parser. Further, the ease of estimating TT feature values makes them easy to be incorporated into virtually any mainstream parsers.

1 Introduction

Many state-of-the-art parsers work with lexicalized parsing models that utilize the information and statistics of word tokens (Magerman, 1995; Collins, 1999, 2003; Charniak, 2000). The performance of lexicalized models is susceptible to vocabulary variation as lexical statistics is often corpus-specific (Ratnaparkhi, 1999; Gildea, 2001). As parsers are typically evaluated using the Penn Treebank (Marcus *et al*., 1993), which is based on financial news, the problems of lexicalized parsing could easily be overlooked. Unlexicalized models, on the other hand, are less sensitive to lexical variation and are more portable across domains. Though the performance of unlexicalized models was believed not to exceed that of lexicalized models (Klein & Manning, 2003), Petrov & Klein (2007) show that unlexicalized parsers can match lexicalized parsers in performance using the grammar rule splitting technique. Given the practical advantages and the latest development, unlexicalized parsing deserves further scrutiny.

A profitable direction of research on unlexicalized parsing is to investigate novel parsing features. This paper examines a set of what we call *tree topological* (TT) features, including phrase span, phrase height, tree skewness, etc. This study is motivated by the fact that conventional parsers rarely consider the shape of subtrees dominated by these nodes and rely primarily on matching tags. As a result, an NP with a complicated structure is treated the same as an NP that dominates only one word. However, our study shows that TT features are useful predictors of phrase boundaries, a critical ambiguity resolution issue. TT features have two more advantages. First, TT features capture linguistic properties, such as branching and grammatical "heaviness", across different syntactic structures. Second, they are easily computable without the need for extra language resources.

The organization of the paper is as follows. Section 2 reviews the features commonly used in parsing. Section 3 provides the details of TT features in the unlexicalized parser. The parser is evaluated in Section 4. In Section 5, we discuss the effectiveness and advantages of TT features in parsing and possible enhancement. This is followed by a conclusion in Section 6.

2.1 Parsing Features

This section reviews major types of information in parsing.

Coling 2008: Poster Volume, pages 117–125,
Beijing, August 2010

Tags: The dominant types of information that drive parsing and chunking algorithms are POS/syntactic tags, context-free grammar (CFG) rules, and their statistical properties. Matching tags against CFG rules to form phrases is central to all basic parsing algorithms such as Cocke-Kasami-Younger (CKY) algorithm, and the Earley algorithm, and the chart parsing.

Word Token-based: Machine learning and statistical modelling emerged in the 90s as an ideal computational approach to feature-rich parsing. Classifiers can typically capitalize on a large set of features in decision making. Magerman (1995), Ratnaparkh (1999) and Charniak (2000) used classifiers to model dependencies between word pairs. They popularized the use word tokens as attributes in lexicalized parsing. Collins (1999, 2003) also integrated information like head word and distance from head into the statistical model to enhance probabilistic chart parsing. Since then, word tokens, head words and their statistical derivatives have become standard features in many parsers. Word token information is also fundamental to dependency parsing (Kübler *et al*., 2009) because dependency grammar is rooted in the idea that the head and the dependent word are related by different dependency relations.

Semantic-based: Some efforts have also been made to consider semantic features, such as sense tags, in parsing. Words are first tagged with semantic classes, often using WordNet-based resources. The lexical semantic class can be instructive to the selection of the correct parse from a set of candidate structures. It has been reported that the lexical semantics of words is effective in resolving structural ambiguity, especially PP-attachment (Black *et al*., 1992; Stetina & Nagao, 1997; Agirre *et al*., 2008). Nevertheless, the use of semantic features has still been relatively rare. They incur overheads in acquiring semantic language resources, such as sense-tagged corpora and WordNet databases. Semantic-based parsing also requires accurate sense-tagging.

Since substantial gain from tag features is unlikely in the near future and deriving semantic features is often a tremendous task, there is a pressing need to seek for new features, particularly in unlexicalized parsing.

2.2 Linguistic-motivated Features

In this section, a review of the linguistic motivation behind the TT features is provided.

Grammatical Weight: Apart from syntactic categories, linguists have long observed that the number of words (often referred to as "weight" or "heaviness") in a phrase can affect syntactic processing of sentences (Quirk *et al.*, 1985; Wasow, 1997; Rosenbach, 2005). It corresponds roughly to the span feature described in Section 3.2. The effect of grammatical weight often manifests in word order variation. Heavy NP shift, dative alternation, particle movement and extraposition in English are canonical examples where "heavy" chunks get dislocated to the end of a sentence. In his corpus analysis, Wasow (1997) found that weight is a very crucial factor in determining dative alternation. Hawkins (1994) also argued that due to processing constraints, the human syntactic processor tends to group an incoming stream of words as rapidly as possible, preferring smaller chunks on the left.

Tree Topology: CFG-based parsing approach hides the structural properties of the dominated subtree from the associated syntactic tag. Structural topology, or tree shape, however, can be useful in guiding the parser to group tags into phrases. Structures significantly deviating from left/right branching, e.g. center embedding, are much more difficult to process and rare in production (Gibson, 1998). Another example is the resolution of scope ambiguity in coordinate structures (*CS*s). *CS*s are common but notoriously difficult to parse due to scope ambiguity when the conjuncts are complex (Collins, 1999; Kübler *et al.*, 2009). One good cue to the problem is that humans prefer *CS*s with parallel internal syntactic structures (Frazier *et al.*, 2000). In a corpus-based study, Dubey *et al.* (2008) show that structural repetition across conjuncts is significantly more frequent. The implication to parsing is that preference should be given to bracketing in which conjuncts are structurally similar. TT information can inform the parser of the structural properties of phrases.

3 An Ensemble-based Parser

To accommodate a large set of features, we opt for classifier-based parsing because classifiers

can easily handle many features, as pointed out in Ratnaparkhi (1999). This is different from chart parsing models popular in many parsers (e.g. Collins, 2003) which require special statistical modelling. Our parser starts from a string of POS tags without any hints from words. As in other similar approaches (Abney 1991; Ramshaw & Marcus, 1995; Sang, 2001; Sagae & Lavie, 2005), the first and the foremost problem that has to be resolved is to identify the boundary points of phrases, without any explicit grammar rules. Here we adopt the ensemble learning technique to unveil boundary points, or *chunking points* hereafter. Two heterogeneous and mutually independent attribute feature sets are introduced in Section 3.2 and 3.3.

3.1 Basic Architecture of the Parser

Our parser has two modules, namely, a chunker and a phrase recognizer. The chunker locates the boundaries of chunks while the phrase recognizer predicts the non-terminal syntactic tag of the identified chunks, e.g. `NP`, `VP`, etc. In the chunker, we explore a new approach that aims at identifying chunk boundaries. Assume that the input of the chunker is a tag sequence $<x_0 \ldots x_n \ldots x_m>$ where $0 \le n \le m$. Let y_n be the point of focus between two consecutive tags x_n and x_{n+1}. The chunker classifies all focus points as either a chunking point or a merging point at the relevant level. A focus point y_n is a merging point if x_n and x_{n+1} are siblings of the same parent node in the target parse tree. Otherwise, y_n is a chunking point. Consider the tag sequence and the expected classification of points in the example below. Chunking points are marked with "`%`" and merging points with "`+`".

```
PRP % VBZ % DT % RB   +  JJ  % NN
He    is    a    very    nice  guy
```

The point between `RB` and `JJ` is a merging point because they are siblings of the parent node `ADJP` in the target parse tree. The point between `DT` and `RB` is a chunking point since `DT` and `RB` are not siblings and do not share the same parent node. Chunks are defined as the consecutive tag sequences not split up by `%`. When a focus point y_n is classified as a chunking point, it effectively means that no fragment preceding y_n can combine with any fragment following y_n to form a phrase, i.e. a *distituent*.

Both the chunker and the recognizer are trained using the Penn Treebank (Marcus *et al*., 1993). In addition, we adopt the ensemble technique to combine two sets of heterogeneous features. The method yields a much more accurate predictive power (Dietterich, 2000). One necessary and sufficient condition for an ensemble of classifiers to be more accurate than any of its individual members is that the classifiers must be diverse. Table 1 summaries the basic rationale of the parser. The two feature sets will be further explained in Section 3.2 and 3.3.

- Prepare training data from the Treebank based on topological & information-theoretic features
- Train the chunker and phrase recognizer using the ensemble technique
- For any input tag sequence *l*,
  WHILE *l* contains more than one element DO
    IDENTIFY the status, + or %, of each focus point in *l*
    RECOGNIZE the syntactic tag (ST) of each identified chunk
    UPDATE *l* with the new ST sequence
  ENDWHILE
- Display the parse tree

Table 1. Basic rationale of the parser

The learning module acquires the knowledge encoded in the Penn Treebank to support various classification tasks. The input tag sequence is first fed into the chunker. The phrase recognizer then analyzes the chunker's output and assigns non-terminal syntactic tags (e.g. `NP`, `VP`, etc.) to identified chunks. The updated tag sequence is fed back to the chunker for processing at the next level. The iteration continues until a complete parse is formed.

3.2 Tree Topological Feature Set

Tree topological (TT) features describe the shape of subtrees quantitatively. Our approach to addressing this problem involves examining a set of topological features, without any assumption of the word tokens. They all have been implemented for chunking.

Node Coordinates (NCs): NCs include the level of focus (*LF*) and the relative position (*RP*) of the target subtree. The level of focus is defined as the total number of levels under the target node, with the terminal level inclusive while the *RP* indicates the linear position of the target node in that level. As in Figure 1, the *LF* for

subtree *A* and *B* are the same; however, the *RP* for subtree *A* is smaller than that for subtree *B*.

Span Ratio (SR): The *SR* is defined as the total number of terminal nodes spanned under the target node and is divided by the length of the sentence. In Figure 1, the span ratio for the target node `VP` at subtree *B* is 5/12. This ratio illustrates not only how many terminal nodes are covered by the target node, but also how far the target node is from the root `S`.

Aspect Ratio (AR): The *AR* of a target node in a subtree is defined as the ratio of the total number of non-terminal nodes involved to the total number of terminal nodes spanned. The *AR* is also indicative of the average branching factor of the subtree.

Skewness Measure (SM): The *SM* estimates the degree to which the subtree leans towards either left or right. In this research, the *SM* of a subtree is evaluated by the distribution of the length of the paths connecting the target node and each terminal node it dominates. The length of a path from a target node *V* to a terminal node *T* is the number of edges between *V* and *T*. For a tree with *n* terminal nodes, there are *n* paths. A pivot is defined as the [*n*/2]th terminal node when *n* is odd and between [*n*/2]th and [(*n*+1)/2]th terminal nodes if *n* is even, where [ ] is a ceiling function. The *SM* is defined as

$$SM = \frac{1}{\sum_{\rho_i>0} \rho_i} \left(\frac{\sum_{i=1}^{n} \rho_i (x_i - \bar{x})^3}{\sigma^3} \right) \qquad \text{Eqn (1)}$$

where x_i is the length of the *i*-th path pointing to the *i*-th terminal node, $\bar{x}$ and σ are the average and standard deviation of the length of all paths at that level of focus (*LF*). ρ_i is the distance measured from the *i*-th terminal node to the pivot. The distance is positive if the terminal node is to the left of the pivot, zero if it is right at the pivot, and negative if the terminal node is to the right of the pivot. Obviously, if the lengths of all paths are the same in the tree, the numerator of Eqn (1) will be crossed out and the *SM* returns to zero. The pivot also provides an axis of vertical flipping where the *SM* still holds. The farther the terminal node from the pivot, the longer the distance. The distances ρ provide the moment factors to quantify the skewness of trees. For illustration, let us consider subtree *B* with the target node `VP` at level of focus (*LF*) = 4 in Figure 1. Since there are five terminal nodes, the pivot is at the third node `VB`. The lengths of the paths x_i from left to right in the subtree are 1, 2, 3, 4, 4 and the moment factors ρ_i for the paths are 2, 1, 0, -1, -2. Assuming that $\bar{x}$ and σ for all the trees in the Treebank at level 4 are, say, 2.9 and 1.2 respectively, then *SM* = -3.55. It implies that subtree *B* under the target node `VP` has a strong right branching tendency, even though it has a very uniform branching factor which is usually defined as the number of children at each node.

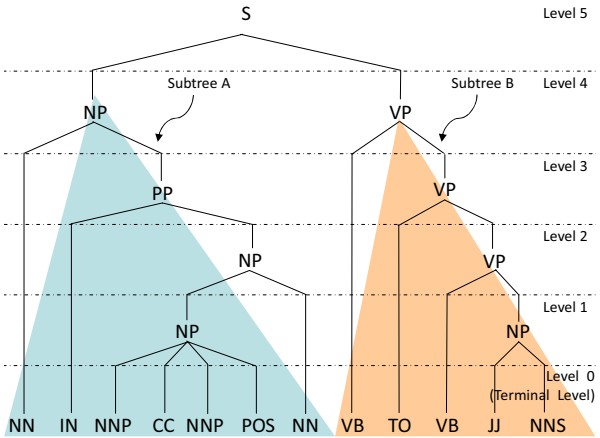

Figure 1. Two different subtrees in the sentence `S`

In our parser, to determine whether the two target nodes at level 4, i.e., `NP` and `VP`, should be merged to form a `S` at level 5 or not, an attribute vector with TT features for both `NP` and `VP` are devised as a training case. The corresponding target attribute is a binary value, i.e., chunking vs. merging. In addition, a set of *if-merged* attributes are introduced. For example, the attribute *SM-if-merged* indicates the changes of the *SM* if both target nodes are merged. This is particularly helpful since they are predictive under our bottom-up derivation strategy.

3.3 Information-Theoretic Feature Set

Context features are usually helpful in many applications of supervised language learning. In modelling context, one of the most central methodological concepts is co-occurrence. While collocation is the probabilistic co-occurrence of pure word tokens, *colligation* is defined as the co-occurrence of word tokens with grammatical patterning such as POS cate-

gories (Hunston, 2001). In this research, to capture the colligation without word tokens, a sliding window of 6 POS tags at the neighborhood of the focus point y_n is defined as our first set of context attributes. In addition, we define a set of information-theoretic (IT) attributes which reflect the likelihood of the fragment collocation. Various adjacent POS fragments around the focus point y_n are constructed, as in Table 2.

x_{n-2}	x_{n-1}	x_n	x_{n+1}	x_{n+2}	x_{n+3}	Colligation meas.
	x_{n-1}	x_n				d_1:$\zeta(x_{n-1}, x_n)$
		x_n	x_{n+1}			d_2:$\zeta(x_n, x_{n+1})$
			x_{n+1}	x_{n+2}		d_3:$\zeta(x_{n+1}, x_{n+2})$
x_{n-2}	x_{n-1}	x_n				d_4:$\zeta(x_{n-2}x_{n-1}, x_n)$
	x_{n-1}	x_n	x_{n+1}			d_5:$\zeta(x_{n-1}x_n, x_{n+1})$
		x_n	x_{n+1}	x_{n+2}		d_6:$\zeta(x_n, x_{n+1}x_{n+2})$
			x_{n+1}	x_{n+2}	x_{n+3}	d_7:$\zeta(x_{n+1}, x_{n+2}x_{n+3})$

Table 2. Colligation as context measure in various adjacent POS fragments where the focus point y_n is between x_n and x_{n+1}

An n-gram is treated as a 2-gram of an n_1-gram and an n_2-gram, where $n_1 + n_2 = n$ (Magerman & Marcus, 1990). The information-theoretic function ζ, namely, mutual information (*MI*), quantifies the co-occurrence of fragments. *MI* compares the probability of observing n_1-gram and n_2-gram together to the probability of observing them by chance (Church & Hanks, 1989). Here is an example illustrating the set of attributes. Take the point y_n between `RB` and `JJ` in Section 3.1 as an example. $d5$ represents the *MI* between (`DT RB`) and `JJ`, i.e. *MI*(`DT/RB`, `JJ`).

3.4 Multiple Classifications using Ensemble Technique

The basic idea of ensemble techniques involves considering several classification methods or multiple outputs to reach a decision. An ensemble of classifiers is a set of classifiers whose individual decisions are combined in some way, typically by weighted or un-weighted voting to classify new examples. Empirically speaking, ensembles methods deliver highly accurate classifiers by combining less accurate ones. They tend to yield better results than a single classifier in those situations when different classifiers have different error characteristics and their errors can compensate each other. Two questions need to be addressed when building and using an ensemble that integrates the predictions of several classifiers. ***First***, what data are used to train the classifiers so that the errors made by one classifier could be remedied by the other? ***Second***, how are the individual classifiers fused or integrated to produce a final ensemble prediction? As shown in the last two sections, we address the first question by introducing two heterogeneous and mutually independent attribute feature sets, namely the tree topological (TT) features and information-theoretic (IT) features. Instead of training all the features to form a single giant classifier, we produce two distinct, sometimes diversified, training sets of data to form two separate moderate classifiers, in the hope that they will produce a highly accurate prediction. The second question is addressed by employing the boosting algorithm. Boosting is an effective method that produces a very accurate prediction rule by combining rough and moderately inaccurate rules of thumb (Schapire & Singer, 2000). It generates the classifiers in an iterative way. At the early beginning, an initial base classifier using a set of training data with equal weight is first constructed. When the prediction of the base classifier differs from the expected outcome, the weight of the poorly predicted data is increased to an extent based on their misclassification rate on the preceding classifiers. As a result, the learning of the subsequent classifier will focus on learning the training data that are misclassified, or poorly predicted. This process continues until a specified number of iterations is reached or a predefined termination condition is met. The ensemble prediction is also a weighted voting process, where the weight of a classifier is based on its errors over the training data used to generate it. The first practical boosting algorithm, *AdaBoost*, was introduced by Freund & Schapire (1997), and solved many practical difficulties of the earlier boosting algorithms. Table 3 illustrates the main idea of the algorithm. Interested readers can refer to the literature for detailed discussion (Freund & Schapire, 1997; Hastie *et al.*, 2001).

Given: $(x_1, y_1),..,(x_m, y_m)$ where $x_i \in X, y_i \in Y = \{-1, +1\}$
Initialize $D_1(i) = 1/m$
For $t = 1, \ldots, T$

- Train a weak learner using distribution D_t
- Get a weak hypothesis $h_t : X \rightarrow \{-1, +1\}$ with error
  $\varepsilon_t = Pr_{i\sim Dt}[h_t(x_i) \neq y_i]$
- Choose $\alpha_t = \frac{1}{2}\ln\left(\frac{1-\varepsilon_t}{\varepsilon_t}\right)$
- Update:

$$D_{t+1}(i) = \frac{D_t(i)}{Z_t} \times \begin{cases} e^{-\alpha_t} & \text{if } h_t(x_i) = y_i \\ e^{\alpha_t} & \text{if } h_t(x_i) \neq y_i \end{cases}$$

$$= \frac{D_t(i)\exp(-\alpha_t y_i h_t(x_i))}{Z_t}$$

where Z_t is a normalization factor

- Output:

$$H(x) = \text{sign}\left(\sum_{t=1}^{T} \alpha_t h_t(x)\right)$$

Table 3. Adaboost algorithm

4 Experimental Results

Table 4 presents some sampled statistics of the skewness measure (*SM*) of some major phrase types, which include VP, NP, S, and PP, based on Sections 2—21 of the Penn Treebank (Marcus *et al*., 1993).

VP	L2-VP	L3-VP	L4-VP	L5-VP
N	18,406	22,052	18,035	15,911
Mean	-1.022	-4.454	-4.004	-3.738
S.D.	1.018	1.406	1.438	1.405
t_{score}	284.085*	-31.483*	-17.216*	
NP	L2-NP	L3-NP	L4-NP	L5-NP
N	23,270	28,172	10,827	8,375
Mean	1.013	-1.313	-1.432	-2.171
S.D.	1.284	2.013	1.821	1.628
t_{score}	158.748*	5.609*	29.614*	
S	L2-S	L3-S	L4-S	L5-S
N	2,233	5,020	7,049	7,572
Mean	0.688	-1.825	-1.459	-1.517
S.D.	1.229	2.732	2.451	2.128
t_{score}	54.031*	-7.568*	1.523

t_{score}	172.352*	42.073*	-33.173*	

Table 4. *SM* values for various phrases (* = the mean in the column is statistically significantly different from the mean in the immediately following column, with degree of freedom in all cases greater than 120)

For illustration purpose, the count of Level 2 VP subtrees, their *SM* mean and standard deviation are -1.022 and 1.018 respectively. We performed *t*-tests for difference in means between various levels, even under the same phrase type. For example, the *t* score for the difference in mean between L2-VP and L3-VP is 284.085, which indicates a strong difference in *SM* values between the two levels.

The means of all phrases beyond level 2 are negative, consistent with the fact that English is generally a right branching language. When we compare the *SM* values across phrase types, it is easy to notice that VPs and PPs have larger negative values, meaning that the skewness to the right is more prominent. Even within the same phrase type, the *SM* values may differ significantly as one moves from its current level to parent level. The *SM* offers an indicator that differentiates different phrase types with different syntactic levels. Chunkers can use this additional parameter to do chunking better.

Our parsing models were trained and tested using the Penn Treebank (Marcus *et al*., 1993). Following the convention of previous studies, we pre-processed the trees by removing NULL elements and functional tags and collapsing ADVP and PRT into ADVP. Sections 2—21 are used for training and Section 23 for testing. To evaluate the contribution of the features, five different experiments were set up, as in Table 5.

Experiment	Features involved
E1	POS tags only (=baseline)
E2	POS+IT
E3	POS+IT+TT (*node coordinates* only)
E4	POS+TT (with all features)
E5	All features in E3 & E4

Table 5. Parsing features in five experiments

E1 is the baseline experiment with tag features only. E2 and E4 include additional IT and TT features respectively. E3 and E5 are partial and full mixture of the two feature types. In the evaluation below, the chunker, phrase recognizer and parser are the same throughout the five sets of experiments. They only differ in terms of features used (i.e. E1—E5). We first study the impact of the feature sets on chunking. Five chunkers CH1—CH5 are evaluated.

Table 6 shows the training and test errors in five different chunkers in the respective experiments. All chunkers were trained using the ensemble-based learning. If one compares CH2 and CH4, it is clear that both IT and TT features

enhance sentence chunking but the gain from TT features (i.e. CH4) is much more substantial. The best chunkers (CH4 and CH5) reduce the test error rate from the baseline 4.36% to 3.25%.

Chunkers	Training error %	Test error %
CH1	1.66	4.36
CH2	1.53	4.32
CH3	0.69	3.79
CH4	0.33	3.25
CH5	0.45	3.25

Table 6. Performance of the five chunkers

Similarly, the phrase recognizer uses ensemble learning to capture the rule patterns. Instead of reading off the rules straight from a lookup table, the learning can predict the syntactic tags even when it encounters rules not covered in the treebank. Certainly, the learning allows the recognizer to take into account features more than just the tags. The error rates in training and testing are 0.09% and 0.68% respectively. The chunker and the phrase recognizer were assembled to form a parser. The features described in Table 5 were used to construct five parsers. We use the PARSEVAL measures to compare the performance as shown in Table 7.

	R	P	F	CBs	0 CBs	≤ 2 CBs
P1	78.9	77.6	78.3	1.6	48.7	76.4
P2	81.9	79.7	80.8	1.5	50.6	78.7
P3	85.1	82.8	83.4	1.4	53.3	80.2
P4	84.1	82.2	83.1	1.5	52.7	78.1
P5	84.7	83.4	84.0	1.3	54.6	80.5

Table 7. Performance of five parsers corresponding to five different experiments E1—E5

Our baseline parser (P1) actually performs quite well. With only tag features, it achieves an F-score of 78.3%. Both IT and TT features can separately enhance the parsing performance (P2 and P4). However, the gain from TT features (78.3→83.1%) is much more than that from IT features (78.3→80.8%). When the two feature sets are combined, they consistently produce better results. The best (P5) has an F-score of 84.0%. Even though the test errors in CH4 and CH5 are the same as shown in Table 6, P5 demonstrates that the cooperative effect of utilizing TT and IT features and leads to better parsing results.

5 Discussion

5.1 Tree Topology and Structures

Our study has provided a way to quantitatively capture linguists' various insights that tree topology is helpful in syntactic structure building (e.g. grammatical weight, subtree shape, etc.). The *SM* seems to capture the basic right branching property. It is noteworthy that Collins (2003) found that the parsing model that can learn the branching property of structures delivers a much better parsing performance over the one that cannot. In our case, chunkers refer to TT features to distinguish different phrase types and levels, and assign chunking points in such a way that the resulting phrases can be maximally similar to the trees in the treebank topologically. Apart from the overall accuracy, one may ask in what way TT features improve parsing. Here we provide our preliminary analysis on one syntactic construction that can be benefitted from a TT-feature-aware parser. The structure is coordinate structures (*CS*s). A practical cue is that conjuncts tend to be similar syntactically (and semantically). TT-feature-aware parsers can produce more symmetrical conjuncts. All rules of the form "XP → XP 'and' XP" were extracted from the training data.

NP	*L3 (-CS)*	*L3-(+CS)*	*L4 (-CS)*	*L4-(+CS)*
N	27,950	222	10,222	605
Mean	-1.321	-0.397	-1.448	-1.162
S.D.	2.010	2.190	1.806	2.047
t_{score}	-6.266*		-3.360*	
VP	*L3 (-CS)*	*L3-(+CS)*	*L4 (-CS)*	*L4-(+CS)*
N	21,855	197	17,711	324
Mean	-4.488	-0.628	-4.063	-0.793
S.D.	1.350	2.136	1.364	1.676
t_{score}	-25.319*		-34.908*	

Table 8. TT feature values of coordinate structures (+*CS* = node that immediately dominates a *CS*; -*CS* otherwise; * = the mean in the column is statistically significantly different from the mean in the immediately following column).

We compared the *SM* of *CS* and non-*CS* phrases using *t*-tests for mean difference. The *t*-score is calculated based on unequal sample sizes and unequal variances. As shown in Table 8, we have to reject the null hypothesis that their means of the *SM*, between phrases with and without a *CS*, are equal at $\alpha = 0.0005$ significance level. In other words, phrases with and without a *CS* are statistically different. +*CS* phrases are much more balanced with a smaller *SM* value from -0.4 to -1.2. -*CS* columns generally have a much larger *SM* value, ranging from

-1.321 to -4.488. The *SM* offers information for the chunkers to avoid over- or under-chunking conjuncts in phrases with a coordination marker (e.g. 'and').

5.2 Implications to Parsing

The findings in Section 4 indicate that the presented initial version of the *unlexicalized* parser performs on a par with the first generation *lexicalized* parsers (e.g. Magerman, 1995). The promising results have two implications. First, the integration of IT and TT features produces substantial gain over the baseline model. TT features consistently outperform IT features by a noticeable margin. To the best of our knowledge, TT features have not been systematically investigated in parsing before. The effectiveness of these new features suggests that in addition to improving algorithms, practitioners should not overlook the development of new features. Second, the implementation of TT and IT features is simple and relatively computationally inexpensive. No extra resources or complicated algorithms are needed to compute TT features. Most importantly, they are suitable to the stringent requirements of unlexicalized parsing in which no word token information is allowed. The features can be added to other parsers relatively easily without substantial changes.

5.3 Further Work

The reported parsing results pertain to the initial version of the parser. There is still room for further improvement. First, it would be interesting to integrate TT features in combination with other design features (e.g. rule splitting) into the unlexicalized parser to enhance the results. Moreover, TT features is likely to enhance lexicalized parsers too. Second, more detailed analysis of TT features can be conducted in different syntactic constructions. It is quite possible that TT features are more useful to some syntactic structures than others. TT features seem to be good cues for identifying *CS*s. It is possible to compare the outputs from parsers with and without TT features (e.g. P1 vs. P4). The contribution of TT features towards specific constructions can be estimated empirically. Third, an insight from Collins (2003) is that head words and their POS tags in lexicalized parsing can improve parsing. In unlexicalized models, one can use the head POS tag alone to approximate similar mechanism.

6 Conclusion

This paper has demonstrated that TT features give rise to substantial gain in our classifier-based unlexicalized parser. The IT features have been explored as well, though the performance gain is more moderate. TT features can be inexpensively computed and flexibly incorporated into different types of parsers. Our parsing model matches early lexicalized parsing models in performance, and has good potential to do even better with adjustment and optimization. The statistical analysis of the treebank shows that TT features are effective in capturing basic linguistic properties, such as grammatical weight and branching direction, which are overlooked in previous studies of parsing. We have also hinted how TT features may have reduced chunking errors of *CS*s by producing balanced conjuncts. Though the present study focuses on unlexicalized parsing, it is likely that TT features can contribute to accuracy enhancement in other parsing models as well.

Abstract

This paper proposes an approach to improve graph-based dependency parsing by using decision history. We introduce a mechanism that considers short dependencies computed in the earlier stages of parsing to improve the accuracy of long dependencies in the later stages. This relies on the fact that short dependencies are generally more accurate than long dependencies in graph-based models and may be used as features to help parse long dependencies. The mechanism can easily be implemented by modifying a graph-based parsing model and introducing a set of new features. The experimental results show that our system achieves state-of-the-art accuracy on the standard PTB test set for English and the standard Penn Chinese Treebank (CTB) test set for Chinese.

1 Introduction

Dependency parsing is an approach to syntactic analysis inspired by dependency grammar. In recent years, interest in this approach has surged due to its usefulness in such applications as machine translation (Nakazawa et al., 2006), information extraction (Culotta and Sorensen, 2004).

Graph-based parsing models (McDonald and Pereira, 2006; Carreras, 2007) have achieved state-of-the-art accuracy for a wide range of languages as shown in recent CoNLL shared tasks (Buchholz et al., 2006; Nivre et al., 2007). However, to make parsing tractable, these models are forced to restrict features over a very limited history of parsing decisions (McDonald and Pereira, 2006; McDonald and Nivre, 2007). Previous work showed that rich features over a wide range of decision history can lead to significant improvements in accuracy for transition-based models (Yamada and Matsumoto, 2003a; Nivre et al., 2004).

In this paper, we propose an approach to improve graph-based dependency parsing by using decision history. Here, we make an assumption: the dependency relations between words with a short distance are more reliable than ones between words with a long distance. This is supported by the fact that the accuracy of short dependencies is in general greater than that of long dependencies as reported in McDonald and Nivre (2007) for graph-based models. Our idea is to use decision history, which is made in previous scans in a bottom-up procedure, to help parse other words in later scans. In the bottom-up procedure, short dependencies are parsed earlier than long dependencies. Thus, we introduce a mechanism in which we treat short dependencies built earlier as decision history to help parse long dependencies in later stages. It can easily be implemented by modifying a graph-based parsing model and designing a set of features for the decision history.

To demonstrate the effectiveness of the proposed approach, we present experimental results on English and Chinese data. The results indicate that the approach greatly improves the accuracy and that richer history-based features indeed make large contributions. The experimental results show that our system achieves state-of-the-art accuracy on the data.

2 Motivation

In this section, we present an example to show the idea of using decision history in a dependency parsing procedure.

Suppose we have two sentences in Chinese, as shown in Figures 1 and 2, where the correct dependencies are represented by the directed links. For example, in Figure 1 the directed link from

Coling 2008: Poster Volume, pages 126–134,
Beijing, August 2010

w_3:买(bought) to w_5:书(books) mean that w_3 is the head and w_5 is the dependent. In Chinese, the relationship between clauses is often not made explicit and two clauses may simply be put together with only a comma (Li and Thompson, 1997). This makes it hard to parse Chinese sentences with several clauses.

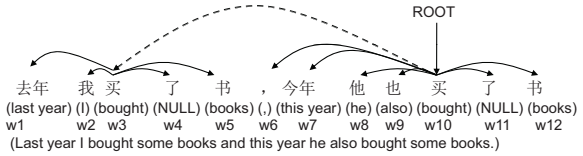

Figure 1: Example A

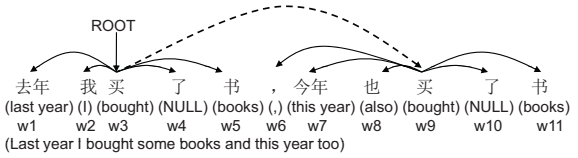

Figure 2: Example B

If we employ a graph-based parsing model, such as the model of (McDonald and Pereira, 2006; Carreras, 2007), it is difficult to assign the relations between w_3 and w_{10} in Example A and between w_3 and w_9 in Example B. For simplicity, we use w_i^A to refer to w_i of Example A and w_i^B to refer to w_i of Example B in what follows.

The key point is whether the second clauses are independent in the sentences. The two sentences are similar except that the second clause of Example A is an independent clause but that of Example B is not. w_{10}^A is the root of the second clause of Example A with subject w_8^A, while w_9^B is the root of the second clause of Example B, but the clause does not have a subject. These mean that the correct decisions are to assign w_{10}^A as the head of w_3^A and w_3^B as the head of w_9^B, as shown by the dash-dot-lines in Figures 1 and 2.

However, the model can use very limited information. Figures 3-(a) and 4-(a) show the right dependency relation cases and Figures 3-(b) and 4-(b) show the left direction cases. For the right direction case of Example A, the model has the information about w_3^A's rightmost child w_5^A and w_{10}^A's leftmost child w_6^A inside w_3^A and w_{10}^A, but it does not have information about the other children

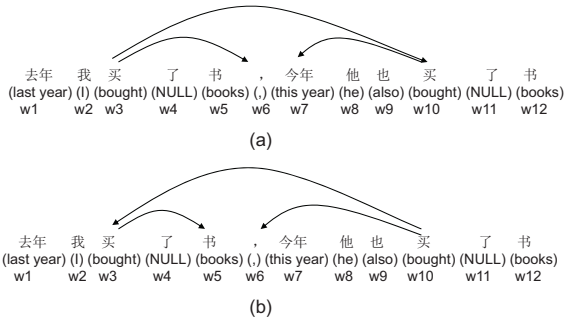

Figure 3: Example A: two directions

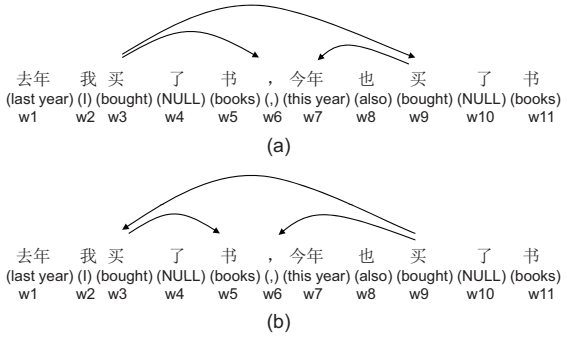

Figure 4: Example B: two directions

(such as w_8^A) of w_3^A and w_{10}^A, which may be useful for judging the relation between w_3^A and w_{10}^A. The parsing model can not find the difference between the syntactic structures of two sentences for pairs (w_3^A, w_{10}^A) and (w_3^B, w_9^B). If we can provide the information about the other children of w_3^A and w_{10}^A to the model, it becomes easier to find the correct direction between w_3^A and w_{10}^A.

Next, we show how to use decision history to help parse w_3^A and w_{10}^A of Example A.

In a bottom up procedure, the relations between the words inside [w_3^A, w_{10}^A] are built as follows before the decision for w_3^A and w_{10}^A. In the first round, we build relations for neighboring words (word distance[1]=1), such as the relations between w_3^A and w_4^A and between w_4^A and w_5^A. In the second round, we build relations for words of distance 2, and then for longer distance words until all the possible relations between the inside words are built. Figure 5 shows all the possible relations inside [w_3^A, w_{10}^A] that we can build. To simplify, we use undirected links to refer to both directions

[1]Word distance between w_i and w_j is $|j-i|$.

of dependency relations between words in the figure.

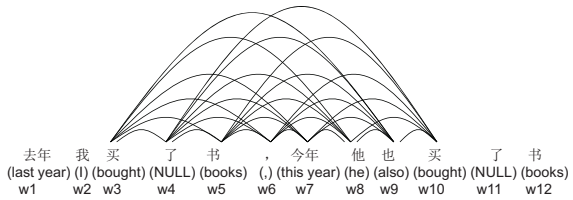

Figure 5: Example A: first step

Then given those inside relations, we choose the inside structure with the highest score for each direction of the dependency relation between w_3^A and w_{10}^A. Figure 6 shows the chosen structures. Note that the chosen structures for two directions could either be identical or different. In Figure 6-(a) and -(b), they are different.

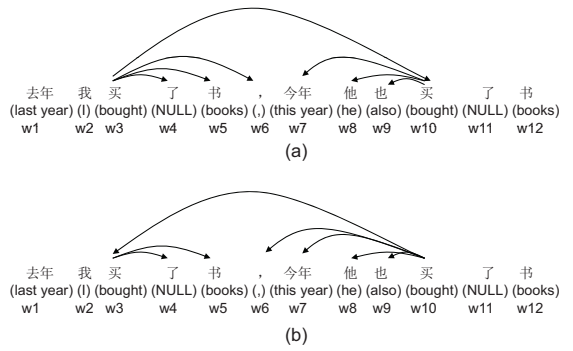

Figure 6: Example A: second step

Finally, we use the chosen structures as decision history to help parse w_3^A and w_{10}^A. For example, the fact that w_8^A is a dependent of w_{10}^A is a clue that suggests that the second clause may be independent. This results in w_{10}^A being the head of w_3^A.

This simple example shows how to use the decision history to help parse the long distance dependencies.

3 Background: graph-based parsing models

Before we describe our method, we briefly introduce the graph-based parsing models. We denote input sentence w by $w = (w_0, w_1, ..., w_n)$, where $w_0 = ROOT$ is an artificial root token inserted at the beginning of the sentence and does not depend on any other token in w and w_i refers to a word.

We employ the second-order projective graph-based parsing model of Carreras (2007), which is an extension of the projective parsing algorithm of Eisner (1996).

The parsing algorithms used in Carreras (2007) independently find the left and right dependents of a word and then combine them later in a bottom-up style based on Eisner (1996). A subtree that spans the words in $[s, t]$ (and roots at s or t) is represented by chart item $[s, t, right/left, C/I]$, where right (left) indicates that the root of the subtree is s (t) and C means that the item is *complete* while I means that the item is *incomplete* (McDonald, 2006). Here, *complete item* in the right (left) direction means that the words other than s (t) cannot have dependents outside $[s, t]$ and *incomplete item* in the right (left) direction, on the other hand, means that t (s) may have dependents outside $[s, t]$. In addition, t (s) is the direct dependent of s (t) in the incomplete item with the right (left) direction.

Larger chart items are created from pairs of smaller chart items by the bottom-up procedure. Figure 7 illustrates the cubic parsing actions of the Eisner's parsing algorithm (Eisner, 1996) in the right direction, where s, r, and t refer to the start and end indices of the chart items. In Figure 7-(a), all the items on the left side are complete and represented by triangles, where the triangle of [s, r] is complete item $[s, r, \rightarrow, C]$ and the triangle of [$r + 1$, t] is complete item $[r + 1, t, \leftarrow, C]$. Then the algorithm creates incomplete item $[s, t, \rightarrow, I]$ (trapezoid on the right side of Figure 7-(a)) by combining the chart items on the left side. This action builds the dependency from s to t. In Figure 7-(b), the item of [s, r] is incomplete and the item of [r, t] is complete. Then the algorithm creates complete item $[s, t, \rightarrow, C]$. For the left direction case, the actions are similar. Note that only the actions of creating the incomplete chart items build new dependency relations between words, while the ones of creating the complete items merge the existing structures without building new relations.

Once the parser has considered the dependency relations between words of distance 1, it goes on

to dependency relations between words of distance 2, and so on by the parsing actions. For words of distance 2 and greater, it considers every possible partition of the structures into two parts and chooses the one with the highest score for each direction. The score is the sum of the feature weights of the chart items. The features are designed over edges of dependency trees and the weights are given by model parameters (McDonald and Pereira, 2006; Carreras, 2007). We store the obtained chart items in a table. The chart item includes the information on the optimal splitting point of itself. Thus, by looking up the table, we can obtain the best tree structure (with the highest score) of any chart item.

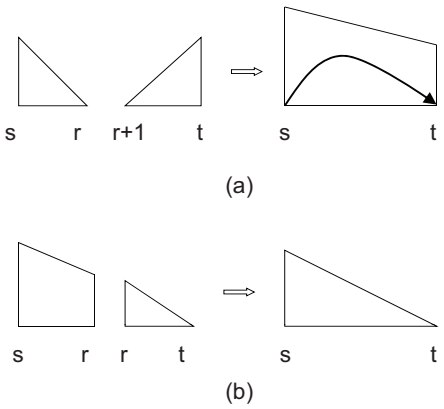

Figure 7: Cubic parsing actions of Eisner (1996)

4 Parsing with decision history

As mentioned above, the actions for creating the incomplete items build the relations between words. In this study, we only consider using history information when creating incomplete items.

4.1 Decision history

Suppose we are going to compute the scores of the relations between w_s and w_t. There are two possible directions for them.

By using the bottom-up style algorithm, the scores of the structures between words with distance $< |s-t|$ are computed in previous scans and the structures are stored in the table. We divide the decision history into two types: history-inside and history-outside. The history-inside type is the decision history made inside [s,t] and the history-outside type is the history made outside [s,t].

4.1.1 History-inside

We obtain the structure with the highest score for each direction of the dependency between w_s and w_t. Figure 8-(b) shows the best solution (with the highest score) of the left direction, where the structure is split into two parts, $[s, r_1, \rightarrow, C]$ and $[r_1 + 1, t, \leftarrow, C]$. Figure 8-(c) shows the best solution of the right case, where the structure is split into two parts, $[s, r_2, \rightarrow, C]$ and $[r_2 + 1, t, \leftarrow, C]$.

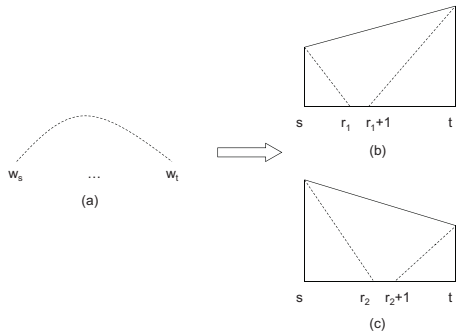

Figure 8: History-inside

By looking up the table, we have a subtree that roots at w_s on the right side of w_s and a subtree that roots at w_t on the left side of w_t. We use these structures as the information on history-inside.

4.1.2 History-outside

For history-outside, we try to obtain the subtree that roots at w_s on the left side of w_s and the one that roots at w_t on the right side of w_t. However, compared to history-inside, obtaining history-outside is more complicated because we do not know the boundaries and the proper structures of the subtrees. Here, we use an simple heuristic method to find a subtree whose root is at w_s on the left side of w_s and one whose root is at w_t on the right side of w_t.

We introduce two assumptions: 1) The structure within a sub-sentence [2] is more reliable than the one that goes across from sub-sentences. 2) More context (more words) can result in a better solution for determining subtree structures.

[2]To simplify, we split one sentence into sub-sentences with punctuation marks.

Algorithm 1 Searching for history-outside boundaries

1: Input: w, s, t
2: **for** $k = s - 1$ to 1 **do**
3: if(isPunct(w_k)) break;
4: if($s - k >= t - s - 1$) break
5: **end for**
6: $b_s = k$
7: **for** $k = t + 1$ to $|w|$ **do**
8: if(isPunct(w_k)) break;
9: if($k - t >= t - s - 1$) break
10: **end for**
11: $b_t = k$
12: Output: b_s, b_t

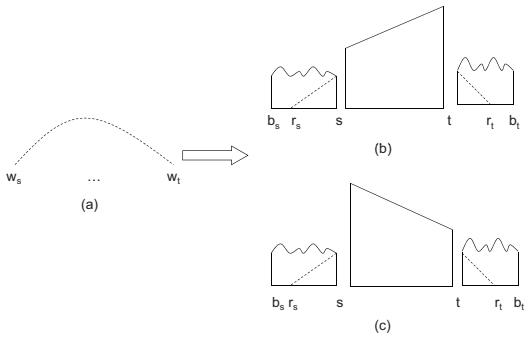

Figure 9: History-outside

Under these two assumptions, Algorithm 1 shows the procedure for searching for history-outside boundaries, where b_s is the boundary for for the descendants on the left side of w_s , b_t is the boundary for searching the descendants on the right side of w_t, and *isPunct* is the function that checks if the word is a punctuation mark. b_s should be in the same sub-sentence with s and $|s - b_s|$ should be less than $|t - s|$. b_t should be in the same sub-sentence with t and $|b_t - t|$ should be less than $|t - s|$.

Next we try to find the subtree structures. First, we collect the part-of-speech (POS) tags of the heads of all the POS tags in training data and remove the tags that occur fewer than 10 times. Then, we determine the directions of the relations by looking up the collected list. For b_s and s, we check if the POS tag of w_s could be the head tag of the POS tag of w_{b_s} by looking up the list. If so, the direction d is $\leftarrow$. Otherwise, we check if the POS tag of w_{b_s} could be the head tag of the POS tag of w_s. If so, d is $\rightarrow$, else d is $\leftarrow$. Finally, we obtain the subtree of w_s from chart item $[b_s, s, d, I]$. Similarly, we obtain the subtree of w_t. Figure 9 shows the history-outside information for w_s and w_t, where the relation between w_{b_s} and w_s and the relation between w_{b_t} and w_t will be determined by the above method. We have subtree $[r_s, s, left, C]$ that roots at w_s on the left side of w_s and subtree $[t, r_t, right, C]$ that roots at w_t on the right side of w_t in Figure 9-(b) and (c).

4.2 Parsing algorithm

Then, we explain how to use these decision history in the parsing algorithm. We use L_{st} to represent the scores of basic features for the left direction and R_{st} for the right case. Then we design history-based features (described in Section 4.3) based on the history-inside and history-outside information, as mentioned above. Finally, we update the scores with the ones of the history-based features by the following equations:

$$L^+_{st} = L_{st} + L^{df}_{st} \quad (1)$$

$$R^+_{st} = R_{st} + R^{df}_{st} \quad (2)$$

where L^+_{st} and R^+_{st} refer to the updated scores, L^{df}_{st} and R^{df}_{st} refer to the scores of the history-based features.

Algorithm 2 Parsing algorithm

1: Initialization: $V[s, s, dir, I/C] = 0.0 \; \forall s, dir$
2: **for** $k = 1$ to n **do**
3: **for** $s = 0$ to $n - k$ **do**
4: $t = s + k$
5: % Create incomplete items
6: L_{st}=$V[s, t, \leftarrow, I]$= $max_{s \leq r < t} VI(r)$;
7: R_{st}=$V[s, t, \rightarrow, I]$= $max_{s \leq r < t} VI(r)$;
8: Calculate L^{df}_{st} and R^{df}_{st};
9: % Update the scores of incomplete chart items
10: $V[s, t, \leftarrow, I]$=L^+_{st}=$L_{st} + L^{df}_{st}$
11: $V[s, t, \rightarrow, I]$=R^+_{st}=$R_{st} + R^{df}_{st}$
12: % Create complete items
13: $V[s, t, \leftarrow, C]$= $max_{s \leq r < t} VC(r)$;
14: $V[s, t, \rightarrow, C]$= $max_{s < r \leq t} VC(r)$;
15: **end for**
16: **end for**

Algorithm 2 is the parsing algorithm with the history-based features, where $V[s, t, dir, I/C]$ refers to the score of chart item $[s, t, dir, I/C]$, $VI(r)$ is a function to search for the optimal sibling and grandchild nodes for the incomplete items (line 6 and 7) (Carreras, 2007) given the

splitting point r and return the score of the structure, and $VC(r)$ is a function to search for the optimal grandchild node for the complete items (line 13 and 14). Compared with the parsing algorithms of Carreras (2007), Algorithm 2 uses history information by adding line 8, 10, and 11.

In Algorithm 2, it first creates chart items with distance 1, then goes on to chart items with distance 2, and so on. In each round, it searches for the structures with the highest scores for incomplete items shown at line 6 and 7 of Algorithm 2. Then we update the scores with the history-based features by Equation 1 and Equation 2 at line 10 and 11 of Algorithm 2. However, note that we can not guarantee to find the candidate with the highest score with Algorithm 2 because new features violate the assumptions of dynamic programming.

4.3 History-based features

In this section, we design features that capture the history information in the recorded decisions.

For a dependency between two words, say s and t, there are four subtrees that root at s or t. We design the features by combining s, t with each child of s and t in the subtrees. The feature templates are shown as follows: (In the following, c means one of the children of s and t, and the nodes in the templates are expanded to their lexical form and POS tags to obtain actual features.):

C+Dir this feature template is a 2-tuple consisting of (1) a c node and (2) the direction of the dependency.

C+Dir+S/C+Dir+T this feature template is a 3-tuple consisting of (1) a c node, (2) the direction of the dependency, and (3) a s or t node.

C+Dir+S+T this feature template is a 4-tuple consisting of (1) a c node, (2) the direction of the dependency, (3) a s node, and (4) a t node.

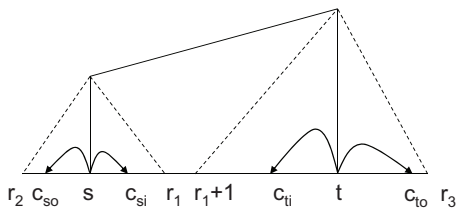

Figure 10: Structure of decision history

We use SHI to represent the subtree of s in the history-inside, THI to represent the one of t in the history-inside, SHO to represent the one of s in the history-outside, and THO to represent the one of t in the history-outside. Based on the subtree types, the features are divided into four sets: F_{SHI}, F_{THI}, F_{SHO}, and F_{THO} refer to the features related to the children that are in subtrees SHI, THI, SHO, and THO respectively.

Figure 10 shows the structure of decision history of a left dependency (between s and t) relation. For the right case, the structure is similar. In the figure, SHI is chart item $[s, r_1, \rightarrow, C]$, THI is chart item $[r_1 + 1, t, \leftarrow, C]$, SHO is chart item $[r_2, s, \leftarrow, C]$, and THO is chart item $[t, r_3, \rightarrow, C]$. We use c_{si}, c_{ti}, c_{so}, and c_{to} to represent a child of s/t in subtrees SHI, THI, SHO, and THO respectively. The lexical form features of F_{SHI} and F_{SHO} are listed as examples in Table 1, where "L" refers to the left direction. We can also expand the nodes in the templates to the POS tags. Compared with the algorithm of Carreras (2007) that only considers the furthest children of s and t, Algorithm 2 considers all the children.

Table 1: Lexical form features of F_{SHI} and F_{SHO}

template	F_{SHI}	F_{SHO}
C+DIR	word-c_{si}+L	word-c_{so}+L
C+DIR+S	word-c_{si}+L+word-s	word-c_{so}+L+word-s
C+DIR+T	word-c_{si}+L+word-t	word-c_{so}+L+word-t
C+DIR +S+T	word-c_{si}+L +word-s+word-t	word-c_{so}+L +word-s+word-t

4.4 Policy of using history

In practice, we define several policies to use the history information for different word pairs as follows:

- All: Use the history-based features for all the word pairs without any restriction.
- Sub-sentences: use the history-based features only for the relation of two words from sub-sentences. Here, we use punctuation marks to split sentences into sub-sentences.
- Distance: use the history-based features for the relation of two words within a predefined distance. We set the thresholds to 3, 5, and 10.

5 Experimental results

In order to evaluate the effectiveness of the history-based features, we conducted experiments on Chinese and English data.

For English, we used the Penn Treebank (Marcus et al., 1993) in our experiments and the tool "Penn2Malt"[3] to convert the data into dependency structures using a standard set of head rules (Yamada and Matsumoto, 2003a). To match previous work (McDonald and Pereira, 2006; Koo et al., 2008), we split the data into a training set (sections 2-21), a development set (Section 22), and a test set (section 23). Following the work of Koo et al. (2008), we used the MXPOST (Ratnaparkhi, 1996) tagger trained on training data to provide part-of-speech tags for the development and the test set, and we used 10-way jackknifing to generate tags for the training set.

For Chinese, we used the Chinese Treebank (CTB) version 4.0[4] in the experiments. We also used the "Penn2Malt" tool to convert the data and created a data split: files 1-270 and files 400-931 for training, files 271-300 for testing, and files 301-325 for development. We used gold standard segmentation and part-of-speech tags in the CTB. The data partition and part-of-speech settings were chosen to match previous work (Chen et al., 2008; Yu et al., 2008).

We measured the parser quality by the unlabeled attachment score (UAS), i.e., the percentage of tokens with the correct HEAD [5]. And we also evaluated on complete dependency analysis.

In our experiments, we implemented our systems on the MSTParser[6] and extended with the parent-child-grandchild structures (McDonald and Pereira, 2006; Carreras, 2007). For the baseline systems, we used the first- and second-order (parent-sibling) features that were used in McDonald and Pereira (2006) and other second-order features (parent-child-grandchild) that were used in Carreras (2007). In the following sections, we call the second-order baseline systems Baseline and our new systems OURS.

5.1 Results with different feature settings

In this section, we test our systems with different settings on the development data.

Table 2: Results with different policies

	Chinese	English
Baseline	89.04	92.43
D_1	88.73	92.27
D_3	88.90	92.36
D_5	89.10	92.59
D_{10}	89.32	92.57
D_{sub}	89.57	92.63

Table 2 shows the parsing results when we used different policies defined in Section 4.4 with all the types of features, where D_{sub} refers to applying the policy: sub-sentence, D_1 refers to applying the policy: all, and $D_{3|5|10}$ refers to applying the policy: distance with the predefined distance 3, 5, or 10. The results indicated that the accuracies of our systems decreased if we used the history information for short distance words. The system with D_{sub} performed the best.

Table 3: Results with different types of Features

	Chinese	English
Baseline	89.04	92.43
+F_{SHI}	89.14	92.53
+F_{THI}	89.33	92.35
+F_{SHO}	89.25	92.47
+F_{THO}	88.99	92.54

Then we investigated the effect of different types of the history-based features. Table 3 shows the results with policy D_{sub}. From the table, we found that F_{THI} provided the largest improvement for Chinese and F_{THO} performed the best for English.

In what follows, we used D_{sub} as the policy for all the languages, the features $F_{SHI} + F_{THI} + F_{SHO}$ for Chinese, and the features $F_{SHI} + F_{SHO} + F_{THO}$ for English.

5.2 Main results

The main results are shown in the upper parts of Tables 4 and 5, where the improvements by OURS over the Baselines are shown in parentheses. The results show that OURS provided better performance over the Baselines by 1.02 points for Chi-

KOO2008	93.16	–
Chen2009	93.16	47.15
Suzuki2009	93.79	–

nese and 0.29 points for English. The improvements of (OURS) were significant in McNemar's Test with $p < 10^{-4}$ for Chinese and $p < 10^{-3}$ for English.

5.3 Comparative results

Table 4 shows the comparative results for Chinese, where Zhao2009 refers to the result of (Zhao et al., 2009), Yu2008 refers to the result of Yu et al. (2008), Chen2009 refers to the result of Chen et al. (2009) that is the best reported result on this data, and STACK refers to our implementation of the combination parser of Nivre and McDonald (2008) using our baseline system and the MALTParser[7]. The results indicated that OURS performed better than Zhao2009, Yu2008, and STACK, but worse than Chen2009 that used large-scale unlabeled data (Chen et al., 2009). We also implemented the combination system of OURS and the MALTParser, referred as OURS+STACK in Table 4. The new system achieved further improvement. In future work, we can combine our approach with the parser of Chen et al. (2009).

Table 5 shows the comparative results for English, where Y&M2003 refers to the parser of Yamada and Matsumoto (2003b), CO2006 refers to the parser of Corston-Oliver et al. (2006), Z&C 2008 refers to the combination system of Zhang and Clark (2008), STACK refers to our implementation of the combination parser of Nivre and McDonald (2008), KOO2008 refers to the parser of Koo et al. (2008), Chen2009 refers to the parser of Chen et al. (2009), and Suzuki2009 refers to the parser of Suzuki et al. (2009) that is the best reported result for this data. The results shows that OURS outperformed the first two systems that were based on single models. Z&C 2008 and STACK were the combination systems of graph-based and transition-based models. OURS performed better than Z&C 2008, but worse than STACK. The last three systems that used large-scale unlabeled data performed better than OURS.

6 Related work

There are several studies that tried to overcome the limited feature scope of graph-based dependency parsing models .

Nakagawa (2007) proposed a method to deal with the intractable inference problem in a graph-based model by introducing the Gibbs sampling algorithm. Compared with their approach, our approach is much simpler yet effective. Hall (2007) used a re-ranking scheme to provide global features while we simply augment the features of an existing parser.

Nivre and McDonald (2008) and Zhang and Clark (2008) proposed stacking methods to combine graph-based parsers with transition-based parsers. One parser uses dependency predictions made by another parser. Our results show that our approach can be used in the stacking frameworks to achieve higher accuracy.

7 Conclusions

This paper proposes an approach for improving graph-based dependency parsing by using the decision history. For the graph-based model, we design a set of features over short dependencies computed in the earlier stages to improve the accuracy of long dependencies in the later stages. The results demonstrate that our proposed approach outperforms baseline systems by 1.02 points for Chinese and 0.29 points for English.

Abstract

We conduct a series of Part-of-Speech (POS) Tagging experiments using Expectation Maximization (EM), Variational Bayes (VB) and Gibbs Sampling (GS) against the Chinese Penn Treebank. We want to first establish a baseline for unsupervised POS tagging in Chinese, which will facilitate future research in this area. Secondly, by comparing and analyzing the results between Chinese and English, we highlight some of the strengths and weaknesses of each of the algorithms in POS tagging task and attempt to explain the differences based on some preliminary linguistics analysis. Comparing to English, we find that all algorithms perform rather poorly in Chinese in 1-to-1 accuracy result but are more competitive in many-to-1 accuracy. We attribute one possible explanation of this to the algorithms' inability to correctly produce tags that match the desired tag count distribution.

1 Introduction

Recently, there has been much work on unsupervised POS tagging using Hidden Markov Models (Johnson, 2007; Goldwater & Griffiths, 2007). Three common approaches are Expectation Maximization (EM), Variational Bayes (VB) and Gibbs Sampling (GS). EM was first used in POS tagging in (Merialdo, 1994) which showed that except in conditions where there are no labeled training data at all, EM performs very poorly. Gao and Johnson (2008) compared EM, VB and GS in English against the Penn Treebank Wall Street Journal (WSJ) text. Their experiments on English showed that GS outperforms EM and VB in almost all cases. Other notable studies in the unsupervised and semi-supervised POS domain include the use of prototype examples (Haghighi & Klien, 2006), dictionary constraints to guide the algorithms (Elworthy 1994; Banko & Moore 2004) and Bayseian LDA-based model (Toutanova and Johnson, 2007).

To our knowledge, little work has been done on unsupervised POS tagging in Chinese against the Chinese Penn Treebank (CTB). The work in Chinese POS tagging has been predominately in the supervised fashion (Huang et al. 2009; Chang & Chen, 1993; Ng & Low, 2004) and achieve accuracy of 92.25% using a traditional ngram HMM tagger. For English, a supervised trigram tagger achieves an accuracy of 96.7% against the Penn Treebank (Thorsten, 2000).

In this study, we analyze and compare the performance of three classes of unsupervised learning algorithms on Chinese and report the experimental results on the CTB. We establish a baseline for unsupervised POS tagging in Chinese. We then compare and analyze the results between Chinese and English, we explore some of the strengths and weaknesses of each of the algorithms in POS tagging task and attempt to explain the differences based on some preliminary linguistics analysis.

2 Models

In this section, we provide a brief overview of the three unsupervised learning methods for POS tagging as described in (Gao & Johnson, 2008), which all uses a traditional bigram Hidden Markov Model (HMM). HMM is a well-

Coling 2008: Poster Volume, pages 135–143,
Beijing, August 2010

known statistical model, used for sequential modeling. To put it formally, let $T = \{t_1, \ldots, t_i, \ldots, t_j, \ldots, t_{|T|}\}$ be the set of possible states and $W = \{w_1, \ldots, w_k, \ldots, w_{|W|}\}$ be the set of possible observations. In the case for POS tagging using a bigram model, the set T corresponds to the set of POS tags and the set W corresponds to the set of words in the language.

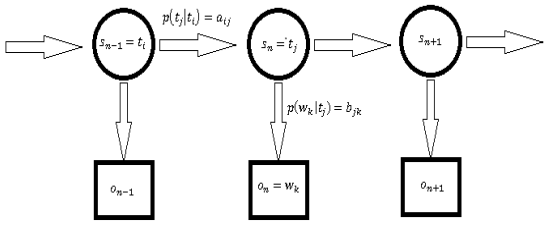

Figure 1: Graphical model of an HMM for a bigram POS tagger. The top row represents a sequence of hidden states where each is conditionally dependent only on the previous state and the bottom row represents a sequence of observations where each is conditionally dependent only on the current state.

An HMM models a sequence of discrete observations $o_{1:N} = \{o_1, \ldots, o_N\}$ where $o_n = w_k$ that are produced by a sequence of hidden states $\boldsymbol{s}_{1:N} = \{s_1, \ldots, s_N\}$ where $s_n = t_i$. The sequence of states is produced by a first order Markov process such that the current state s_n depends only on its previous state s_{n-1}; correspondingly each of the observations o_n depends only on the state s_n:

$$p(s_n|\boldsymbol{s_{1:n-1}}) \cong p(s_n|s_{n-1}) \\ p(o_n|\boldsymbol{s_{1:n}}\, \boldsymbol{o}_{1:n-1}) \cong p(o_n|s_n) \qquad (1)$$

where $a_{ij} = p(s_n|s_{n-1})$ is the probability of transition to state $s_n = t_j$ from $s_{n-1} = t_i$ and $b_{jk} = p(o_n|s_n)$ is the probability of observation $o_n = w_k$ produced by $s_n = t_j$. The parameter θ for the HMM is defined by the transition probability distribution $A \equiv (a_{ij})$, emission (observation) probability distribution $B \equiv (b_{jk})$ and the initial probability $\pi \equiv \prod p(s_0 = t_i)$. Direct calculation of the likelihood $p(s, o|\theta)$ is computationally inefficient, and we can use dynamic programming techniques to speed up the calculation by calculating the forward probability:

$$\alpha_i(n) \equiv p(o_{1:n}, s_n = t_i|\theta) \qquad (2)$$

and backward probability

$$\beta_i(n) \equiv p(o_{n:N}|s_n = t_i, \theta). \qquad (3)$$

See (Mannings & Schutze, 1999) for details on the calculation.

2.1 Expectation Maximization (EM)

EM is a general class of algorithms for finding the maximum likelihood estimator of parameters in probabilistic models. It is an iterative algorithm where we alternate between calculating the expectation of the log likelihood of the model given the parameters:

$$Q(\theta|\theta^t) = \mathbb{E}_{p(s|o,\theta)} \ln p(s, o|\theta) \qquad (4)$$

and then finding the parameters that maximizes the expected log likelihood. Using Lagrange multipliers with constraint that each parameter is a probability distribution, we have these update steps for the well-known forward-backward Algorithm for EM HMM:

$$\pi^{t+1} : \pi_i = \alpha_i(1)\beta_i(1)$$

$$A^{t+1} : a_{ij} = \frac{\sum_{n=2} \alpha_i(n) a_{ij} b_{jo_n} \beta_j(n+1)}{\sum_{i=1}^{T} \alpha_i(n) \beta_{\ i}(n)} \qquad (5)$$

$$B^{t+1} : b_{jk} = \sum_{n=1}^{N} \frac{\alpha_i(n) a_{ij} b_{jo_n} \beta_j(n+1) \delta(o_n, k)}{\sum_{i=1}^{T} \alpha_i(n) \beta_i(n)}$$

where $\delta(o_n, k) = \begin{cases} 1, & o_n = w_k \\ 0, & o.w. \end{cases}$.

2.2 Variational Bayes (VB)

One of the drawbacks of EM is that the resulting distribution is very uniform; that is, EM applies roughly the same number of observations for each state. Instead of using only the best model for decoding, the Bayesian approach uses and considers all the models; that is, the model is treated as a hidden variable. This is done by assigning a probability distribution over the model parameters as a prior distribution, $p(\theta)$.

In HMM, we calculate the probability of the observation by considering all models and integrating over the distribution over the priors:

$$p(\boldsymbol{o}_{1:N}) = \int p(o_{1:N}|\theta)p(\theta)\,d\theta \quad (6)$$

where $p(\theta) = p(\pi)p(A)p(B)$.

As with the standard in the literature, we use Dirichlet Prior as it allows us to model the tag distribution more closely and because they are in the same conjugate exponential family as the log likelihood. The Dirichlet distribution is parameterized by a vector of real values $\boldsymbol{\alpha}$ (hyper-parameters). There are two ways that we can view the vector $\boldsymbol{\alpha}$. First, the parameter controls the sharpness of distribution for each of the components. This is in contrast to the EM model where we essentially have a uniform prior. Thus, we can view $\boldsymbol{\alpha}$ as our prior beliefs on the shape of the distribution and we can make our choices based on our linguistics knowledge. Second, we can view the role of $\boldsymbol{\alpha}$ in terms of predictive distribution based on the statistics from observed counts. For HMM, we can set a separate prior for each state-state transition and word-state emission distribution, effectively giving us control over the distribution of each entry in the transition matrix. However, to simplify the model and without the need to fine tune each parameters, we use two fixed hyper-parameters: all of the state-state probability will have the hyper-parameter α_{TT} and all of the word-state probability will have hyper-parameter α_{WT}.

To begin our estimation and maximization procedure, we create $q(\theta, s_{1:N}) \approx q(\theta)q(s_{1:N})$ as an approximation of the posterior of the log likelihood:

$$\ln p(\boldsymbol{o}_{1:N}) \geq \int \sum_{s} q(\theta, s_{1:N}) \ln \frac{p(o_{1:N}, s_{1:N}|\theta)p(\theta)}{q(\theta, s_{1:N})} d\theta \quad (7)$$

By taking the functional derivative with respect to $q(\theta)$ to find the distribution that maximizes the log likelihood, and following the derivation from (Beal, 2003), we arrive at the following EM-like procedure:

$$\begin{aligned} &\mathrm{E}_{q(s)}[\delta(s_1, t_i)] \\ &= \alpha_i(1)\beta_i(1)\mathrm{E}_{q(s)}\big[\delta(s_{n-1}, t_i)\delta\big(s_n, t_j\big)\big] \\ &= \frac{\alpha_i(n)a_{ij}b_{jo_n}\beta_j(n+1)}{\sum_{i=1}^{T}\alpha_i(n)\beta_i(n)} \end{aligned} \quad (8)$$

$$\begin{aligned} &\mathrm{E}_{q(s)}[\delta(s_n, t_i)\delta(o_n, w_k)] \\ &= \frac{\alpha_i(n)a_{ij}b_{jo_n}\beta_j(n+1)\delta(o_n, w_k)}{\sum_{i=1}^{T}\alpha_i(n)\beta_i(n)} \end{aligned}$$

This is the Expectation step where α and β is the forward and backward probabilities and $\delta(o_n, w_k)$ is the indicator function as in EM.

The Maximization step is as follows:

$$\begin{aligned} &\pi^{t+1} : \pi_i \\ &= \frac{\exp(\psi(\alpha_{TT} + \mathrm{E}_{q(s)}[\delta(s_1, t_i)]))}{\exp(\psi(\sum_{i=1}^{T}\alpha_{TT} + \mathrm{E}_{q(s)}[\delta(s_1, t_i)]))} \\ &A^{t+1} : a_{ij} \\ &= \frac{\exp(\psi(\alpha_{TT} + \sum_{n=2}^{N}\mathrm{E}_{q(s)}[*]))}{\exp(\psi(\sum_{i=1}^{T}\alpha_{TT} + \sum_{n=2}^{N}\mathrm{E}_{q(s)}[*]))} \\ &B^{t+1} : b_{jk} \\ &= \frac{\exp(\psi(\alpha_{WT} + \sum_{n=1}^{N}\mathrm{E}_{q(s)}[**]))}{\exp(\psi(\sum_{i=1}^{T}\alpha_{WT} + \sum_{n=1}^{N}\mathrm{E}_{q(s)}[**]))} \end{aligned} \quad (9)$$

where $\mathrm{E}_{q(s)}[*] = E_{q(s)}[\delta(s_{n-1}, t_i)\delta(s_n, t_j)]$, $\mathrm{E}_{q(s)}[**] = E_{q(s)}[\delta(s_n, t_j)\delta(o_n, w_k)]$ and ψ is the digamma function.

2.3 Gibbs Sampling (GS)

Gibbs sampling (Geman & Geman, 1984) is a widely used MCMC algorithm designed especially for cases where we can sample from the conditional probability easily. It is a straightforward application of the Metropolis Hasting algorithm where we sample a variable t_k while keeping $t_{\setminus k}$ constant where $t_{\setminus k} = \{t_1, \ldots, t_{k-1}, t_{k+1}, \ldots, t_T\}$. We set the proposal distribution to

$$q_k(t^*|t^n) = p\big(t_k\big|t_{\setminus k}\big). \quad (10)$$

So the sampling procedure is the following: initialize the components of $\boldsymbol{t} = \{t_1, , \ldots, t_T\}$. Then sample t_1 from $p(t_1|t_2, \ldots, t_T)$, t_2 from $p(t_2|t_1, t_3, \ldots, t_T)$, and so on for each component of t. For POS tagging, the main idea is that we sample the tag t based on the $p(t|t')$ and $p(w|t)$ distribution.

The main idea for using GS for POS tagging is that in each iteration, we sample the tag t based on the $p(t|t')$ and $p(w|t)$ distribution.

Then from the samples, we count the number for each state-state and word-state pairs and update the probabilities accordingly. How we sample the data depends on whether we are using word based or sentence based sampling (the Expectation Step). Whereas how we update the probabilities depend on whether we are using a collapsed or explicit Gibbs sampler (the Maximization Step).

Word Based vs. Sentence Based: Word-based and sentence-based approaches to GS determine how we sample the each tag t at position n in the data set. For the word-based approach, instead of going through sentence by sentence (as in EM and VB procedures), we pick a word position in the corpus at random (without repetition) and sample a new tag t_i at position n using the probability:

$$p(s_n = t_i) = p(t_i|s_{n-1})p(w_k = o_n|t_i)p(s_{n+1}|t_i) \quad (11)$$

Notice that since we are selecting each position at random, the tag s_{n-1} at position n-1 and s_{n+1} at position n+1 are our samples at the previous iteration or an already updated samples at the current iteration.

The sentence-based approach use the forward and backward probability to sample the tag based on the sentence (Besag, 2004). Specifically, we use the backward probability $\beta_i(n) \equiv p(o_{1:n}|s_n = t_i, \theta)$ to sample the sentence from start $(n = 1)$ to finish $(n = N)$. We sample a new tag t_i at position n using the probability:

$$p(s_n = t_i|o_{1:n}, s_{1:n-1}, \theta) = p(t_i|s_{n-1})p(w_k = o_n|t_i)\beta_i(n) \quad (12)$$

where the transition and emission probability distribution are from the current model parameters. Again s_{n-1} is our "guess" at the previous sampling step of the tag of s_{n-1}.

Explicit vs. Collapsed Based: We use the tags estimated at the previous step to maximize the parameters. Our choice of using Dirichlet distributions over the parameters $P(A)$ and $P(B)$ give us some nice mathematical properties. We show that $p(A|\boldsymbol{o}_{1:N})$ and $p(B|\boldsymbol{o}_{1:N})$ also calculate to be Dirichlet distributions. Following (MacKay & Peto, 1994), the posterior probability of A can be derived as follows:

$$\begin{aligned} p(A|\boldsymbol{o}_{1:N}) &= \frac{p(\boldsymbol{o}_{1:N}|A)p(A)}{p(\boldsymbol{o}_{1:N})} \\ &= \frac{1}{p(\boldsymbol{o}_{1:N})}\prod_{n=1}^{N} a_{s_n,s_{n-1}} \prod_i^T \prod_j^T \frac{a_{ij}^{\alpha-1}\Gamma(\alpha_{TT})}{\Gamma(|T|\alpha_{TT})} \\ &= \prod_{i=1}^{T}\prod_{j=1}^{T} \frac{a_{ij}^{C(t_i,t_j)+\alpha_{TT}-1}\Gamma\left(\alpha_{TT} + C(t_i,t_j)\right)}{\Gamma(|T|\alpha_{TT} + \sum c(t_i,t_j)} \\ &= \prod_j Dir(a_{ij}|\, c(t_i,t_j) + \alpha_{TT}) \end{aligned} \quad (13)$$

where $c(t_i, t_j)$ is the number of times t_i is followed by t_j in the sample from the previous iteration.

Similarly, we can define $p(B|o_{1:N})$ using the count $c(w_k, t_j)$ to show that:

$$p(B|\boldsymbol{o}_{1:N}) = \prod_k Dir(b_{jk}|\, c(w_k,t_j) + \alpha_{WT}) \quad (14)$$

For the collapsed Gibbs sampler, we want to integrate over all possible model parameters A to maximize the new transition probabilities using Maximum a posteriori (MAP) estimator:

$$\begin{aligned} p(t_j|t_i, o_{1:N}) &= \int p(t_j|t_i, A, o_{1:N})p(A|\boldsymbol{o}_{1:N})dA \\ &= \int a_{ij}\prod_j Dir(a_{ij}|\, c(t_i,t_j) + \alpha_{TT})\, dA \\ &= \frac{c(t_i,t_j) + \alpha_{TT}}{\sum c(t_i,t_j) + |T|\alpha_{TT}} \end{aligned} \quad (15)$$

The last equality uses the following result:

$$\int \boldsymbol{\pi} Dir(\boldsymbol{\pi}|u)d\boldsymbol{\pi} = \frac{u}{|\pi|u} \quad (16)$$

We can derive a similar result for $p(w_k|t_i, o_{1:N})$. Then we can use the sample count to update the new parameter values.

An explicit sampler samples the HMM parameters θ in addition to the states. Specifically, in the Bayesian model, we will need to sample from the Dirichlet distribution for the parameters

$$p(A|o_{1:N}) = \prod_j Dir(a_{ij}|\, c(t_i, t_j) + \alpha_{TT}) \quad (17)$$

$$p(B|\boldsymbol{o}_{1:N}) = \prod_k Dir(b_{jk}|\, c(t_j, w_k) + \alpha_{WT})$$

derived above. An n-dimensional Dirichlet distribution variable can be generated from gamma variate (Wolfram Mathematica, 2009):

$$u_{ij} \sim f(x, c(t_i, t_j) + \alpha_{TT}) = \frac{x^{c(t_i,t_j)+\alpha_{TT}-1} e^{-x}}{\Gamma(c(t_i, t_j) + \alpha_{TT})} \quad (18)$$

we can update the transition probability by generating the gamma variate for the Dirichlet distribution:

$$a_{ij} \leftarrow \frac{u_{ij}}{\sum_j u_{ij}}. \quad (19)$$

Similarly, we sample the emission probability using the count for word-tag with $c(w_k, t_j) + \alpha_{WT}$ as the hyper-parameter.

3 Experiment Setup

Our experiment setup is similar to the ones used in (Gao & Johnson, 2007). They are summarized in Table 1:

Parameters	**Values**
Data Size	24k, 120k, 500k
Algorithm	EM, VB, GS(c,w), GS(c,s), GS(e,s), GS(e,w)
# of states	Chinese: 33 English: 50
α_{TT}	0.0001, 0.1, 0.5, 1
α_{WT}	0.0001, 0.1, 0.5, 1

Table 1: The list of experiments conducted. For the hyper-parameters $(\alpha_{TT}, \alpha_{WT})$, we try the combination of the adjacent pairs – (0.0001,0.0001), (0.1,0.0001), (0.0001,0.1), (0.1, 0.1), (0.1, 0.5), etc.

3.1 Data

For our experiments, we use the data set Chinese Penn Treebank (CTB) v5.0. The Chinese Treebank project began at the University of Pennsylvania in 1998 and the team created a set of annotation guidelines for word segmentation, POS tagging and bracketing (Xia, 2000; Xue et al., 2002; Xue et al., 2005). The version used in this paper is the Chinese Treebank 5.0 which consists of over 500k words and over 800k Chinese characters. The text comes from various sources including newswire, magazine articles, website news, transcripts from various broadcast news program.

Chinese POS tagging faces additional challenges because it has very little, if any, inflectional morphology. Words are not inflected with number, gender, case, or tense. For example, a word such as 毁灭 in Chinese corresponds to d*estroy /destroys /destroyed/destruction* in English. This fuels the discussion in Chinese NLP communities on whether the POS tags should be based on meaning or on syntactic distribution (Xia, 2000). If only the meaning is used, 毁灭 should be a verb all the time. If syntactic distribution is used, the word is a verb or a noun depending on the context. For the CTB, syntactic distribution is used, which complies with the principles of contemporary linguistics theories.

Following the experiment done for English in (Gao & Johnson, 2008), we split the data into three sizes: 24k words, 120k words and all words (500k), and used the same data set for training and testing. The idea is to track the effectiveness of an algorithm across different corpus sizes. Instead of using two different tag set sizes (17 and 50) as it is done for English POS tagging, we opt to keep the original 33 tag set for Chinese without further modification. In addition to reporting the results for English from (Gao & Johnson, 2008), we run additional experiments on English using only 500k words for comparison.

3.2 Decoding

For decoding, we use max marginal likelihood estimator (as opposed to using Viterbi algorithm) to assign a tag for each word in the result tag. (Gao & Johnson, 2008) finds that max marginal decoder performs as well as Viterbi algorithm and runs significantly faster as we can reuse the forward and backwards probabilities already calculated during the estimation and update step.

3.3 Hyperparameters

For the Bayesian approaches (VB and GS), we have a choice of hyperparameters. We choose uniform hyperparameters α_{TT} and α_{WT} instead

of choosing a specific hyper-parameter for each of the tag-tag and word-tag distribution. The values for the hyper-parameters are chosen such that we can see more clearly the interactions between the two values. For GS, we use the notation GS(c,s) to denote collapsed sentence-based approach, GS(e,s) for explicit sentence based, GS(c,w) for collapsed word-based and GS(e,w) for explicit word based.

3.4 Evaluation Metrics

We use POS tagging accuracy as our primary evaluation method. There are two commonly used methods to map the state sequences from the system output to POS tags. In both methods, we first create a matrix where each row corresponds to a hidden state, each column corresponds to a POS tag, and each cell (i,j) represents the number of times a word position in the test data comes from the hidden state t_i according to the system output and the position has tag t_j according to the gold standard. In greedy 1-to-1 mapping, we find the largest value in the table – suppose the value is for the cell (i,j). We map state i to tag j, and remove both row i and column j from the table. We repeat the process until all the rows have been removed. Greedy many-to-1 allow multiple hidden states to map to a single POS tag. That is, when the highest value in the table is found, only the corresponding row is removed. In other words, we simply map each hidden state to the POS tag that the hidden state co-occurs with the most.

4 Results and Analysis

We compare and analyze the results between the different algorithms and between Chinese and English using Greedy 1-to-1 accuracy, Greedy many-to-1 accuracy.

4.1 Greedy 1-to-1 accuracy

When measure using 1-to-1 mapping, the best algorithm – Collapsed word based Gibbs Sampling GS(c,w) - achieve 0.358 in Chinese on the full data set but remains close to 0.499 in English for the full dataset. GS(c,w) outperforms other algorithm in almost all categories. But EM posts the highest relative improvement with an increase of 70% when the data size increases from 24k to 500k words. The full result is listed in Table 2.

		Greedy 1-to-1		
		24k	120k	500k
Chinese	**EM**	0.1483	0.1838	0.2406
	VB	0.1925	0.2498	0.3105
	GS(e,w)	0.2167	0.3108	0.3475
	GS(e,s)	0.2262	0.2596	0.3572
	GS(c,s)	0.2351	0.2931	**0.3577**
	GS(c,w)	**0.2932**	**0.3289**	0.3558
Eng	**EM**	0.1862	0.2930	0.3837
	VB	0.2382	0.3468	0.4327
	GS(c,w)	**0.3918**	**0.4276**	**0.4348**

Table 2: Tagging accuracy for Chinese and English with greedy 1-to-1 mapping. The English 24k and 120k results are taken from (Gao & Johnson 2008) with the 50-tag set.

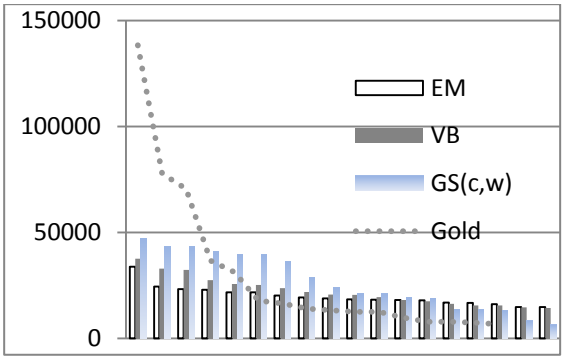

Figure 2: Tag distribution for 1-to-1 greedy mapping in Chinese 500k. Only the top 18 tags are shown. The figure compares the tag distribution between the gold standard for Chinese (33 tags) and the algorithm's results. The gold tags are shown as lines, and each algorithm's result is shown as bar graphs.

As expected, the increase in data size improves the accuracy as EM algorithm optimizes the likelihood better with more data. We ran additional experiments on English using a reduced 500k dataset to match the dataset used for Chinese; EM in this setting achieve an accuracy of 0.384 on average for 50 tags (down from 0.405). So even in the reduced data size setting, EM on English performs better than Chinese although the difference is reduced. We analyze the tag distribution of the 1-to-1 mapping. (Johnson, 2007) finds that EM generally assigns roughly as equal number of words for each state. In Figure 2, we find the same phenomenon for Chinese.

One of the advantages of Bayesian approaches (VB and GS) is that we can assign a prior to attempt to encourage a sparse model distribution. Despite using small values 0.0001 as hyperparameters, we find that the resulting distribution for number of words mapping to a particular state is very different from the gold standard.

4.2 Greedy many-to-1 accuracy

Collapsed Word Based Gibbs Sampler GS(c,w) is the clear winner for both English and Chinese unsupervised POS tagging. Table 3 shows the result of Greedy many-to-1 mapping for Chinese in different data size as well as English with the full data set. In Greedy many-to-1 mapping, GS(c,w) in both Chinese and English achieve 60%+ accuracy. In addition, the size of the dataset does not affect GS(c,w) as much as the other algorithms. In fact, the change from 24k to 500k dataset only increases the relative accuracy by less than 6%.

	Greedy many-to-1			
		24k	120k	500k
Chinese	**EM**	0.4049	0.4564	0.4791
	VB	0.4411	0.5023	0.5390
	GS(e,w)	0.4758	0.4969	0.5499
	GS(e,s)	0.4904	0.5369	0.5658
	GS(c,s)	0.5070	0.5701	0.5757
	GS(c,w)	**0.5874**	**0.6180**	**0.6213**
Eng	**EM**	0.2828	0.44135	0.5872
	VB	0.3595	0.48427	0.6025
	GS(c,w)	**0.5815**	**0.6529**	**0.6644**

Table 3: Many-to-1 accuracy for Chinese and English. The English 24k and 120k results are taken from (Gao & Johnson 2008) with the 50-tag set.

However, despite the relatively high accuracy, when analyzing the result, we notice that there are overwhelmingly many states which maps to a single POS tag (NN). Figure 3 shows the number of states mapping to different POS tags in Chinese over the 500k data size. There are a large number of states mapping to relatively few POS tags. In the most extreme example, for the POS tag NN, GS(e,s) assigns 18 (the most) hidden states, accounts for 44% of the word tokens mapping to NN whereas GS(e,w) assigns 13 states, which is actually the least among all the algorithms and accounts for 31% of the word tokens mapping to NN. Notice that we have only a total of 33 hidden states in our model. This means that over half the states are mapped to NN, which is a rather disappointing result. The actual empirical result for the gold standard in CTB is that only 27% of the word should be mapped to NN. For EM in particular, we see 17 states accounting for 42% of the words tagged as NN.

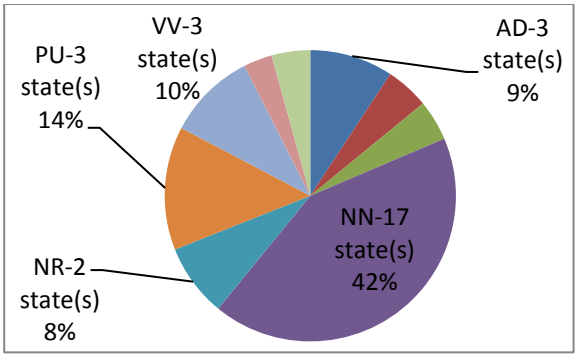

Figure 3: The distribution of POS tags based on the output EM algorithm in Chinese using the 500k dataset. Tag T-N-y% means that there are N hidden states mapped to the specific POS tag T accounting for y% of word tokens tagged with these N states by the EM algorithm.

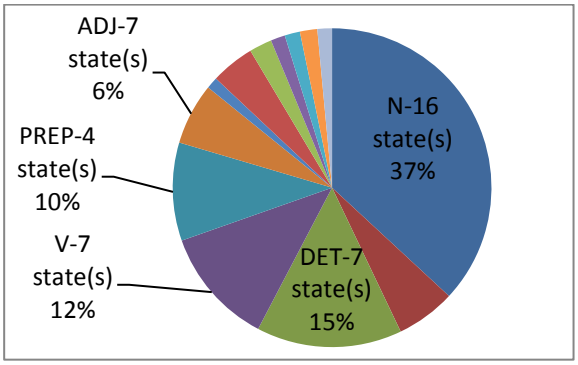

Figure 4: English tag distribution for EM using 500k dataset with 50 states mapping to the 17 pos tag set. Tag T-N-y% means that there are N hidden states mapped to the specific POS tag T accounting for y% of word tokens tagged with these N states.

We also ran additional experiments on the algorithms for English using a reduced data size of 500k to match that of our Chinese experiment to see whether we see the same phenomena. We notice that the tag distribution for English EM is more consistent to the empirical distribution found in the gold standard.

With the English 50 tag set with 500k words, we experiment with mapping the English 50 tag set result to the 17 tag set, we see that in Figure 4, 16 (of 50) states mapped to the N tag, accounting for 37% of the words in the dataset. This is close to the actual empirical distribution for English for 17 tags where N accounts for about 32%.

4.3 Convergence

We analyze how each algorithm converges to its local maxima. Figure 5 shows the change in greedy 1-to-1 accuracy over the 50% of the run.

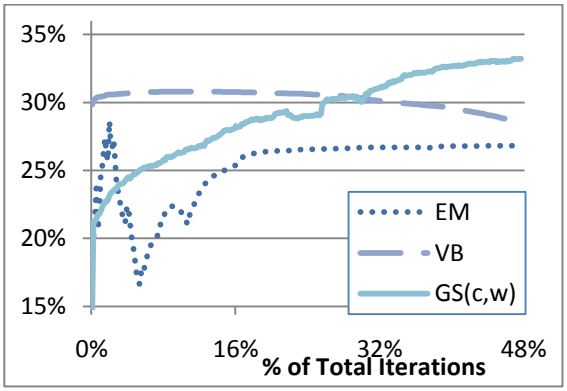

Figure 5: Greedy 1-to-1 accuracy of EM, VB and GS(c,w) over the first 50% of the algorithms' iterations for the Chinese 500k dataset. Note: the percentage of iterations is used here because each algorithms converge at a different number of iterations, thus the progress is scaled accordingly.

The greedy 1-to-1 accuracy actually fluctuates through the run. VB has an interesting dip at around 80% of its iteration before climbing to its max (not showing in the graph). All the Gibbs sampling variations follow a relatively steady hill climb before converging (only GS(c,w) is shown in Figure 5). EM is particularly interesting; Looking at the initial 15% of the algorithm's run, we can see that EM climbs to a "local" max very quickly before dropping and then slowly improving in its accuracy. The greedy 1-to-1 accuracy in the initial top is actually higher than the final convergence value in most runs. This initial peak in value following by a drop and then a slow hill climb in EM for Chinese POS tagging is consistent with the finding in (Johnson, 2007) for English POS tagging.

5 Conclusion and Future Work

We have only scratched the surface of the research in unsupervised techniques in Chinese NLP. We have established a baseline of EM, VB and GS against the CTB 5.0. The experiment shows that for both Chinese and English, GS(c,w) produces the best result. We have also found that Chinese performs rather poorly in the 1-to-1 accuracy when comparing against English in the same data size. We find that in many-to-1 mapping, we have a disproportionate large number of states mapping to individual POS tags comparing to the gold distribution and also in comparison to English against its gold distribution.

Graça et al. (2009) addresses the problem we observe in our resulting tag distributions in our model where EM, VB and GS fails to capture the shape of the true distribution. They propose a Posterior Regularization framework where it poses linear constraints on the posterior expectation. They define a set distributions Q over hidden states with a constraint on the expectation over the features. The log likelihood is penalized using the KL-divergence between the Q distribution and the model. The distributions that their model predicted are far more similar to the gold standard than traditional EM.

Liang and Klein (2009) propose some interesting error analysis techniques for unsupervised POS tagging. One of their analyses on EM is done by observing the approximation errors being created during each iteration of the algorithm's execution. We can also perform these analyses on VB and GS and observe the changes of output tags by starting from the Gold Standard distribution in EM and VB, and gold standard tags in GS. We can then follow how and which set of tags start to deviate from the gold standard. This will allow us to see which categories of errors (ex. noun-verb, adj-adv errors) occur most in these algorithms and how the error progresses.

Abstract

This article delves into the scoring function of the statistical paraphrase generation model. It presents an algorithm for exact computation and two applicative experiments. The first experiment analyses the behaviour of a statistical paraphrase generation decoder, and raises some issues with the ordering of n-best outputs. The second experiment shows that a major boost of performance can be obtained by embedding a true score computation inside a Monte-Carlo sampling based paraphrase generator.

1 Introduction

A paraphrase generator is a program which, given a source sentence, produces a new sentence with almost the same meaning. The modification place is not imposed but the paraphrase has to differ from the original sentence.

Paraphrase generation is useful in applications where it is needed to choose between different forms to keep the most fit. For instance, automatic summary can be seen as a particular paraphrasing task (Barzilay and Lee, 2003) by selecting the shortest paraphrase. They can help human writers by proposing alternatives and having them choose the most appropriate (Max and Zock, 2008).

Paraphrases can also be used to improve natural language processing (NLP) systems. In this direction, (Callison-Burch et al., 2006) tried to improve machine translations by enlarging the coverage of patterns that can be translated. In the same way, most NLP systems like information retrieval (Sekine, 2005) or question-answering (Duclaye et al., 2003), based on pattern recognition, can be improved by a paraphrase generator.

Most of these applications need a n-best set of solutions in order to rerank them according to a task-specific criterion.

In order to produce the paraphrases, a promising approach is to see the paraphrase generation problem as a statistical translation problem. In that approach, the target language becomes the same as the source language (Quirk et al., 2004; Bannard and Callison-Burch, 2005; Max and Zock, 2008).

The first difficulty of this approach is the need of a paraphrase table. A paraphrase table is a monolingual version of a translation table in the statistical machine translation (SMT) field. In this field, the difficulty is basically overcome by using huge aligned bilingual corpora like the Europarl (Koehn, 2005) corpus. In the paraphrase generation field, one needs a huge aligned monolingual corpus to build a paraphrase table.

The low availability of such monolingual corpora nurtures researches in order to find heuristics to produce them (Barzilay and Lee, 2003; Quirk et al., 2004). On the other hand, an interesting method proposed by (Bannard and Callison-Burch, 2005) tries to make a paraphrase table using a translation table learned on bilingual corpora. The method uses a well-known heuristic (Lepage and Denoual, 2005) which says that if two sentences have the same translation, then they should be paraphrases of each others.

Another aspect, less studied, is the generation process of paraphrases, *i.e.* the decoding process in SMT. This process is subject to combinatorial

Coling 2008: Poster Volume, pages 144–152,
Beijing, August 2010

explosions. Heuristics are then frequently used to drive the exploration process in the *a priori* intractable high dimensional spaces. On the one hand, these heuristics are used to build a paraphrase step by step according to the paraphrase table. On the other hand, they try to evaluate the relevance of a step according to the global paraphrase generation model. The SMT model score is related to the path followed to generate a paraphrase. Because of the step-by-step computation, different ways can produce the same paraphrase, but with different scores. Amongst these scores, the best one is the true score of a paraphrase according to the SMT model.

Most paraphrase generators use some standard SMT decoding algorithms (Quirk et al., 2004) or some off-the-shelf decoding tools like MOSES. The goal of these decoders is to find the best path in the lattice produced by the paraphrase table. This is basically achieved by using dynamic programming – especially the *Viterbi* algorithm – and beam searching (Koehn et al., 2007). The best paraphrase proposed by these programs is known not to be the optimal paraphrase. One can even question if the score returned is the true score.

We first show in Section 2 that in the particular domain of statistical paraphrase generation, one can compute true *a posteriori* scores of generated paraphrases. We then explore some applications of the true score algorithm in the paraphrase generation field. In Section 3, we show that scores returned by SMT decoders are not always true scores and they plague the ranking of output n-best solutions. In Section 4, we show that the true score can give a major boost for holistic paraphrases generators which do not rely on decoding approaches.

2 True Score Computing

2.1 Context

The phrase based SMT model (Koehn et al., 2003) can be transposed to paraphrase generation as follows:

$$t^* = \arg\max_t P(t) \times P(s|t, B)$$

where s is the source sentence, t the target sentence *i.e.* the paraphrase, t^* the best paraphrase and B a model of the noisy channel between the source and target languages *i.e.* the paraphrase table. This can be decomposed into:

$$t^* \approx \arg\max_{t,I} P(t) \prod_{i \in I} P(s_i^I | t_i^I, B)$$

where I is a partition of the source sentence and x_i^I the i^{th} segment in the sentence x. For a given couple of s, t sentences, it exists several segmentations I with different probabilities.

This is illustrated in Example 1. Depending on the quality of the paraphrase table, one can find up to thousands of paraphrase segments for a source sentence. Note that the generated paraphrases are not always semantically or even syntactically correct, as in P2. P3 illustrates the score evaluation problem: it can be generated by applying to the source sentence the sequences of transformations $\{T1, T2\}$, $\{T1, T4, T5\}$ or even $\{T5, T1, T4\}$ ...

Example 1 Decoding

Source sentence:

The dog runs after the young cat.

Paraphrase table excerpt:

T1: P(the beast | the dog) = 0.8

T2: P(the kitten | the young cat) = 0.7

T3: P(after it | after the) = 0.4

T4: P(the | the young) = 0.05

T5: P(cat | kitten) = 0.1

Some possible generated paraphrases:

P1: the beast runs after the young cat.

P2: *the dog runs after it young cat.

P3: the beast runs after the kitten.

We define the score of a potential paraphrase t following a segmentation I as:

$$Z_t^I = P(t) \prod_{i \in I} P(s_i^I | t_i^I, B)$$

The true score of a potential paraphrase t is defined as:

$$Z_t^* = \max_I Z_t^I$$

Because of high-dimension problems, decoders apply sub-optimal algorithms to search for t^*. They produce estimated solutions over all possible paraphrases t and over all possible segmentations I. Actually, for a given paraphrase t, they consider only some Z_t^I where they should estimate Z_I^*. SMT decoders are overlooking the partitioning step in their computations.

There is no reason for the decoder solution to reach the true score. Troubles arise when one needs the scores of generated paraphrases, for instance when the system must produce an ordered n-best solution. What is the relevance of the estimated scores – and orders – with respect to the true scores – and orders – of the model? Is the true score able to help the generation process?

2.2 Algorithm

Let us first adopt the point of view proposed in (Chevelu et al., 2009). The paraphrase generation problem can be seen as an exploration problem. We seek the best paraphrase according to a scoring function in a space to search by applying successive transformations. This space is composed of states connected by actions. An action is a transformation rule with a place where it applies in the sentence. States are a sentence with a set of possible actions. Applying an action in a given state consists in transforming the sentence of the state and removing all rules that are no more applicable. In this framework, each state, except the root, can be a final state.

The SMT approach fits within this point of view. However, generation and evaluation need not to be coupled any longer. Computing the true score of a generated paraphrase is in reality a task computationally easier than generating the best paraphrases. Once the target result is fixed, the number of sequences transforming the source sentence into the target paraphrase becomes computationally tractable under a reasonable set of assumptions:

A1: the transformation rules have disjoint supports (meaning that no rule in the sequence should transform a segment of the sentence already transformed by one of of the previous applied rules) ;

A2: no reordering model is applied during the paraphrasing transformation.

Under this set of assumptions, the sequence (ordered) of transformation rules becomes a set (unordered) of transformation rules. One can therefore easily determine all the sets of transformation rules from the source sentence to the target paraphrase: they are a subset of the cross-product set of every transformation rule with a source included in the source sentence and with a result included in the target paraphrase. And this cross-product set remains computationally tractable. Note that to guarantee a solution, the corpus of all rules should be augmented with an identity rule for each word of the source sentence (with an associated probability of applicability set to 1) missing in the paraphrase table.

The algorithm for computing *ex post* the true score is given on algorithm 1.

Algorithm 1 Algorithm for true score

Let S be the source sentence.
Let T be the target sentence.
Let $R : s_R \rightarrow t_R$ be a transformation rule

Let $map : (S, T) \rightarrow C$ be a function

Let $C = \{\emptyset\}$

$\forall s_{head} | S = s_{head}.s_{tail}$,

$\forall R \in \{\Omega | s_R = s_{head}, T = t_R.t_{tail}\}$

$C = C \cup (\{R\} \otimes map(S_{tail}, T_{tail}))$

return C

Let $score$ be the scoring function for a transformation rule set

$$truescore_{S,\Omega}(T) = \arg \max_{c \in map(S,T)} (score(c))$$

For our toy example, we would get the steps shown in Example 2.

3 True Score of SMT Decoders

We have shown that it is possible to compute the true score according to the paraphrase model. We now evaluate scores from a state-of-the-art

Example 2 True Score Computation

Generated sets:

$\{R1\}, \{R1, R3\}, \{R1, R2\},$

$\{R1, R4\}, \{R1, R4, R5\},$

$\{R3\},$

$\{R2\},$

$\{R4\}, \{R4, R5\},$

$\{R5\}$

For a better readability, all identity rules are omitted.

The true scores are computed as in the following examples:

$score($ "the dog runs after the small cat." $\rightarrow$
"the beast runs after it small cat")
$= score(\{R1\})$

$score($ "the dog runs after the small cat." $\rightarrow$
"the beast runs after the kitten")
$= \max(score(\{R1, R2\}), score(\{R1, R4, R5\}))$

decoder against this baseline. In particular, we are interested in the order of n-best outputs. We use the MOSES decoder (Koehn et al., 2007) as a representative SMT decoder inside the system described below.

3.1 System description

Paraphrase generation tools based on SMT methods need a language model and a paraphrase table. Both are computed on a training corpus.

The language models we use are n-gram language models with back-off. We use SRILM (Stolcke, 2002) with its default parameters for this purpose. The length of the n-grams is five.

To build a paraphrase table, we use a variant of the construction method via a pivot language proposed in (Bannard and Callison-Burch, 2005). The first step consists in building a bilingual translation table from the aligned corpus. Given a source phrase s^i and another phrase t^i in a different language, a bilingual translation table provides the two probabilities $p(s^i|t^i)$ and $p(t^i|s^i)$. We use GIZA++ (Och and Ney, 2003) with its default parameters to produce phrase alignments. The paraphrase table is then built from the phrase translation table. The probability for a phrase s^i to be paraphrased by a phrase s'^i in the same language is estimated by the sum of each round-trip from s^i to s'^i through any phrase t^i of a pivot language.

The construction of this table is very simple. Given a bilingual translation table sorted by pivot phrases, the algorithm retrieves all the phrases linked with the same pivot (named a *pivot cluster*). For each ordered pair of phrases, the program assigns a probability that is the product of there probabilities. This process realizes a self-join of the bilingual translation table. It produces a paraphrase table composed of tokens, instead of items. The program just needs to sum up all probabilities for all entries with identical paraphrase tokens to produce the final paraphrase table.

Three heuristics are used to prune the paraphrase table. The first heuristic prunes any entry in the paraphrase table composed of tokens with a probability lower than a threshold ϵ. The second, called *pruning pivot heuristic*, consists in deleting all pivot clusters larger than a threshold τ. The last heuristic keeps only the κ most probable paraphrases for each source phrase in the final paraphrase table. For this study, we empirically fix $\epsilon = 10^{-5}$, $\tau = 200$ and $\kappa = 20$.

The MOSES scoring function is set by four weighting factors $\alpha_\Phi, \alpha_{LM}, \alpha_D, \alpha_W$. Conventionally, these four weights are adjusted during a tuning step on a training corpus. The tuning step is inappropriate for paraphrasing because there is no such tuning corpus available. We empirically set $\alpha_\Phi = 1$, $\alpha_{LM} = 1$, $\alpha_D = 10$ and $\alpha_W = 0$. This means that the paraphrase table and the language model are given the same weight, no reordering is allowed and no specific sentence length is favored.

3.2 Experimental Protocol

For experiments reported in this paper, we use one of the largest, multi-lingual, freely available aligned corpus, Europarl (Koehn, 2005). It consists of European parliament debates. We choose French as the language for paraphrases and English as the pivot language. For this pair of languages, the corpus consists of 1,723,705 sentences. Note that the sentences in this corpus are long, with an average length of 30 words per French sentence and 27.8 for English. We randomly extract 100 French sentences as a test cor-

pus.

For each source sentence from the test corpus, the SMT decoder tries to produce a 100-best distinct paraphrase sequence. Using the algorithm 1, we compute the true score of each paraphrase and rerank them. We then compare orders output by the decoder with the true score order by using the Kendall rank correlation coefficient (τ_A) (Kendall, 1938). In this context, the Kendall rank correlation coefficient considers each couple of paraphrases and checks if their relative order is preserved by the reranking. The τ_A formula is:

$$\tau_A = \frac{n_p - n_i}{\frac{1}{2}n(n-1)}$$

where n_p the number of preserved orders, n_d the number of inverted orders and n the number of elements in the sequence. The coefficient provides a score – between -1 and 1 – that can be interpreted as a correlation coefficient between the two orders. In order to compare same length sequences, we filter out source sentences when MOSES can not produce enough distinct paraphrases. The test corpus is therefore reduced to 94 sentences.

3.3 Results

The evolution of τ_A means relative to the length of the n-best sequence is given Figure 1. The τ_A means drops to 0.73 with a standard deviation of 0.41 for a 5-best sequence which means that the orders are clearly different but not decorrelated.

A finer study of the results reveals that amongst the generated paraphrases, 32% have seen their score modified. 18% of the MOSES 1-best paraphrases were not optimal anymore after the true score reranking. After reranking, the old top best solutions have dropped to a mean rank of 2.0 ± 17.7 (40th rank at worse). When considering only the paraphrases no longer optimal, they have dropped to a mean rank of 6.8 ± 12.9.

From the opposite point of view, new top paraphrases after reranking have come from a mean rank of 4.4 ± 12.1. When considering only the paraphrases that were not optimal, they have come from a mean rank of 21.2 ± 23.5. Some have come from the 67th rank. Even an *a posteriori* reranking would not have retrieved this top solution if the size of MOSES n-best list were too short. This

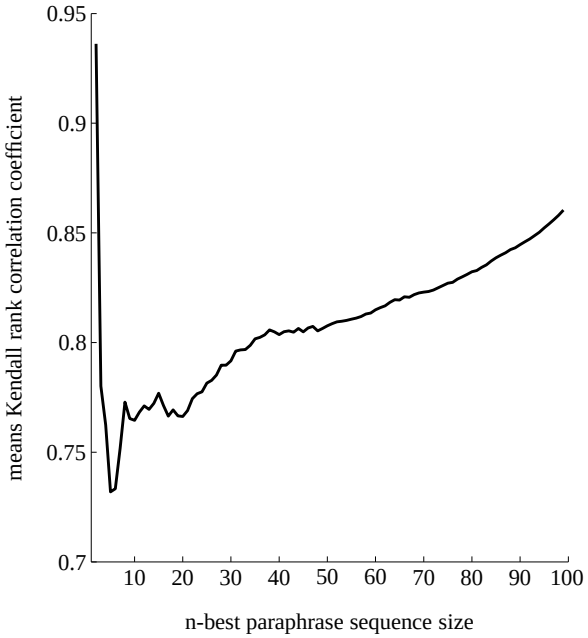

Figure 1: Evolution of τ_A means relative to the length of the n-best sequence

advocates for a direct embedding of the true score function inside the generation process.

In this section we have shown that MOSES scores are not consistent with the true score as expected from the paraphrase model. In particular, the n-best paraphrase sequence computed by MOSES is not trustworthy while it is an input for the task system.

4 True Score to boost Monte-Carlo based Paraphrase Generation

There exist other less common approaches more lenient than the *Viterbi* algorithm, which are holistic, *i.e.* they work on the whole sentence rather than step-by-step. The *Monte-Carlo based Paraphrase Generation* algorithm (MCPG) proposed in (Chevelu et al., 2009) turns out to be an interesting algorithm for the study of paraphrase generation. It does not constraint the scoring function to be incremental. In this section, we embed the non incremental true score function in MCPG to drive the generation step and produce n-best orders compliant with the paraphrase model, and show that the true score function can be used to provide a major boost to the performance of such

an algorithm.

4.1 Description

The MCPG algorithm is a derivative of the *Upper Confidence bound applied to Tree* algorithm (UCT). UCT (Kocsis and Szepesvári, 2006), a *Monte-Carlo* planning algorithm, has recently become popular in two-player game problems.

UCT has some interesting properties:

- it expands the search tree non-uniformly and favours the most promising sequences, without pruning branch;
- it can deal with high branching factors;
- it is an any-time algorithm and returns best solutions found so far when interrupted;
- it does not require expert domain knowledge to evaluate states.

These properties make it ideally suited for problems with high branching factors and for which there is no strong evaluation function.

For the same reasons, this algorithm is interesting for paraphrase generation. In particular, it does not put constraint on the scoring function. A diagram of the MCPG algorithm is presented Figure 2.

The main part of the algorithm is the sampling step. An episode of this step is a sequence of states and actions, $s_1, a_1, s_2, a_2, \ldots, s_T$, from the root state to a final state. Basically, a state is a partially generated paraphrase associated with a set of available actions. A final state is a potential paraphrase. An action is a transformation rule from the paraphrase table. During an episode construction, there are two ways to select the action a_i to perform from a state s_i.

If the current state was already explored in a previous episode, the action is selected according to a compromise between exploration and exploitation. This compromise is computed using the UCB-Tunned formula (Auer et al., 2001) associated with the RAVE heuristic (Gelly and Silver, 2007). If the current state is explored for the first time, its score is estimated using *Monte-Carlo* sampling. In other words, to complete the

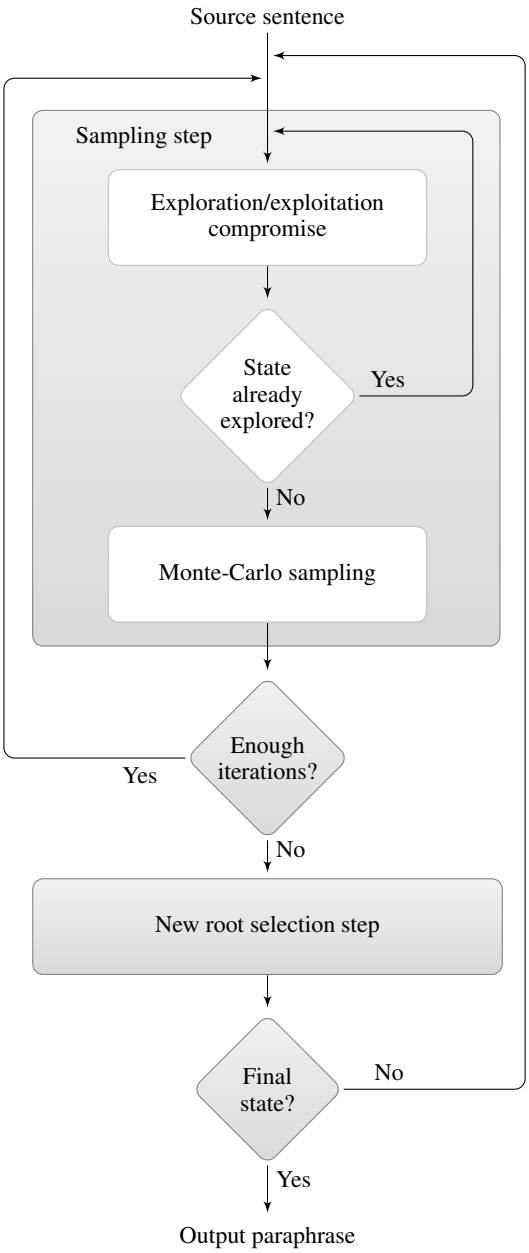

Figure 2: The MCPG algorithm.

episode, the actions $a_i, a_{i+1}, \ldots, a_{T-1}, a_T$ are selected randomly until reaching a final state.

At the end of each episode, a reward is computed for the final state s_T using a scoring function, and the value of each (state, action) pair of the episode is updated. Then, the algorithm computes another episode with the new values.

Periodically, the sampling step is stopped and the best action at the root state is selected. This action is then definitively applied and a sampling is restarted from the new root state. The action sequence is incrementally built and selected after being sufficiently sampled. For our experiment, we have chosen to stop sampling regularly after a fixed amount η of episodes.

The adaptation of the original algorithm takes place in the (state, action) value updating procedure. Since the goal of the algorithm is to maximise a scoring function, it uses the maximum reachable score from a state as value instead of the score expectation. This algorithm suits the paradigm recalled in Section 2 for paraphrase generation.

To provide scores comparable with the paraphrase model scores, the standard version of MCPG has to apply rules until the whole source sentence is covered. With this behaviour, MCPG acts in a monolingual "translator" mode.

The embedding of the true score algorithm in MCPG has given meaningful scores to all states. The algorithm needs not to "translate" the whole sentence to get a potential paraphrase and its score. This MCPG algorithm in "true-score" mode can choose to stop its processing with segments still unchanged, which solves, amongst others, out-of-vocabulary questions found in decoder-based approaches.

4.2 Experimental Protocol

For this experiment, we reuse the paraphrase table and the corpora generated for the experiment presented in Section 3.2;

We compare the 1-best outputs from MOSES reranked by the true score function and from MCPG in both "translator" and "true-score" modes. For MCPG systems, we set the following parameters: $\eta = 100{,}000$ iterations.

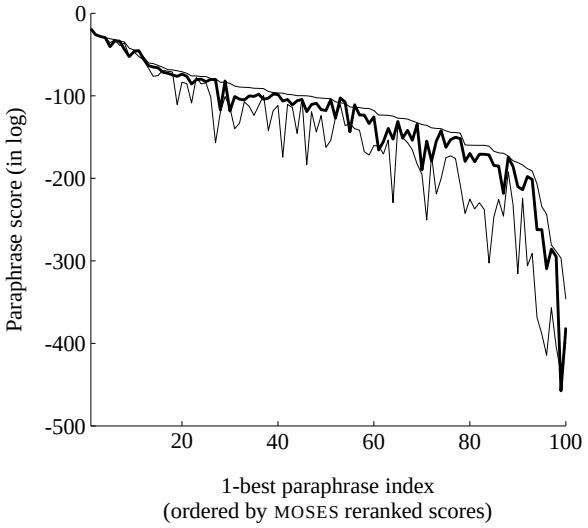

Figure 3: Comparison of paraphrase generators. Top: the MOSES baseline; middle and bold: the "true-score" MCPG; down: the "translator" MCPG. The use of "true-score" improves the MCPG performances. MCPG reaches MOSES performance level.

4.3 Results

Figure 3 presents a comparison between the scores from each systems, ordered by MOSES reranked scores.

The boost of performance gained by using true scores inside the MCPG algorithm reaches a means of 28.79 with a standard deviation of 34.19. The mean difference between "true-score" MCPG and MOSES is -14.13 (standard deviation 19.99). Although the performance remains inferior to the MOSES true score baseline, it still leads to an improvement over the "translator" MCPG system. The later system has a mean difference of performance with MOSES of -42.92 (standard deviation of 40.14).

The true score reduces the number of transformations needed to generate a paraphrase, which simplifies the exploration task. Moreover, it reduces the number of states in the exploration space: two sets of transformations producing the same paraphrase now leads to the same state. These points explain why MCPG has become more efficient.

Although MCPG is improved by embedding the

true score algorithm, there is still room for improvement. In its current version, MCPG does not adapt the number of exploration episodes to the input sentence.

5 Conclusion and perspectives

In this paper, we have developed a true scoring algorithm adapted to the statistical paraphrase generation model. We have studied its impacts on a common SMT decoder and a Monte-Carlo sampling based paraphrase generator. It has revealed that the n-best outputs by SMT decoders were not viable. It has also proved useful in simplifying the exploration task and in improving holistic paraphrase generators.

Thanks to the boost introduced by the true score algorithm in holistic paraphrase generators, their performances are now on a par with scores produced by statistical translation decoders. Moreover, they produce guaranteed ordering, and enable the integration of a global task scoring function, which seems still out of reach for decoder-based systems.

A more general problem remains open: what do the scores and the orders output by the model mean when compared to a human subjective evaluation?

In preliminary results on our test corpus, less than 37% of the MOSES generated paraphrases can be considered both syntactically correct and semantically a paraphrase of their original sentence. One could study the relations between scores from the model and subjective evaluations to create predictive regression models. The true score algorithm can autonomously score existing paraphrase corpora which could be used to adapt the SMT tuning step for paraphrase generation.

We note that the hundredth best paraphrases from MOSES have a score close to the best paraphrase: the mean difference is 5.9 (standard deviation 4.5) on our test corpus. This is smaller than the mean difference score between MOSES and MCPG. In (Chevelu et al., 2009), both systems were rated similar by a subjective evaluation. One could question the relevance of small score differences and why the best paraphrase should be selected instead of the hundred next ones. Given the current state of the art, the next step to improve paraphrase generation does not lie in score optimisation but in refining the model and its components: the language model and the paraphrase table.

Human based evaluations reveal that the current most important issue of paraphrase generation lies in the syntax (Chevelu et al., 2009). It seems difficult to assess the syntax of a potential paraphrase while not considering it as a whole, which is impossible with a local scoring function inherent to the SMT decoding paradigm. Holistic paraphrase generators have now reached a level of performance comparable to SMT decoders, without suffering from their limitations. They are paving the way for experiments with more complex semantic and linguistic models to improve paraphrase generation.

Acquisition of Unknown Word Paradigms for Large-Scale Grammars

Abstract

Unknown words are a major issue for large-scale grammars of natural language. We propose a machine learning based algorithm for acquiring lexical entries for all forms in the paradigm of a given unknown word. The main advantages of our method are the usage of word paradigms to obtain valuable morphological knowledge, the consideration of different contexts which the unknown word and all members of its paradigm occur in and the employment of a full-blown syntactic parser and the grammar we want to improve to analyse these contexts and provide elaborate syntactic constraints. We test our algorithm on a large-scale grammar of Dutch and show that its application leads to an improved parsing accuracy.

1 Introduction

In this paper, we present an efficient machine learning based method for automated lexical acquisition (LA) which improves the performance of large-scale computational grammars on real-life tasks.

Our approach has three main advantages which distinguish it from other methods applied to the same task. First, it enables the acquisition of the *whole paradigm* of a given unknown word while other approaches are only concerned with the particular word form encountered in the data subject to LA. Second, we analyse *different contexts* which the unknown word occurs in. Third, the analysis of these contexts is provided by a *full-blown syntactic parser* and the *grammar* we aim to improve which gives the grammar the opportunity to participate *directly* in the LA process.

Our method achieves an F-measure of 84.6% on unknown words in experiments with the wide-coverage Alpino grammar (van Noord, 2006) of Dutch. The integration of this method in the parser leads to a 4.2% error reduction in terms of labelled dependencies.

To predict a lexical entry for a given unknown word, we take into account two factors– its morphology and the syntactic constraints imposed by its context. As for the former, the acquisition of the whole paradigm provides us with a valuable source of morphological information. If we were to deal with only one form of the unknown word, this information would not be accessible.

Further, looking at different contexts of the unknown word gives us the possibility to work with linguistically diverse data and to incorporate more syntactic information into the LA process. Cases where this is particularly important include morphologically ambiguous words and verbs which subcategorize for various types of syntactic arguments. We also consider contexts of the other members of the paradigm of the unknown word in order to increase the amount of linguistic data our method has access to.

Finally, the usage of a *full-blown syntactic parser* and the *grammar* we want to acquire lexical entries for has two advantages. First, LA can benefit from the high-quality analyses such a parser produces and the elaborate syntactic information they provide. Second, this information comes directly from the grammar, thus allowing the LA process to make predictions based on what the grammar considers to be best suited for it.

Coling 2008: Poster Volume, pages 153–161,
Beijing, August 2010

The remainder of the paper is organised as follows. Section 2 describes the basic steps in our LA algorithm. Section 3 presents initial experiments conducted with Alpino and shows that the main problems our LA method encounters are the acquisition of morphologically ambiguous words, the learning of the proper subcategorization frames for verbs and the acquisition of particular types of adjectives. In Section 4 we make extensive use of the paradigms of the unknown words to develop specific solutions for these problems. Section 5 describes experiments with our LA method applied to a set of real unknown words. Section 6 provides a comparison between our approach and work previously done on LA. This section also discusses the application of our method to other systems and languages.

2 Basic Algorithm

The Alpino wide-coverage dependency parser is based on a large stochastic attribute value grammar. The grammar takes a 'constructional' approach, with rich lexical representations stored in the lexicon and a large number of detailed, construction specific rules (about 800). Currently, the lexicon contains about 100K lexical entries and a list of about 200K named entities. Each word is assigned one or more lexical types. For example, the verb *amuseert* (to amuse) is assigned two lexical types– *verb(hebben,sg3,intransitive)* and *verb(hebben,sg3,transitive)*– because it can be used either transitively or intransitively. The other type features indicate that it is a present third person singular verb and it forms perfect tense with the auxiliary verb *hebben*.

The goal of our LA method is to *assign* the correct lexical type(s) to a given unknown word. The method takes into account only open-class lexical types: nouns, adjectives and verbs, under the assumption that the grammar is already able to handle all closed-class cases. We call the types considered by our method *universal types*. The adjectives can be used as adverbs in Dutch and thus, we do not consider the latter to be an open class.

We employ a ME-based classifier which, for some unknown word, takes various morphological and syntactic features as input and outputs lexical types. The probability of a lexical type *t*, given an unknown word and its context *c* is:

$$(1) \qquad p(t|c) = \frac{exp(\sum_i \Theta_i f_i(t,c))}{\sum_{t' \in T} exp(\sum_i \Theta_i f_i(t',c))}$$

where $f_i(t, c)$ may encode arbitrary characteristics of the context and $< \Theta_1, \Theta_2, ... >$ can be evaluated by maximising the pseudo-likelihood on a training corpus (Malouf, 2002).

Table 1 shows the features for the noun *inspraakprocedures* (consultation procedures). Row **(i)** contains 4 separate features derived from the prefix of the word and 4 other suffix features are given in row **(ii)**. The two features in rows **(iii)** and **(iv)** indicate whether the word starts with a particle and if it contains a hyphen, respectively.

Another source of morphological features is the paradigm of the unknown word which provides information that is otherwise inaccessible. For example, in Dutch, neuter nouns always take the *het* definite article while all other noun forms are used with the *de* article. Since the article is distinguishable only in the singular noun form, the correct article of a word, assigned a plural noun type, can be determined if we know its singular form.

We adopt the method presented in Cholakov and van Noord (2009) where a finite state morphology is applied to generate the paradigm(s) of a given word. The morphology does not have access to any additional linguistic information and thus, it generates all possible paradigms allowed by the word structure. Then, the number of search hits Yahoo returns for each form in a given paradigm is combined with some simple heuristics to determine the correct paradigm(s).

However, we make some modifications to this method because it deals only with *regular* morphological phenomena. Though all typical irregularities are included in the Alpino lexicon, there are cases of irregular verbs composed with particles which are not listed there. One such example is the irregular verb *meevliegen* (to fly with someone) for which no paradigm would be generated.

To avoid this, we use a list of common particles to strip off any particle from a given unknown word. Once we have removed a particle, we check if what is left from the word is listed in the lexicon as a verb (e.g. *vliegen* in the case of ***mee****vliegen*). If so, we extract all members of its paradigm from

Features
i) i, in, ins, insp
ii) s, es, res, ures
iii) particle_yes #in this case *in*
iv) hyphen_no
v) noun⟨de,pl⟩
vi) noun(de,count,pl), tmp_noun(de,count,sg)
vii) noun(de), noun(count), noun(pl), tmp_noun(de) tmp_noun(count), tmp_noun(sg)

Table 1: Features for *inspraakprocedures*

the lexicon and use them to build the paradigm of the unknown word. All forms are validated by using the same web-based heuristics as in the original model of Cholakov and van Noord (2009).

A single paradigm is generated for *inspraakprocedures* indicating that this word is a plural *de* noun. This information is explicitly used as a feature in the classifier which is shown in row **(v)** of Table 1.

Next, we obtain syntactic features for *inspraakprocedures* by extracting a number of sentences which it occurs in from large corpora or Internet. These sentences are parsed with a different 'mode' of Alpino where this word is assigned all universal types, i.e. it is treated as being maximally *ambiguous*. For each sentence only the best parse is preserved. Then, the lexical type that has been assigned to *inspraakprocedures* in this parse is stored. During parsing, Alpino's POS tagger (Prins and van Noord, 2001) keeps filtering implausible type combinations. For example, if a determiner occurs before the unknown word, all verb types are typically not taken into consideration. This heavily reduces the computational overload and makes parsing with universal types computationally feasible. When all sentences have been parsed, a list can be drawn up with the types that have been used and their frequency:

(2)
noun(de,count,pl) 78
tmp_noun(de,count,sg) 7
tmp_noun(het,count,pl) 6
proper_name(pl,'PER') 5
proper_name(pl,'ORG') 3
verb(hebben,pl,vp) 1

The lexical types assigned to *inspraakprocedures* in at least 80% of the parses are used as features in the classifier. These are the two features in row **(vi)** of Table 1. Further, as illustrated in row **(vii)**, each attribute of the considered types is also taken as a separate feature. By doing this, we let the grammar decide which lexical type is best suited for a given unknown word. This is a new and effective way to include the *syntactic constraints* of the context in the LA process.

However, for the parsing method to work properly, the disambiguation model of the parser needs to be adapted. The model heavily relies on the lexicon and it has learnt preferences how to parse certain phrases. For example, it has learnt a preference to parse prepositional phrases as verb complements, if the verb includes such a subcategorization frame. This is problematic when parsing with universal types. If the unknown word is a verb and it occurs together with a PP, it would always get analysed as a verb which subcategorizes for a PP.

To avoid this, the disambiguation model is retrained on a specific set of sentences meant to make it more robust to input containing many unknown words. We have selected words with low frequency in large corpora and removed them temporarily from the Alpino lexicon. Less frequent words are typically not listed in the lexicon and the selected words are meant to simulate their behaviour. Then, all sentences from the Alpino treebank which contain these words are extracted and used to retrain the disambiguation model.

3 Initial Experiments and Evaluation

To evaluate the performance of the classifier, we conduct an experiment with a target type inventory of 611 universal types. A type is considered universal only if it is assigned to at least 15 distinct words occurring in large Dutch newspaper corpora ($\sim$16M sentences) automatically parsed with Alpino.

In order to train the classifier, 2000 words are temporarily removed from the Alpino lexicon. The same is done for another 500 words which are used as a test set. All words have between 50 and 100 occurrences in the corpora. This selection is again meant to simulate the behaviour of unknown words. Experiments with a minimum lower than 50 occurrences have shown that this is a reasonable threshold to filter out typos, words written together, etc.

The classifier yields a probability score for each predicted type. Since a given unknown word can have more than one correct type, we want to predict multiple types. However, the least frequent types, accounting together for less than 5% of probability mass, are discarded.

We evaluate the results in terms of precision and recall. Precision indicates how many types found by the method are correct and recall indicates how many of the lexical types of a given word are actually found. The presented results are the average precision and recall for the 500 test words.

Additionally, there are three baseline methods:

- *Naive*– each unknown word is assigned the most frequent type in the lexicon: *noun(de,count,sg)*
- *POS tagger*– the unknown word is given the type most frequently assigned by the Alpino POS tagger in the parsing stage
- *Alpino*– the unknown word is assigned the most frequently used type in the parsing stage

The overall results are given in Table 2. Table 3 shows the results for each POS in our model.

Model	Precision(%)	Recall(%)	F-measure(%)
Naive	19.60	18.77	19.17
POS tagger	30	26.21	27.98
Alpino	44.60	37.59	40.80
Our model	86.59	78.62	82.41

Table 2: Overall experiment results

POS	Precision(%)	Recall(%)	F-measure(%)
Nouns	93.83	88.61	91.15
Adjectives	75.50	73.12	74.29
Verbs	77.32	55.37	64.53

Table 3: Detailed results for our model

Our LA method clearly improves upon the baselines. However, as we see in Table 3, adjectives and especially verbs remain difficult to predict.

The problems with the former are due to the fact that Alpino employs a rather complicated adjective system. The classifier has difficulties distinguishing between 3 kinds of adjectives: **i)** adjectives which can attach to and modify verbs and verbal phrases (VPs) (3-a), **ii)** adjectives which can attach to verbs and VPs but modify one of the complements of the verb, typically the subject (3-b) and **iii)** adjectives which cannot attach to verbs and VPs (3-c).

(3)
a. De hardloper loopt *mooi*.
DET runner walks nice
'The runner runs nicely = The runner has a good running technique'
b. Hij loopt *dronken* naar huis.
he walks drunk to home
'He walks home drunk = He is walking home while being drunk'
c. *Hij loopt *nederlandstalig*.
he walks Dutch speaking
'He walks Dutch speaking.'

Each of these is marked by a special attribute in the lexical type definitions– *adv*, *padv* and *nonadv*, respectively. Since all three of them are seen in 'typical' adjectival contexts where they modify nouns, it is hard for the classifier to make a distinction. The predictions appear to be arbitrary and there are many cases where the unknown word is classified both as a *nonadv* and an *adv* adjective. It is even more difficult to distinguish between *padv* and *adv* adjectives since this is a solely semantic distinction.

The main issue with verbs is the prediction of the correct subcategorization frame. The classifier tends to predict mostly transitive and intransitive verb types. As a result, it either fails to capture infrequent frames which decreases the recall or, in cases where it is very uncertain what to predict, it assigns a lot of types that differ only in the subcat frame, thus damaging the precision. For example, *onderschrijf* ('to agree with') has 2 correct subcat frames but receives 8 predictions which differ only in the subcat features.

One last issue is the prediction, in some rare cases, of types of the wrong POS for morphologically ambiguous words. In most of these cases adjectives are wrongly assigned a past participle type but also some nouns receive verb predictions. For instance, *OESO-landen* ('countries of the OESO organisation') has one correct noun type but because *landen* is also the Dutch verb for 'to land' the classifier wrongly assigns a verb type as well.

4 Improving LA

4.1 POS Correction

Since the vast majority of wrong POS predictions has to do with the assignment of incorrect verb types, we decided to explicitly use the generated verb paradigms as a filtering mechanism. For each word which is assigned a verb type, we check if there is a verb paradigm generated for it. If not, all verb types predicted for the word are discarded.

In very rare cases a word is assigned *only* verb types and therefore, it ends up with no predictions. For such words, we examine the ranked list of predicted types yielded by the classifier and the word receives the non-verb lexical type with the highest probability score. If this type happens to be an adjective one, we first check whether there is an adjective paradigm generated for the word in question. If not, the word gets the noun type with the highest probability score.

The same procedure is also applied to all words which are assigned an adjective type. However, it is not used for words predicted to be nouns because the classifier is already very good at predicting nouns. Further, the generated noun paradigms are not reliable enough to be a filtering mechanism because there are mass nouns with no plural forms and thus with no paradigms generated.

Another modification we make to the classifier output has to do with the fact that past participles (psp) in Dutch can also be used as adjectives. This systematic ambiguity, however, is not treated as such in Alpino. Each psp should also have a separate adjective lexical entry but this is not always the case. That is why, in some cases, the classifier fails to capture the adjective type of a given psp. To account for it, all words predicted to be past participles but not adjectives are assigned two additional adjective types– one with the *nonadv* and one with the *adv* feature. For reasons explained later on, a type with the *padv* feature is not added.

After the application of these techniques, all cases of words wrongly predicted to be verbs or adjectives have been eliminated.

4.2 Guessing Subcategorization Frames

Our next step is to guess the correct subcategorization feature for verbs. Learning the proper subcat frame is well studied (Brent, 1993; Manning, 1993; Briscoe and Caroll, 1997; Kinyon and Prolo, 2002; O'Donovan et al., 2005). Most of the work follows the 'classical' Briscoe and Caroll (1997) approach where the verb and the subcategorized complements are extracted from the output analyses of a probabilistic parser and stored as syntactic patterns. Further, some statistical techniques are applied to select the most probable frames out of the proposed syntactic patterns.

Following the observations made in Korhonen et al. (2000), Lapata (1999) and Messiant (2008), we employ a maximum likelihood estimate (MLE) from observed relative frequencies with an empirical threshold to filter out low probability frames. For each word predicted to be a verb, we look up the verb types assigned to it during the parsing with universal types. Then, the MLE for each subcat frame is determined and only frames with MLE of 0.2 and above are considered. For example, *jammert* (to moan.3SG.PRES) is assigned a single type– *verb(hebben,sg3,intransitive)*. However, the correct subcat features for it are *intransitive* and *sbar*. Here is the list of all verb types assigned to *jammert* during the parsing with universal types:

(4)
verb(hebben,sg3,intransitive) 48
verb(hebben,sg3,transitive) 15
verb(hebben,past(sg),np_sbar) 3
verb(hebben,past(sg),tr_sbar) 3
verb(zijn,sg3,intransitive) 2
verb(hebben,past(sg),ld_pp) 2
verb(hebben,sg3,sbar) 1

The MLE for the intransitive subcat feature is 0.68 and for the transitive one– 0.2. All previously predicted verb types are discarded and each considered subcat frame is used to create a new lexical type. That is how *jammert* gets two types at the end– the correct *verb(hebben,sg3,intransitive)* and the incorrect *verb(hebben,sg3,transitive)*. The *sbar* frame is wrongly discarded.

To avoid such cases, the generated word paradigms are used to increase the number of contexts observed for a given verb. Up to 200 sentences are extracted for each form in the paradigm of a given word predicted to be a verb. These sentences are again parsed with the universal types and then, the MLE for each subcat frame is recal-

culated.

We evaluated the performance of our MLE-based method on the 116 test words predicted to be verbs. We extracted the subcat features from their type definitions in the Alpino lexicon to create a gold standard of subcat frames. Additionally, we developed two baseline methods: **i)** all frames assigned during parsing are considered and **ii)** each verb is taken to be both transitive and intransitive. Since most verbs have both or one of these frames, the purpose of the second baseline is to see if there is a simpler solution to the problem of finding the correct subcat frame. The results are given in Table 4.

Model	Precision(%)	Recall(%)	F-measure(%)
all frames	16.76	94.34	28.46
tr./intr.	62.29	69.17	65.55
our model	85.82	67.28	75.43

Table 4: Subcat frames guessing results

Our method significantly outperforms both baselines. It is able to correctly identify the transitive and/or the intransitive frames. Since they are the most frequent ones in the test data, this boosts up the precision. However, the method is also able to capture other, less frequent subcat frames. For example, after parsing the additional sentences for *jammert*, the *sbar* frame had enough occurrences to get above the threshold. The MLE for the transitive one, on the other hand, fell below 0.2 and it was correctly discarded.

4.3 Guessing Adjective Types

We follow a similar approach for finding the correct adjective type. It should be noted that the distinction among *nonadv*, *adv* and *padv* does not exist for every adjective form. Most adjectives in Dutch get an *-e* suffix when used attributively– *de mooi**e**/mooier**e**/mooist**e** jongen* (the nice/nicer/nicest boy). Since these inflected forms can only occur before nouns, the distinction we are dealing with is not relevant for them. Thus we are only interested in the noninflected base, comparative and superlative adjective forms.

One of the possible output formats of Alpino is dependency triples. Here is the output for the sentence in (3-a):

(5)
```
verb:loop|hd/su|noun:hardloper
noun:hardloper|hd/det|det:de
verb:loop|hd/mod|adj:mooi
verb:loop|–/–|punct:.
```

Each line is a single dependency triple. The line contains three fields separated by the '|' character. The first field contains the root of the head word and its POS, the second field indicates the type of the dependency relation and the third one contains the root of the dependent word and its POS. The third line in (5) shows that the adjective *mooi* is a modifier of the head, in this case the verb *loopt*. Such a dependency relation indicates that this adjective can modify a verb and therefore, it belongs to the *adv* type.

As already mentioned, *padv* adjectives cannot be distinguished from the ones of the *adv* kind. That is why, if the classifier has decided to assign a *padv* type to a given unknown word, we discard all other adjective types assigned to it (if any) and do not apply the technique described below to this word.

For each of the 59 words assigned an non-inflected adjective type after the POS correction stage, we extract up to 200 sentences for all non-inflected forms in its paradigm. These sentences are parsed with Alpino and the universal types and the output is dependency triples. All triples where the unknown word occurs as a dependent word in a head modifier dependency (*hd/mod*, as shown in (5)) and its POS is adjective are extracted from the parse output. We calculate the MLE of the cases where the head word is a verb, i.e. where the unknown word modifies a verb. If the MLE is 0.05 or larger, the word is assigned an *adv* lexical type.

For example, the classifier correctly identifies the word *doortimmerd* (solid) as being of the *adjective(no_e(nonadv))* type but it also predicts the *adjective(no_e(adv))*[1] type for it. Since we have not found enough sentences where this word modifies a verb, the latter type is correctly discarded. Our technique produced correct results for 53 out of the 59 adjectives processed.

[1]The *no_e* type attribute denotes a noninflected base adjective form.

4.4 Improved Results and Discussion

Table 5 presents the results obtained after applying the improvement techniques described in this section to the output of the classifier (the 'Model 2' rows). For comparison, we also give the results from Table 3 again (the 'Model 1' rows). The numbers for the nouns happen to remain unchanged and that is why they are not shown in Table 5.

POS	Models	Prec.(%)	Rec.(%)	F-meas.(%)
Adj	Model 1	75.50	73.12	74.29
	Model 2	85.16	80.16	82.58
Verbs	Model 1	77.32	55.37	64.53
	Model 2	80.56	56.24	66.24
Overall	Model 1	86.59	78.62	82.41
	Model 2	89.08	80.52	84.58

Table 5: Improved results

The automatic addition of adjective types for past participles improved significantly the recall for adjectives and our method for choosing between *adv* and *nonadv* types caused a 10% increase in precision.

However, these procedures also revealed some incomplete lexical entries in Alpino. For example, there are two past participles not listed as adjectives in the lexicon though they should be. Thus when our method *correctly* assigned them adjective types, it got punished since these types were not in the gold standard.

We see in Table 5 that the increase in precision for the verbs is small and recall remains practically unchanged. The unimproved recall shows that we have not gained much from the subcat frame heuristics. Even when the number of the observed sentences was increased, less frequent frames often remained unrecognisable from the noise in the parsed data. This could be seen as a proof that in the vast majority of cases verbs are used *transitively* and/or *intransitively*. Since the MLE method we employ proved to be good at recognising these two frames and differentiating between them, we have decided to continue using it.

The overall F-score improved by only 2% because the modified verb and adjective predictions are less than 30% of the total predictions made by the classifier.

5 Experiment with Real Unknown Words

To investigate whether the proposed LA method is also beneficial for the parser, we observe how parsing accuracy changes when the method is employed. Accuracy in Alpino is measured in terms of labelled dependencies.

We have conducted an experiment with a test set of 300 sentences which contain 188 real unknown words. The sentences have been randomly selected from the manually annotated LASSY corpus (van Noord, 2009) which contains text from various domains. The average sentence length is 26.54 tokens.

The results are given in Table 6. The standard Alpino model uses its guesser to assign types to the unknown words. Model 1 employs the trained ME-based classifier to predict lexical entries for the unknown words offline and then uses them during parsing. Model 2 uses lexical entries modified by applying the methods described in Section 4 to the output of the classifier (Model 1).

Model	Accuracy (%)	msec/sentence
Alpino	88.77	8658
Model 1	89.06	8772
Model 2	89.24	8906

Table 6: Results with real unknown words

Our LA system as a whole shows an error reduction rate of more than 4% with parse times remaining similar to those of the standard Alpino version. It should also be noted that though much of the unknown words are generally nouns, we see from the results that it makes sense to also employ the methods for improving the predictions for the other POS types. A wrong verb or even adjective prediction can cause much more damage to the analysis than a wrong noun one.

These results illustrate that the integration of our method in the parser can improve its performance on real-life data.

6 Discussion

6.1 Comparison to Previous Work

The performance of the LA method we presented in this paper can be compared to the performance

of a number of other approaches previously applied to the same task.

Baldwin (2005) uses a set of binary classifiers to learn lexical entries for a large-scale grammar of English (ERG; (Copestake and Flickinger, 2000)). The main disadvantage of the method is that it uses information obtained from secondary language resources– POS taggers, chunkers, etc. Therefore, the grammar takes no part in the LA process and the method acquires lexical entries based on incomplete linguistic information provided by the various resources. The highest F-measure (about 65%) is achieved by using features from a chunker but it is still 20% lower than the results we report here. Further, no evaluation is done on how the method affects the performance of the ERG when the grammar is used for parsing.

Zhang and Kordoni (2006) and Cholakov et al. (2008), on the other hand, include features from the grammar in a maximum entropy (ME) classifier to predict new lexical entries for the ERG and a large German grammar (GG; (Crysmann, 2003)), respectively. The development data for this method consist of linguistically annotated sentences from treebanks and the grammar features used in the classifier are derived from this annotation. However, when the method is applied to open-text unannotated data, the grammar features are replaced with POS tags. Therefore, the grammar is no longer directly involved in the LA process which affects the quality of the predictions. Evaluation on sentences containing real unknown words shows improvement of the coverage for the GG when LA is employed but the accuracy decreases by 2%. Such evaluation has not been done for the ERG. The results on the development data are not comparable with ours because evaluation is done only in terms of precision while we are also able to measure recall.

Statistical LA has previously been applied to Alpino as well (van de Cruys, 2006). However, his method employs less morphosyntactic features in comparison to our approach and does not make use of word paradigms. Further, though experiments on development data are performed on a smaller scale, the results in terms of F-measure are 10% lower than those reported in our case study. Experiments with real unknown words have not been performed.

Other, non-statistical LA methods also exist. Cussens and Pulman (2000) describe a symbolic approach which employs *inductive logic programming* and Barg and Walther (1998) and Fouvry (2003) follow a unification-based approach. However, the generated lexical entries might be both too general or too specific and it is doubtful if these methods can be used on a large scale. They have not been applied to broad-coverage grammars and no evaluation is provided.

6.2 Application to Other Systems and Languages

We stress the fact that the experiments with Alpino represent only a case study. The proposed LA method can be applied to other computational grammars and languages providing that the following conditions are fulfilled.

First, words have to be mapped onto some finite set of labels of which a subset of open-class (universal) labels has to be selected. This subset represents the labels which the ME-based classifier can predict for unknown words. Second, a (large) corpus has to be available, so that various sentences in which a given unknown word occurs can be extracted. This is crucial for obtaining different contexts in which this word is found.

Next, we need a parser to analyse the extracted sentences which allows for the syntactic constraints imposed by these contexts to be included in the prediction process.

Finally, as for the paradigm generation, the idea of combining a finite state morphology and web heuristics is general enough to be implemented for different languages. It is also important to note that the classifier allows for arbitrary combinations of features and therefore, a researcher is free to include any (language-specific) features he or she considers useful for performing LA.

We have already started investigating the applicability of our LA method to large-scale grammars of German and French and the initial experiments and results we have obtained are promising.

Abstract

Word co-occurrence networks are one of the most common linguistic networks studied in the past and they are known to exhibit several interesting topological characteristics. In this article, we investigate the global topological properties of word co-occurrence networks and, in particular, present a detailed study of their spectrum. Our experiments reveal certain universal trends found across the networks for seven different languages from three different language families, which are neither reported nor explained by any of the previous studies and models of word-cooccurrence networks. We hypothesize that since word co-occurrences are governed by syntactic properties of a language, the network has much constrained topology than that predicted by the previously proposed growth model. A deeper empirical and theoretical investigation into the evolution of these networks further suggests that they have a core-periphery structure, where the core hardly evolves with time and new words are only attached to the periphery of the network. These properties are fundamental to the nature of word co-occurrence across languages.

1 Introduction

In a natural language, words interact among themselves in different ways – some words co-occur with certain words at a very high probability than other words. These co-occurrences are non-trivial, as in their patterns cannot be inferred from the frequency distribution of the individual words. Understanding the structure and the emergence of these patterns can present us with important clues and insights about how we evolved this extremely complex phenomenon, that is language.

In this paper, we present an in-depth study of the word co-occurrence patterns of a language in the framework of complex networks. The choice of this framework is strongly motivated by its success in explaining various properties of word co-occurrences previously (Ferrer-i-Cancho and Solé, 2001; Ferrer-i-Cancho et al, 2007; Kapustin and Jamsen, 2007). Local properties, such as the degree distribution and clustering coefficient of the word co-occurrence networks, have been thoroughly studied for a few languages (Ferrer-i-Cancho and Solé, 2001; Ferrer-i-Cancho et al, 2007; Kapustin and Jamsen, 2007) and many interesting conclusions have been drawn. For instance, it has been found that these networks are small-world in nature and are characterized by a *two regime power-law* degree distribution. Efforts have also been made to explain the emergence of such a two regime degree distribution through network growth models (Dorogovstev and Mendes, 2001). Although it is tempting to believe that a lot is known about word co-occurrences, in order to obtain a deeper insight into how these co-occurrence patterns emerged there are many other interesting properties that need to be investigated. One such property is the *spectrum* of the word co-

Coling 2008: Poster Volume, pages 162–170,
Beijing, August 2010

occurrence network which can provide important information about its global organization. In fact, the application of this powerful mathematical machinery to infer global patterns in linguistic networks is rarely found in the literature (few exceptions are (Belkin and Goldsmith, 2002; Mukherjee et al, 2009)). However, note that spectral analysis has been quite successfully applied in the analysis of biological and social networks (Banerjee and Jost, 2007; Farkas et al, 2001).

The aim of the present work is to investigate the spectral properties of a word co-occurrence network in order to understand its global structure. In particular, we study the properties of seven different languages namely Bangla (Indo-European family), English (Indo-European family), Estonian (Finno-Ugric family), French (Indo-European family), German (Indo-European family), Hindi (Indo-European family) and Tamil (Dravidian family). Quite importantly, as we shall see, the most popular growth model proposed by Dorogovtsev and Mendes (DM) (Dorogovstev and Mendes, 2001) for explaining the degree distribution of such a network is not adequate to reproduce the spectrum of the network. This observation holds for all the seven different languages under investigation. We shall further attempt to identify the precise (linguistic) reasons behind this difference in the spectrum of the empirical network and the one reproduced by the model. Finally, as an additional objective, we shall present a hitherto unreported deeper analysis of this popular model and show how its most important parameter is correlated to the size of the corpus from which the empirical network is constructed.

The rest of the paper is laid out as follows. In section 2, we shall present a brief review of the previous works on word co-occurrence networks. This is followed by a short primer to spectral analysis. In section 4, we outline the construction methodology of the word co-occurrence networks and present the experiments comparing the spectrum of these real networks with those generated by the DM model. Section 5 shows how the most important parameter of the DM model varies with the size of the corpus from which the co-occurrence networks are constructed. Finally, we conclude in section 6 by summarizing our contributions and pointing out some of the implications of the current work.

2 Word Co-occurrence Networks

In this section, we present a short review of the earlier works on word co-occurrence networks, where the nodes are the words and an edge between two words indicate that the words have co-occurred in a language in certain context(s). The most basic and well studied form of word co-occurrence networks are the *word collocation networks*, where two words are linked by an edge if they are neighbors (i.e., they collocate) in a sentence (Ferrer-i-Cancho and Solé, 2001).

In (Ferrer-i-Cancho and Solé, 2001), the authors study the properties of two types of collocation networks for English, namely the *unrestricted* and the *restricted* ones. While in the unrestricted network, all the collocation edges are preserved, in the restricted one only those edges are preserved for which the probability of occurrence of the edge is higher than the case when the two words collocate independently. They found that both the networks exhibit small-world properties; while the average path length between any two nodes in these networks is small (between 2 and 3), the clustering coefficients are high (0.69 for the unrestricted and 0.44 for the restricted networks). Nevertheless, the most striking observation about these networks is that the degree distributions follow a two regime power-law. The degree distribution of the 5000 most connected words (i.e., the kernel lexicon) follow a power-law with an exponent -3.07, which is very close to that predicted by the Barabási-Albert growth model (Barabási and Albert, 1999). These findings led the authors to argue that the word usage of the human languages is preferential in nature, where the frequency of a word defines the comprehensibility and production capability. Thus, higher the usage frequency of a word, higher is the probability that the speakers will be able to produce it easily and the listeners will comprehend it fast. This idea is closely related to the *recency effect* in linguistics (Akmajian, 1995).

Properties of word collocation networks have also been studied for languages other than English (Ferrer-i-Cancho et al, 2007; Kapustin and

Jamsen, 2007). The basic topological characteristics of all these networks (e.g., scale-free, small world, assortative) are similar across languages and thus, point to the fact that like Zipf's law, these are also linguistic universals whose emergence and existence call for a non-trivial psycholinguistic account.

In order to explain the two regime power-law in word collocation networks, Dorogovtsev and Mendes (Dorogovstev and Mendes, 2001) proposed a preferential attachment based growth model (henceforth referred to as the DM model). In this model, at every time step t, a new word (i.e., a node) enters the language (i.e., the network) and connects itself preferentially to one of the pre-existing nodes. Simultaneously, ct (where c is a positive constant and a parameter of the model) new edges are grown between pairs of old nodes that are chosen preferentially. Through mathematical analysis and simulations, the authors successfully establish that this model gives rise to a two regime power-law with exponents very close to those observed in (Ferrer-i-Cancho and Solé, 2001). In fact, for English, the values k_{cross} (i.e., the point where the two power law regimes intersect) and k_{cut} (i.e., the point where the degree distribution cuts the x-axis) obtained from the model are in perfect agreement with those observed for the empirical network.

Although the DM model is capable of explaining the local topological properties of the word collocation network, as we shall see in the forthcoming sections, it is unable to reproduce the global properties (e.g., the *spectrum*) of the network.

3 A Primer to Spectral Analysis

Spectral analysis[1] is a powerful mathematical method capable of revealing the global structural patterns underlying an enormous and complicated environment of interacting entities. Essentially, it refers to the systematic investigation of the eigenvalues and the eigenvectors of the adjacency matrix of the network of these interacting entities. In this section, we shall briefly outline the basic concepts involved in spectral analysis and discuss some of its applications (see (Chung, 1994) for details).

A network consisting of n nodes (labeled as 1 through n) can be represented by an $n \times n$ square matrix $\mathbf{A}$, where the entry a_{ij} represents the weight of the edge from node i to node j. Note that $\mathbf{A}$, which is known as the *adjacency matrix*, is symmetric for an undirected graph and have binary entries for an unweighted graph. λ is an eigenvalue of $\mathbf{A}$ if there is an n-dimensional vector $\mathbf{x}$ such that

$$\mathbf{Ax} = \lambda\mathbf{x}$$

Any real symmetric matrix $\mathbf{A}$ has n (possibly non-distinct) eigenvalues $\lambda_0 \leq \lambda_1 \leq \ldots \leq \lambda_{n-1}$, and corresponding n eigenvectors that are mutually orthogonal. The *spectrum* of a network is the set of the distinct eigenvalues of the graph and their corresponding multiplicities. It is a distribution usually represented in the form of a plot with the eigenvalues in x-axis and their multiplicities in the y-axis.

The spectrum of real and random networks display several interesting properties. Banerjee and Jost (Banerjee and Jost, 2007) report the spectrum of several biological networks and show that these are significantly different from the spectrum of artificially generated networks. It is worthwhile to mention here that spectral analysis is also closely related to *Principal Component Analysis* and *Multidimensional Scaling*. If the first few (say d) eigenvalues of a matrix are much higher than the rest of the eigenvalues, then one can conclude that the rows of the matrix can be approximately represented as linear combinations of d orthogonal vectors. This further implies that the corresponding graph has a few motifs (subgraphs) that are repeated a large number of time to obtain the global structure of the graph (Banerjee and Jost, 2009).

In the next section, we shall present a thorough study of the spectrum of the word co-occurrence networks across various languages.

4 Experiments and Results

For the purpose of our experiments, we construct word collocation networks for seven different languages namely, Bangla, English, Esto-

[1]The term spectral analysis is also used in the context of signal processing, where it refers to the study of the frequency spectrum of a signal.

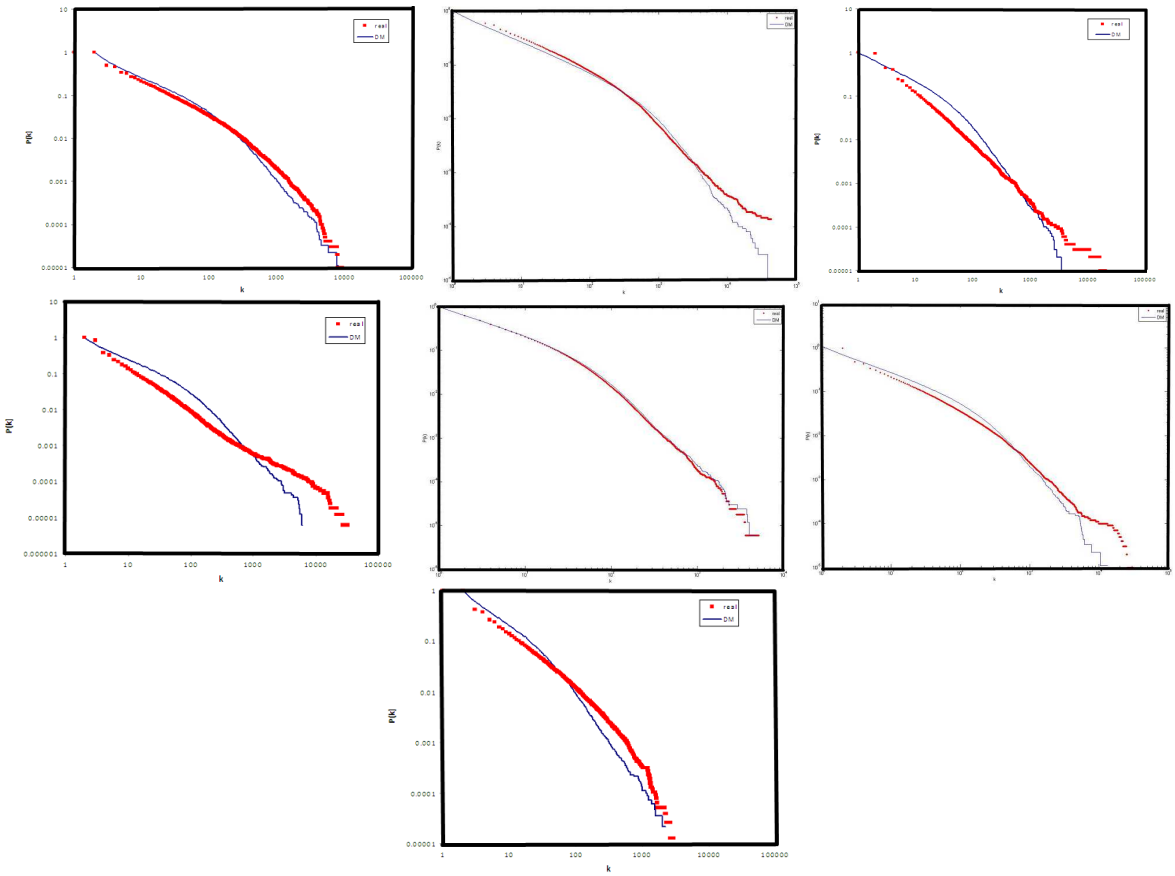

Figure 1: Cumulative degree distributions for Bangla, English, Estonian, French, German, Hindi and Tamil respectively. Each red line signifies the degree distribution for the empirical network while each blue line signifies the one obtained from the DM model.

Lang.	Tokens (Mill.)	Words	KLD	c	Max. Eig. (Real)	Max. Eig. (DM)
English	32.5	97144	0.21	5.0e-4	849.1	756.8
Hindi	20.2	99210	0.32	2.3e-4	472.5	329.5
Bangla	12.7	100000	0.29	2.0e-3	326.2	245.0
German	5.0	159842	0.19	6.3e-5	192.3	110.7
Estonian	4.0	100000	0.25	1.1e-4	158.6	124.0
Tamil	2.3	75929	0.24	9.9e-4	116.4	73.06
French	1.8	100006	0.44	8.0e-5	236.1	170.1

Table 1: Summary of results comparing the structural properties of the empirical networks for the seven languages and the corresponding best fits (in terms of KLD) obtained from the DM model.

nian, French, German, Hindi and Tamil. We used the corpora available in the *Lipezig Corpora Collection* (http://corpora.informatik.uni-leipzig.de/) for English, Estonian, French and German. The Hindi, Bangla and Tamil corpora were collected by crawling some online newspapers. In these networks, each distinct word corresponds to a vertex and two vertices are connected by an edge if the corresponding two words are adjacent in one or more sentences in the corpus. We assume the network to be undirected and unweighted (as in (Ferrer-i-Cancho and Solé, 2001)).

As a following step, we simulate the DM model and reproduce the degree distribution of the collocation networks for the seven languages. We vary the parameter c in order to minimize the KL

divergence (KLD) (Kullback and Leibler, 1951) between the empirical and the synthesized distributions and, thereby, obtain the best match. The results of these experiments are summarized through Figure 1 and Table 1. The results clearly show that the DM model is indeed capable of generating the degree distribution of the collocation networks to a very close approximation for certain values of the parameter c (see Table 1 for the values of c and the corresponding KLD).

Subsequently, for the purpose of spectral analysis, we construct subgraphs induced by the top 5000 nodes for each of the seven empirical networks as well as those generated by the DM model (i.e., those for which the degree distribution fits best in terms of KLD with the real data). We then compute and compare the spectrum of the real and the synthesized networks (see Figure 2 and Table 1). It is quite apparent from these results that the spectra of the empirical networks are significantly different from those obtained using the DM model. In general, the spectral plots indicate that the adjacency matrices for networks obtained from the DM model have a higher rank than those for the empirical networks. Further, in case of the synthesized networks, the first eigenvalue is significantly larger than the second whereas for the empirical networks the top 3 to 4 eigenvalues are found to dominate. Interestingly, this property is observed across all the languages under investigation.

We believe that the difference in the spectra is due to the fact that the ordering of the words in a sentence are strongly governed by the grammar or the syntax of the language. Words belong to a smaller set of lexico-syntactic categories, which are more commonly known as the parts-of-speech (POS). The co-occurrence patterns of the words are influenced, primarily, by its POS category. For instance, *nouns* are typically preceded by *articles* or *adjectives*, whereas *verbs* might be preceded by *auxiliary verbs*, *adverbs* or *nouns*, but never *articles* or *adjectives*. Therefore, the words "car" and "camera" are more likely to be structurally similar in the word co-occurrence network, than "car" and "jumped". In general, the local neighborhoods of the words belonging to a particular POS is expected to be very similar, which means that several rows in the adjacency matrix will be very similar to each other. Thus, the matrix is expected to have low rank.

In fact, this property is not only applicable to syntax, but also semantics. For instance, even though adjectives are typically followed by nouns, semantic constraints make certain adjective-noun co-occurrences (e.g., "green leaves") much more likely than some others (e.g., "green dreams" or "happy leaves"). These notions are at the core of latent semantics and vector space models of semantics (see, for instance, Turney and Pantel (Turney and Pantel, 2010) for a recent study). The DM model, on the other hand, is based on the *recency effect* that says that the words which are produced most recently are easier to remember and therefore, easier to produce in the future. Preferential attachment models the recency effect in word production, which perhaps is sufficient to replicate the degree distribution of the networks. However, the model fails to explain the global properties, precisely because it does not take into account the constraints that govern the distribution of the words.

It is quite well known that the spectrum of a network can be usually obtained by iteratively powering the adjacency matrix of the network (aka power iteration method). Note that if the adjacency matrices of the empirical and the synthesized networks are powered even once (i.e., they are squared)[2], their degree distributions match no longer (see Figure 3). This result further corroborates that although the degree distribution of a word co-occurrence network is quite appropriately reproduced by the DM model, more global structural properties remain unexplained. We believe that word association in human languages is not arbitrary and therefore, a model which accounts for the clustering of words around their POS categories might possibly turn out to present a more accurate explanation of the spectral properties of the co-occurrence networks.

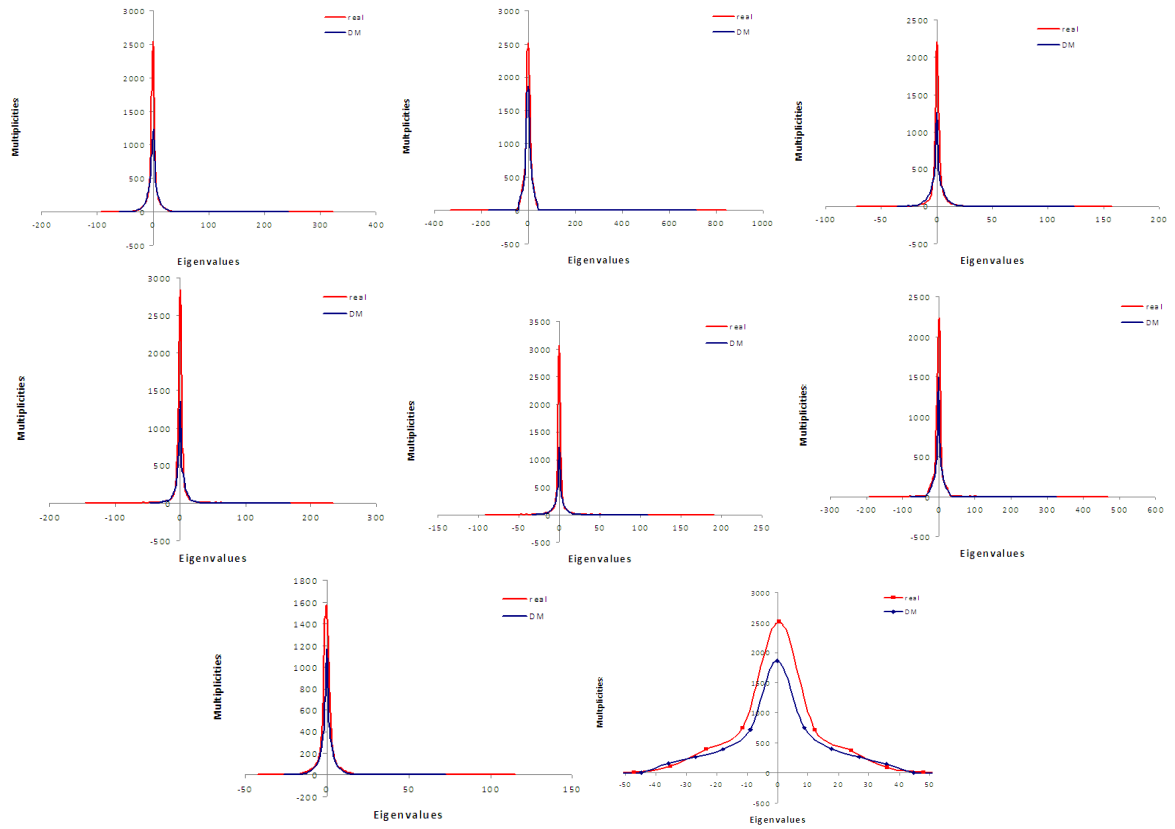

Figure 2: The spectrum for Bangla, English, Estonian, French, German, Hindi and Tamil respectively. The last plot shows a portion of the spectrum for English magnified around 0 for better visualization. All the curves are binned distributions with bin size = 100. The blue line in each case is the spectrum for the network obtained from the DM model while each red line corresponds to the spectrum for the empirical network.

5 Reinvestigating the DM Model

In this section, we shall delve deeper into exploring the properties of the DM model since it is one of the most popular and well accepted models for explaining the emergence of word associations in a language. In particular, we shall investigate the influence of the model parameter c on the emergent results.

If we plot the value of the parameter c (from Table 1) versus the size of the corpora (from Table 1) used to construct the empirical networks for the different languages we find that the two are highly correlated (see Figure 4).

[2]Note that this squared network is weighted in nature. We threshold all edges below the weight 0.07 so that the resultant network is neither too dense nor too sparse. The value of the threshold is chosen based on the inspection of the data.

In order to further check the dependence of c on the corpus size we perform the following experiment. We draw samples of varying corpus size and construct empirical networks from each of them. We then simulate the DM model and attempt to reproduce the degree distribution for each of these empirical networks. In each case, we note the value c for which the KLD between the empirical and the corresponding synthesized network is minimum. Figure 5 shows the result of the above experiment for English. The figure clearly indicates that as the corpus size increases the value of the parameter c decreases. Similar trends are observed for all the other languages.

In general, one can mathematically prove that the parameter c is equal to the rate of change of the average degree of the network with respect to

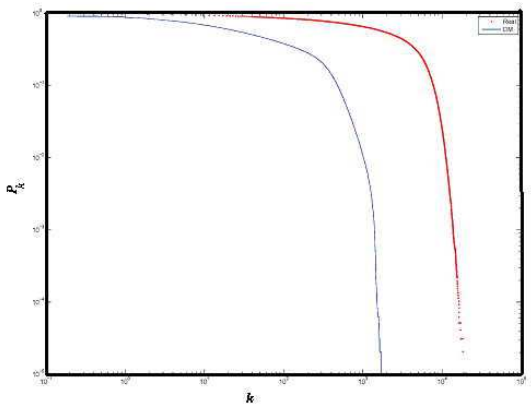

Figure 3: Cumulative degree distribution for the squared version of the networks for English. The red line is the degree distribution for the squared version of the empirical network while the blue line is degree distribution of the squared version of the network obtained from the DM model. The trends are similar for all the other languages.

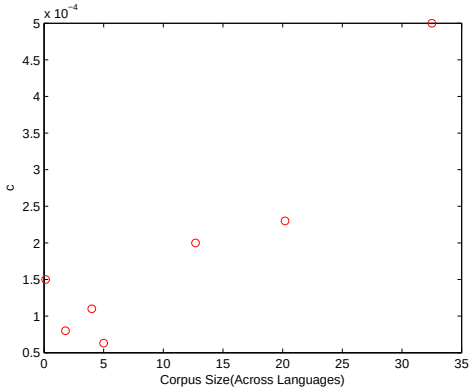

Figure 4: The parameter c versus the corpus size for the seven languages.

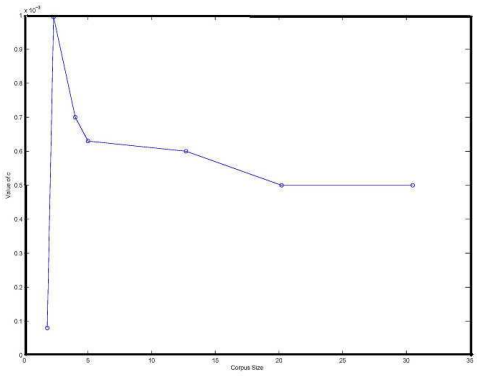

Figure 5: The parameter c versus the corpus size for English.

the time t. The proof is as follows.

At every time step t, the number of new edges formed is (1+ct). Since each edge contributes to a total degree of 2 to the network, the sum of the degrees of all the nodes in the network (k_{tot}) is

$$k_{tot} = 2\sum_{t=1}^{T}(1+ct) = 2T + cT(T+1) \quad (1)$$

At every time step, only one new node is added to the network and therefore the total number of nodes at the end of time T is exactly equal to T. Thus the average degree of the network is

$$\langle k \rangle = \frac{2T + cT(T+1)}{T} = 2 + c(T+1) \quad (2)$$

The rate of change of average degree is

$$\frac{d\langle k \rangle}{dT} = c \quad (3)$$

and this completes the proof.

In fact, it is also possible to make a precise empirical estimate of the value of the parameter c. One can express the average degree of the co-occurrence networks as the ratio of twice the bigram frequency (i.e., twice the number of edges in the network) to the unigram frequency (i.e., the number of nodes or unique words in the network). Therefore, if we can estimate this ratio we can easily estimate the value of c using equation 3. Let us denote the total number of distinct bigrams and unigrams after processing a corpus of size N by $B(N)$ and $W(N)$ respectively. Hence we have

$$\langle k \rangle = \frac{2B(N)}{W(N)} \quad (4)$$

Further, the number of distinct new unigrams after

Language	$B(N)$	$W(N)$	c
English	$29.2N^{.67}$	$59.3N^{.43}$	$.009N^{-.20}$
Hindi	$26.2N^{.66}$	$49.7N^{.46}$	$.009N^{-.26}$
Tamil	$1.9N^{.91}$	$6.4N^{.71}$	$.207N^{-.50}$

Table 2: Summary of expressions for $B(N)$, $W(N)$ and c for English, Hindi and Tamil.

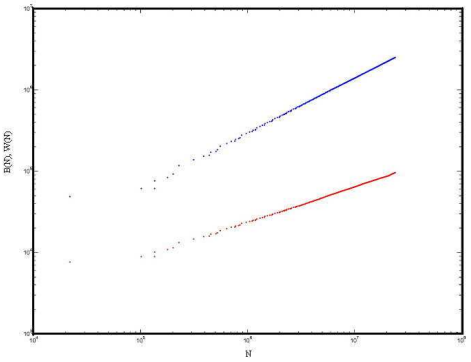

Figure 6: Variation of $B(N)$ and $W(N)$ with N for English (in doubly-logarithmic scale). The blue dots correspond to variation of $B(N)$ while the red dots correspond to the variation of $W(N)$.

processing a corpus of size N is equivalent to T and therefore

$$T = W(N) \tag{5}$$

Sampling experiments across different languages demonstrate that $W(N)$ and $B(N)$ are of the form ηN^{α} ($\alpha < 1$) where η and α are constants. For instance, Figure 6 shows in doubly-logarithmic scale how $B(N)$ and $W(N)$ varies with N for English. The R^2 values obtained as a result of fitting the $B(N)$ versus N and the $W(N)$ versus N plots using equations of the form ηN^{α} for English, Hindi and Tamil are greater than 0.99. This reflects the high accuracy of the fits. Similar trends are observed for all the other languages.

Finally, using equations 3, 4 and 5 we have

$$c = \frac{d\langle k \rangle}{dT} = \frac{d\langle k \rangle}{dN}\frac{dN}{dT} \tag{6}$$

and plugging the values of $B(N)$ and $W(N)$ in equation 6 we find that c has the form $\kappa N^{-\beta}$ ($\beta < 1$) where κ and β are language dependent positive constants. The values of c obtained in this way for three different languages English, Hindi and Tamil are noted in Table 5.

Thus, we find that as $N \rightarrow \infty$, $c \rightarrow 0$. In other words, as the corpus size grows the number of distinct new bigrams goes on decreasing and ultimately reaches (almost) zero for a very large sized corpus. Now, if one plugs in the values of c and T obtained above in the expressions for k_{cross} and k_{cut} in (Dorogovstev and Mendes, 2001), one observes that $\lim_{N\rightarrow\infty} \frac{k_{cross}}{k_{cut}} = 0$. This implies that as the corpus size becomes very large, the two-regime power law (almost) converges to a single regime with an exponent equal to -3 as is exhibited by the Barabási-Albert model (Barabási and Albert, 1999). Therefore, it is reasonable to conclude that although the DM model provides a good explanation of the degree distribution of a word co-occurrence network built from a medium sized corpora, it does not perform well for very small or very large sized corpora.

6 Conclusions

In this paper, we have tried to investigate in detail the co-occurrence properties of words in a language. Some of our important observations are: (a) while the DM model is able to reproduce the degree distributions of the word co-occurrence networks, it is not quite appropriate for explaining the spectrum of these networks; (b) the parameter c in the DM model signifies the rate of change of the average degree of the network with respect to time; and (c) the DM model does not perform well in explaining the degree distribution of a word co-occurrence network when the corpus size is very large.

It is worthwhile to mention here that our analysis of the DM model leads us to a very important observation. As N grows, the value of k_{cut} grows at a much faster rate than the value of k_{cross} and in the limit $N \rightarrow \infty$ the value of k_{cut} is so high as compared to k_{cross} that the ratio $\frac{k_{cross}}{k_{cut}}$ becomes (almost) zero. In other words, the kernel lexicon, formed of the words in the first regime of the two regime power-law and required to "say everything or almost everything" (Ferrer-i-Cancho and Solé, 2001) in a language, grows quite slowly as new words creep into the language. In contrast, the peripheral lexicon making the other part of the two regime grows very fast as new words enter the language. Consequently, it may be argued that since the kernel lexicon remains almost unaffected, the effort to learn and retain a language by its speakers increases only negligibly as new words creep into the language.

Exploiting Paraphrases and Deferred Sense Commitment to Interpret Questions more Reliably

Peter Clark and Phil Harrison
Boeing Research & Technology
{peter.e.clark,philip.harrison}@boeing.com

Abstract

Creating correct, semantic representations of questions is essential for applications that can use formal reasoning to answer them. However, even within a restricted domain, it is hard to anticipate all the possible ways that a question might be phrased, and engineer reliable processing modules to produce a correct semantic interpretation for the reasoner. In our work on posing questions to a biology knowledge base, we address this brittleness in two ways: First, we exploit the DIRT paraphrase database to introduce alternative phrasings of a question; Second, we defer word sense and semantic role commitment until question answering. Resulting ambiguities are then resolved by interleaving additional interpretation with question-answering, allowing the combinatorics of alternatives to be controlled and domain knowledge to guide paraphrase and sense selection. Our evaluation suggests that the resulting system is able to understand exam-style questions more reliably.

1 Introduction

Our goal is to allow users to pose exam-style questions to a biology knowledge base (KB), containing formal representations of biological structures and processes expressed in first-order logic. As the questions typically require automated reasoning to answer them, a semantic interpretation of each question is needed. In our earlier work (Clark et al, 2007), questions were interpreted using a conventional pipeline (parse, coreference, sense and role disambiguation). However, despite moderate performance, the original ("base") system suffered from well-known problems of brittleness, arising from both premature commitments in the pipeline and the system's limited knowledge of the multiple ways that questions can be expressed. In this paper, we describe how deferred commitment and a large paraphrase database can be used to reduce these problems, drawing on prior work and applying it in the context of a large KB being available. In particular, by interleaving interpretation and answering, we are able to control the combinatorics of alternatives that would otherwise arise. An evaluation suggests that this improves the ability of the system to correctly interpret, and hence answer, questions.

2 Context and Related Work

Our system aims to interpret and answer high-school level, exam-style biology questions, expressed in sentence form. Our source of answers is a formal knowledge-base and reasoning engine (rather than a text corpus), placing specific requirements on the interpretation process - in particular, a full semantic interpretation of the question is required. Questions are typically one or two sentences long, for example:

(1) Does a prokaryotic cell contain ribosomes?
(2) A eukaryotic cell has a nucleus. Does that nucleus contain RRNA?
(3) Is adenine found in RNA molecules?
(4) Does a prokaryotic cell have a region consisting of cytosol?
(5) Do ribosomes synthesize proteins in the cytoplasm?
(6) What is the material, containing DNA and protein, that forms into chromosomes during mitosis?

Coling 2008: Poster Volume, pages 171–179,
Beijing, August 2010

Interpreting and answering this style of question has a long history in NLP, both for answers found via database retrieval and formal reasoning, and for answers extracted from a large text corpus.

For answers found using reasoning, the focus of this paper, early NL systems typically used a pipelined architecture for question interpretation (e.g., Bobrow, 1964; Woods 1977), with later systems also using semantic constraints to guide disambiguation decisions (e.g., Novak, 1977). More recently, as well as there being significant improvements in the performance of typical pipeline modules, e.g., word sense disambiguation (Navigli, 2009), there has been substantial work on various forms of deferred commitment, underspecification, and paraphrasing to expand the space of interpretations considered, and thus improve interpretation. Underspecified representations (e.g., van Deemter and Peters, 1996; Pinkal, 1999) allow ambiguity (in particular scope ambiguity) to be preserved in a single structure and commitments deferred until later, allowing multiple interpretations to be carried through the system. Similarly, a system can defer commitment by simply carrying multiple, alternative interpretations forward as individual structures, or packed together into a single structure (e.g., Alshawi and van Eijck, 1989, Bobrow et al., 2005; Kim et al., 2010a,b). Finally, canonicalized representations are often used to represent (and hence carry through the system) multiple, equivalent surface forms as a single structure, e.g., normalizing active and passive forms, or alternative forms of noun modification (Rinaldi et al., 2003). All these techniques help avoid premature commitment in interpretation.

As well as avoiding early rejection of interpretations in these ways, there has been substantial, recent work on expanding the space of possible interpretations considered through the use of paraphases (e.g., Sekine and Inui, 2007). Paraphrasing is based on the observation that there are many ways of saying (roughly) the same thing, and that syntatic manipulation alone is not sufficient to enumerate them all. Paraphrases aim to enumerate these additional alternatives, and may be generated synthetically (e.g., Rinaldi et al., 2003), drawn from similar texts (e.g., from similar questions for QA, Harabagiu et al., 2000), or mined from a corpus using machine learning techniques (e.g., Lin and Pantel, 2001). They have proved to be particularly useful in the context of textual entailment (e.g., Bentivogli et al., 2009), and in corpus-based question answering (e.g., Harabagiu et al., 2003).

Our work builds on this prior work, applying and extending these ideas to the context where a formal knowledge base and reasoning engine is available. In particular, we interleave the process of expanding the space of interpretations considered (using paraphrases and deferred commitment) with the process of question answering (which narrows down that space by selecting interpretations supported by the KB), thus controlling the otherwise combinatorial explosion of alternatives. This makes it feasible to use the DIRT paraphrase database (12 million paraphrases) for generating a full semantic interpretation of the original question, extending its previous use in the semi-formal context of textual entailment (Bentivogli et al., 2009). Our use of reasoning to guide disambiguation follows Hobbs et als (1993) method of "interpretation as abduction", where the system searches a space of possible interpretations for one(s) that are provable from the KB, preferring those interpretations.

3 The Problem

Although the biology KB we are using contains the knowledge to answer the six earlier questions (1)-(6), only the first two are correctly answered with the original pipelined ("base") system. For question (3):

(3) Is adenine found in RNA molecules?

the system (mis-)interprets this as referring to some actual "finding" event, not recognizing that this is an alternative way of phrasing a question about physical structure. Similarly, the notion of "consisting of" in question (4) is an unexpected phrasing that the system does not understand. Questions (5) and (6) are also answered incorrectly by the base system due to errors in semantic role labeling during interpretation. In (5):

(5) Do ribosomes synthesize proteins in the cytoplasm?

"in" is (mis-)interpreted by the language interpreter as an is-inside(x,y) relation, while the KB itself represents this relationship as site(x,y), hence the system fails to produce the correct answer (yes). Similarly, for (6) "into" is (mis)interpreted as destination(x,y) but represented in the KB as result(x,y).

Clearly, one can tweak the original interpreter to overcome these particular problems. However, it is a slow, expensive process, and in general it is impossible to anticipate all such problems up front. Statistical methods (e.g., Manning and Schutze, 1999) offer an alternative approach but one that is similarly noisy, problematic for question-answering applications.

4 Solution Approach

The brittleness of the base system can be partially attributed to its eager commitments, ahead of specifics that might be discovered during question-answering itself. To address this, we have modified the system in two ways. First, we have added use of paraphrases to explore additional interpretations of the question during question-answering. Second, we defer sense and semantic role disambiguation until question answering. As a result, part of interpretation occurs during answering itself: multiple interpretations are tried and a commitment is made to the one(s) that produce a non-null answer. The justification for this commitment is a **benevolent user** assumption, namely that the interpretation that "makes sense" with respect to the KB (i.e., produces a non-null answer) is the one that the user intended.

This use of question-answering to drive disambiguation follows Hobbs et als. (1993) work on Interpretation as Abduction. In that framework, a system searches for an interpretation that is provable from the KB plus a minimal cost set of assumptions, the interpretation corresponding to a particular way to disambiguate the text. In our work we do a similar thing, although restrict the assumptions to disambiguation decisions and exclude assuming new knowledge, as we are dealing with questions rather than assertions (if no interpretations are provable, then we treat the answer as "no" rather than treating the unproven query as something that should be asserted as true).

4.1 Paraphrases

Several paraphrase databases are now available to the NLP community[1], typically built by automatically finding phrases that occur in distributionally similar contexts (e.g., Dras et al, 2005). To date, paraphrase databases have primarily been exploited for recognizing textual entailment (e.g., Bentivogli et al., 2009, Clark et al, 2009), and for corpus-based question answering (e.g., Harabagiu et al., 2003). Here we use them for generating a full semantic interpretation in the context of querying a formal knowledge resource.

We use the DIRT paraphrase database (Lin and Pantel, 2001), containing approximately 12 million automatically learned rules of the form:

IF X *relation* Y THEN X *relation'* Y

where *relation* is a path in the dependency tree between constitutents X and Y, or equivalently (as we use later) a *chain of literals*:

$$\{p_0(x_0,x_1), w_1(x_1), \ldots p_{n-1}(x_{n-1},x_n)\}$$

where p_i is the syntactic relation between (non-prepositional) constituents x_i and x_{i+1}, and w_i is the word used for x_i. An example from DIRT is:

IF X is found in Y THEN X is inside Y

The condition "X is found in Y" can be expressed as the chain of literals:

{ object-of(x,f), "find"(f), "in"(f,y) }

The database itself is noisy, containing both good and nonsensical paraphrases. Interestingly, their use in question-answering tends to filter out most bad paraphrases, as it is rare that a nonsensical paraphrases will by chance produce an answer (i.e., the question + KB together help "triangulate" on good paraphrases). Nevertheless, bad paraphrases can sometimes produce incorrect answers. To handle this in a practical setting, we are adding an interactive interface (outside the scope of this paper) that shows the user any paraphrases used, and allows him/her to verify/block them as desired.

4.2 Deferred Sense Commitment

A second, common cause of failure of the base system was incorrect assignment of senses and

[1] e.g., http://www.aclweb.org/aclwiki/index.php?title=RTE_Knowledge_Resources

semantic relations during word sense disambiguation (WSD) and semantic role labeling (SRL). While domain-specific terms are generally reliably disambiguated, disambiguation of general terms (e.g., whether "split" denotes the concept of Separate or Divide) and semantic roles (e.g., whether "into" denotes destination(x,y) or result(x,y)) is less reliable, with only limited improvement attainable through manual engineering or machine learning. The problem is compounded by a degree of subjectivity in the way knowledge is encoded in the KB, for example whether the KB engineer chose to conceptualize a biological object as the "agent" or "instrument" or "site" of an activity is to a degree a matter of viewpoint.

To overcome this, we defer WSD and SRL commitments until question-answering itself. One can view this as a trivial form of preserving underspecification (eg. Pinkal, 1999) in the initial language processing, where the words themselves denote their possible meanings.

4.3 Algorithm and Implementation

Questions are first parsed using a broad coverage, phrase structure parser, followed by coreference resolution, producing an initial "syntactic" logical form, for example:

Question: *Do mitotic spindles consist of hollow microtubules?*

Logical Form (LF): "mitotic-spindle"(s), "consist"(c), "hollow"(h), "microtubule"(m), subject(c,s), "of"(c,m), modifier(m,h).

Next, rather than attempting word sense disambiguation (WSD) and semantic role labeling (SRL) as would be done in the base system, the system immediately starts work on answering the question, even though a complete semantic interpretation has not yet been produced. In the process of answering, the system explores alternative word senses, semantic roles, and paraphrases for the particular literals it is working on (described shortly), and if any are provable from the knowledge in the knowledge base then those branch(es) of the search are explored further. There are two basic steps in this process:

(a) **setup:** create an instance X0 of the object being universally quantified over[2] (identified during initial language interpretation)

(b) **query:** for each literal in the LF with at least one bound variable, iteratively query the KB to see if some interpretation of those literals are provable i.e., already known.

In this example, illustrated in Figure 1, for step (a) the system first creates an instance X0 of a mitotic spindle, i.e., asserts the instantiated first literal isa(X0,Mitotic-Spindle), and then queries the inference engine with the remaining LF literals. (If there are multiple senses for "mitotic spindle", then an instance for each sense is created, to be explored in parallel). For step (b), the system uses the algorithm as follows:

repeat
  select a chain C_u of "syntactic" literals in the LF with at least 1 bound variable
    C_u = {p(x,y)} or {w(x)} or
      {p_1(x,z), w(z), p_2(z,y)}
  select some interpretation C of C_u where:
    C is a possible interpretation of C_u
    or C'_u is a possible paraphrase for C_u and
      C is a possible interpretation of C'_u
  try prove C[bindings] → new-bindings
  If success:
    replace C_u with C
    add new-bindings to bindings
until
  all clauses are proved

where:

- A *syntactic literal* is a literal whose predicate is a word or syntactic role (subject, object, modifier, etc.) All literals in the initial LF are syntactic literals.
- A *chain of literals* is a set of syntactic literals in the LF of the form {p(x,y)} or {w(x)} or {p_1(x,z), w(z), p_2(z,y)}, where p_i, w are words or syntactic roles (subject, mod, etc).
- A *possible paraphrase* is a possible substitution of one chain of literals with another, listed in the DIRT paraphrase database.

[2] If the system can prove the answer for a (new) instance X0 of the universally quantified class, then it holds for all instances, i.e., if KB ∪ f(X0) ├ g(X0) then KB ├ f(X0)→g(X0), hence KB ├ ∀x f(x)→g(x) via the principle of universal generalization (UG).

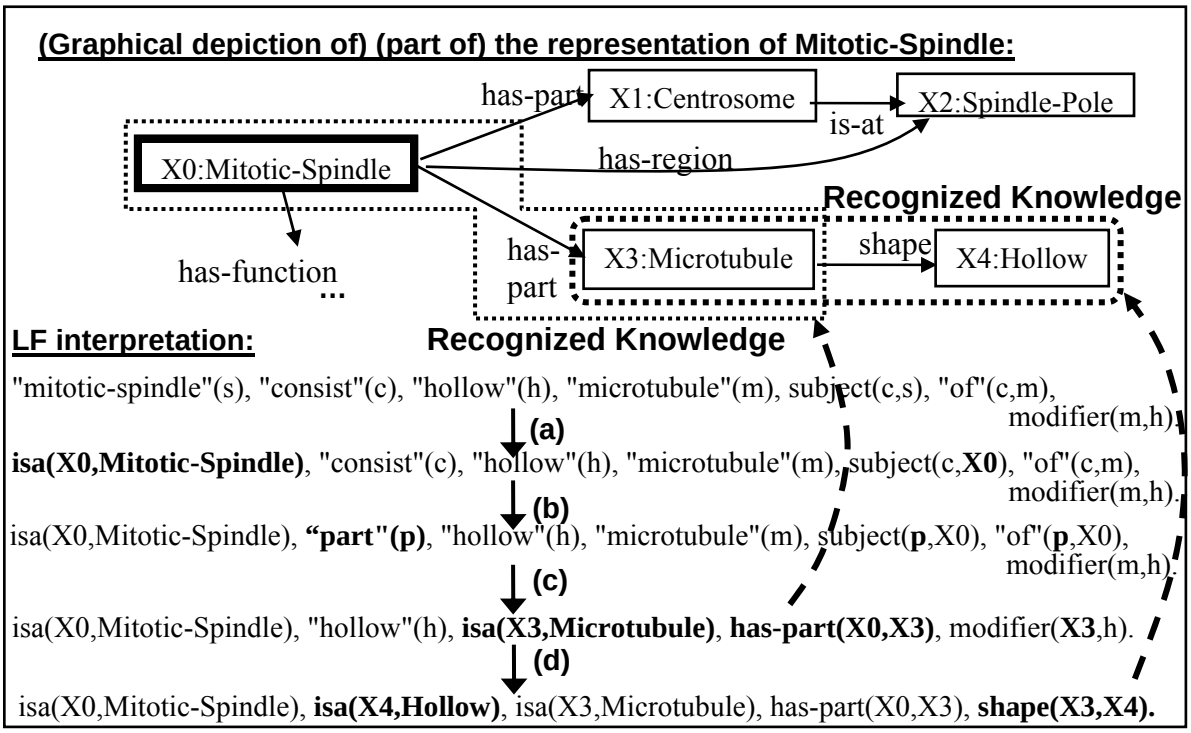

Figure 1: The path found through the search space for an interpretation of the example question. (a) setup (b) paraphrase substitution (IF X consists of Y THEN Y is part of X) (c) interpretation of {subject-of(X0,p),"part"(p), "of"(p,X0)} as has-part(X0,m), preferred as it is provable from the KB, resulting in m=X3 (d) interpretation of the syntactic modifier(X3,h) relation (from "hollow microtubule") as shape(X3,h) as it is provable from the KB.

- A *possible interpretation* of the singleton chain of literals {w(x)} is isa(x,*class*), where *class* is a possible sense of word w.
- A *possible interpretation* of a chain of literals {p(x,y)} or {p1(x,z),w(z),p2(z,y)} is r(x,y), where r is a semantic relation corresponding to syntactic relation p (e.g., "in"(x,y) → is-inside(x,y)) or word w (e.g., {subject-of(e,h), "have"(h), "of"(h,n)} → has-part(e,n)).

Possible word-to-class and word-to-predicate mappings are specified in the KB.

Figure 1 illustrates this procedure for the example sentence. The procedure iteratively replaces syntactic literals with semantic literals that correspond to an interpretation that is provable from the KB. If all the literals are proved, then the answer is "yes", as there exists an interpretation under which it can be proved from the KB, under the benevolent user assumption that this is the interpretation that the user intended.

As there are several points of non-determinism in the algorithm, e.g., which literals to select, which interpretation to explore, it is a search process. Our current implementation uses most-instantiated-first query ordering plus breadth-first search, although other implementations could traverse the space in other ways.

5 Evaluation

To evaluate the system, we measured its question-answering performance on a set of 141 true/false biology questions, ablating paraphrases and deferred commitment to measure their impact. The 141 questions were sentencized versions of the multiple choice options in 22 original AP-level exam questions that, in an earlier evaluation (Clark, 2009), users had difficulty rephrasing into a form that the system understood. Each original multiple choice option was minimally rewritten as a complete sentence (most multiple choice questions were partial se-

Configuration	Accuracy (score = y/y+n/n)	system/actual answers			
		y/y	n/y	y/n	n/n
Naive(all false)	67% (94)	0	47	0	94
Base system	72% (102)	8	41	0	94
+ Paraphrases	75% (106)	13	34	1	93
+ Deferred commitment	76% (107)	13	34	0	94
+ Both (full system)	84% (118)	25	22	1	93

Table 1: Performance of different configurations of the system. The y/y column shows the number of questions for which the system answered "yes" and the correct answer is "yes", etc.

ntences), while preserving the original English phrasing. For example the original question:

73. Which of the following best describes the DNA molecule?
   a. Two parallel strands of nitrogen bases held together by hydrogen bonding
   b. Two complementary strands of deoxyribose and phosphates held together by hydrogen bonding
   c. Two antiparallel strands of nucleotides held together by hydrogen bonding
   d. A single strand of nitrogen bases coiled upon itself by hydrogen bonding
   e. A single strand of nucleotides coiled into a helix.

was rewritten as five questions:

- Does a DNA molecule have two parallel strands of nitrogen bases held together by hydrogen bonding?
- Does a DNA molecule have two complementary strands of deoxyribose and phosphates held together by hydrogen bonding?
- Does a DNA molecule have two antiparallel strands of nucleotides held together by hydrogen bonding?
- Does a DNA molecule have a single strand of nitrogen bases coiled upon itself by hydrogen bonding?
- Does a DNA molecule have a single strand of nucleotides coiled into a helix?

Similarly:

79. All of the following organelles are associated with protein synthesis EXCEPT:
   a. ribosomes; b. Golgi bodies;...; e...

was rewritten as five questions:

- Are ribosomes associated with protein synthesis?
- Are Golgi bodies associated with...*etc*.

For 18 of the original questions, each of the 5 options expanded to 1 true/false question. For 3 comparison questions ("Which X is in Y but not Z?"), each option expanded into 2 questions ("Is X in Y?" "Is X in Z?"). Finally 1 question involved parallelism ("Which of the following A,B,C do X,Y,Z respectively?") which expanded into 21 questions ("Does A do X?" "Does A do Y?" etc.) after removing duplicates. Of the resulting 141 questions, 47 had the "gold" answer of true, 94 false. Of the 47 positives, 4 were out of scope of the reasoning engine, involving questions about possibility rather than truth, for example:

- Can a DNA adenine bond to an RNA uracil?

Another 3 were out of scope of the knowledge in the KB (2 requiring unrepresented temporal knowledge and 1 requiring commonsense knowledge). Thus the upper bound on performance, given the particular KB and reasoning engine that we are using, is 134/141 (95%).

We ran the base system alone, with paraphrasing (only), with deferred commitment (only), and with both. The results are shown in Table 1. As can be seen, true negatives (n/y) are a substantially larger challenge than false positives (y/n), as the system answers "no" by defalt if it is unable to prove the facts in the interpreted question from the KB. During interpretation, the base "pipeline" system commits to disambiguation decisions at each step, and if any commitment is wrong then it will also get the answer wrong, as reflected

by the only small (8) increase in number correctly answered.

Paraphrases allow the system to search for alternative interpretations, adding five more questions to be answered correctly but also introducing one false positive (y/n). The false positive was for the question:

Do peroxisomes make proteins?

This was (incorrectly) answered "yes" by the system as it used a bad DIRT paraphrase (IF X makes Y THEN X is made from Y), selected because it led to a provable interpretation (peroxisomes are made (synthesized) from proteins), but not the one the author intended. It is an interesting and perhaps somewhat surprising result that this was the only false positive, given that the DIRT database is noisy (approximately half its paraphrases are questionable or invalid). The low number of false positives appears to be due to the fact that the vast number of invalid paraphrases produce nonsensical, hence unprovable and rejected, interpretations.

Similarly, deferred commitment (alone) allowed five additional questions (different to those for paraphrasing) to be answered, again as premature word sense and semantic role labeling was avoided. For example, for "...the polymerase builds a strand...", the pipeline prematurely commits to the strand being the object of the build, while in the KB it is represented as the result of the build. Deferred commitment allows the system to search and find such alternatives.

Finally there were several (7) questions requiring both paraphrases and deferred commitment to answer. For example, "Do mitochondria provide cellular energy?" was answered using both a paraphrase (IF X provides Y THEN X creates Y) and deferred commitment (mitochondria was correctly interpreted as the site of the creation, as represented in the KB, while the pipeline prematurely committed to agent).

Although deferring SRL and WSD commitment, the final system still eagerly commits to a single syntactic analysis, and in some cases that analysis was wrong (e.g., wrong PP attachment), causing failure for some of the 16 in-scope, positive examples that the final system failed to answer. Clearly deferred commitment can be further extended to explore alternative syntactic analyses. The remaining failures were due to incorrect semantic interpretation of the syntactic analysis, primarily due to poor handling of coordination.

The median, average, and maximum cpu times per question were 0.7, 4.9, and 20.3 seconds respectively.

6 Discussion and Conclusion

Although question interpretation is challenging, we are in the unusual position of having substantial, formal domain (biology) knowledge available. We have illustrated how this knowledge can be exploited to improve question understanding by interleaving interpretation and answering together, allowing the DIRT paraphrase database to be feasibly used and avoiding premature sense commitment. The result is an improved understanding of the original biology questions.

Our work extends previous work (Section 2) on exploring multiple interpretations and exploiting paraphrases, doing so in the context of a task involving formal reasoning. In particular, by interleaving the expansion of possible interpretations with reasoning (that contracts those alternatives), a viable system can be constructed in which the combinatorics are controlled. However, although the system defers WSD and SRL commitment, there are other sources of brittleness – in particular its commitment to a single semantic analysis – that could also benefit from exploration of alternatives, e.g., by using packed representations (Bobrow et al., 2005).

A second limitation of the current approach is that it assumes the (semantics of the) question is a generalized subset of information in (or inferrable from) the KB, i.e., questions are "pure queries" about the KB that do not posit any new information. However some questions, in particular hypotheticals ("X is true. Does Y follow?"), violate this "pure query" assumption by asserting a novel premise (X) that is not in the KB, and hence cannot be disambiguated by searching for the premise X. Although such questions are relatively rare

in biology, they are common in other sciences (e.g., physics). Handling such questions would require extension of this approach, eg by matching a generalized form of the assertion X against the KB to identify how to disambiguate it. Similarly, if we wished to use the system to read new knowledge, as opposed to identify old knowledge, further extensions would be needed, as new knowledge by definition cannot be proved from the KB.

Finally, this work suggests that paraphrase databases such as DIRT offer potential for language understanding in the context of posing formal questions to a reasoning system or database, by bridging gaps that would otherwise have to be hand-engineered, extending their previous use in semi-formal settings such as textual entailment (Bentivogli et al., 2009). Despite noise, the question plus KB help "triangulate" on good paraphrases, and with a suitable user interface to expose their use, this work suggests that there is substantial potential for deploying them in a practical, end-user environment.

Two Methods for Extending Hierarchical Rules from the Bilingual Chart Parsing

Martin Čmejrek and **Bowen Zhou**
IBM T. J. Watson Research Center
{martin.cmejrek, zhou}@us.ibm.com

Abstract

This paper studies two methods for training hierarchical MT rules independently of word alignments. Bilingual chart parsing and EM algorithm are used to train bitext correspondences. The first method, rule arithmetic, constructs new rules as combinations of existing and reliable rules used in the bilingual chart, significantly improving the translation accuracy on the German-English and Farsi-English translation task. The second method is proposed to construct additional rules directly from the chart using inside and outside probabilities to determine the span of the rule and its non-terminals. The paper also presents evidence that the rule arithmetic can recover from alignment errors, and that it can learn rules that are difficult to learn from bilingual alignments.

1 Introduction

Hierarchical phrase-based systems for machine translation usually share the same pattern for obtaining rules: using heuristic approaches to extract phrase and rule pairs from word alignments. Although these approaches are very successful in handling local linguistic phenomena, handling longer distance reorderings can be more difficult. To avoid the combinatorial explosion, various restrictions, such as limitations of the phrase length or non-terminal span are used, that sometimes prevent from extracting good rules. Another reason is the deterministic nature of those heuristics that does not easily recover from errors in the word alignment.

In this work, we learn rules for hierarchical phrase based MT systems directly from the parallel data, independently of bilingual word alignments.

Let us have an example of a German-English sentence pair from the Europarl corpus (Koehn, 2005).

(1) GER: die herausforderung besteht darin diese systeme zu den besten der welt zu machen
ENG: the challenge is to make the system the very best

The two pairs of corresponding sequences *diese systeme ... der welt—the system ... best* and *zu machen—to make* are swapped. We believe that the following rule could handle long distance reorderings, still with a reasonably low number of terminals, for example:

(2) $X \rightarrow \langle$besteht darin X_1 zu X_2, is to $X_2 X_1 \rangle$,

There are 127 sentence pairs out of 300K of the training data that contain this pattern, but this rule was not learned using the conventional approach (Chiang, 2007). There are three potential risks: (1) alignment errors (the first *zu* aligned to *to*, or *der welt* (*of the world*) aligned to null); (2) maximum phrase length for extracting rules lower than 11 words; (3) requirement of non-terminals spanning at least 2 words.

The *rule arithmetic* (Cmejrek et al., 2009) constructs the new rule (2) as a combination of good rule usages:

(3) $X \rightarrow \langle$besteht darin, is $\rangle$
$X \rightarrow \langle X_1$ zu X_2, to $X_2 X_1 \rangle$

Coling 2008: Poster Volume, pages 180–188,
Beijing, August 2010

The approach consists of bilingual chart parsing (BCP) of the training data, combining rules found in the chart using a *rule arithmetic* to propose new rules, and using EM to estimate rule probabilities.

In this paper, we study the behavior of the rule arithmetic on two different language pairs: German-English and Farsi-English. We also propose an additional method for constructing new rules directly from the bilingual chart, and compare it with the rule arithmetic.

The paper is structured as follows: In Sec. 1, we explain our main motivation, summarize previous work, and briefly introduce the formalism of hierarchical phrase-based translation. In Sec. 2, we describe the bilingual chart parsing and the EM algorithm. The rule arithmetic is introduced in Sec. 3. The new method for proposing new rules directly from the chart is described in Sec. 4. The experimental setup is described in Sec. 5. Results are thoroughly discussed in Sec. 6. Finally, we conclude in Sec. 7.

1.1 Related work

Many previous works use the EM algorithm to estimate probabilities of translation rules: Wu (1997) uses EM to directly estimate joint word alignment probabilities of Inversion Transduction Grammar (ITG). Marcu and Wong (2002) use EM to estimate joint phrasal translation model (JPTM). Birch et al. (2006) reduce its complexity by using only concepts that match the high-confidence GIZA++ alignments. Similarly, Cherry and Lin (2007) use ITG for pruning. May and Knight (2007) use EM algorithm to train tree-to-string rule probabilities, and use the Viterbi derivations to re-align the training data. Huang and Zhou (2009) use EM to estimate conditional rule probabilities $P(\alpha|\gamma)$ and $P(\gamma|\alpha)$ for Synchronous Context-free Grammar. Others try to overcome the deterministic nature of using bilingual alignments for rule extraction by sampling techniques (Blunsom et al., 2009; DeNero et al., 2008). Galley et al. (2006) define minimal rules for tree-to-string translation, merge them into composed rules (similarly to the rule arithmetic), and train weights by EM. While in their method, word alignments are used to define all rules, rule arithmetic proposes new rules independently of word alignments. Similarly, Liu and Gildea (2009) identify matching long sequences ("big templates") using word alignments and "liberate" matching small subtrees based on chart probabilities. Our method of proposing rules directly from the chart does not use word alignment at all.

1.2 Formally syntax-based models

Our baseline model follows the Chiang's hierarchical model (Chiang, 2007; Chiang, 2005; Zhou et al., 2008) based on Synchronous Context-free Grammar (SCFG). The rules have form

$$X \rightarrow \langle \gamma, \alpha, \sim \rangle, \tag{4}$$

where X is the only non-terminal in the grammar, γ and α are source and target strings with terminals and up to two non-terminals, $\sim$ is the correspondence between the non-terminals. Corresponding non-terminals have to be expanded at the same time.

2 Bilingual chart parsing and EM algorithm

In this section, we briefly overview the algorithm for bilingual chart parsing and EM estimation of SCFG rule features.

Let $\mathbf{e} = e_1^M$ and $\mathbf{f} = f_1^N$ of source and target sentences. For each sentence pair $\mathbf{e}, \mathbf{f}$, the 'E' step of the EM algorithm will use the bilingual chart parser to enumerate all possible derivations Φ, compute inside probabilities $\beta_{ijkl}(X)$ and outside probabilities $\alpha_{ijkl}(X)$, and finally calculate expected counts $c(r)$ how many times each rule r produced the corpus C.

The inside probabilities can be defined recursively and computed dynamically during the chart parsing:

$$\beta_{ijkl} = \sum_{\rho \in t_{ijkl}} P(\rho.r) \prod_{(i'j'k'l') \in \rho.bp} \beta_{i'j'k'l'}, \tag{5}$$

where t_{ijkl} represents the chart cell spanning (e_i^j, f_k^l), and the data structure ρ stores the rule $\rho.r$. If r has non-terminals, then $\rho.bp$ stores backpointers $\rho.bp_1$ and $\rho.bp_2$ to the cells representing their derivations.

The outside probabilities can be computed recursively by iterating the chart in top-down ordering. We start from the root cell $\alpha_{1,M,1,N} := 1$ and propagate the probability mass as

$$\alpha_{\rho.bp_1} += P(\rho.r)\alpha_{ijkl} \quad (6)$$

for rules with one non-terminal, and

$$\alpha_{\rho.bp_1} += P(\rho.r)\alpha_{ijkl}\beta_{\rho.bp_2}, \quad (7)$$
$$\alpha_{\rho.bp_2} += P(\rho.r)\alpha_{ijkl}\beta_{\rho.bp_1}, \quad (8)$$

for rules with two non-terminals. The top-down ordering ensures that each α_{ijkl} accumulates updates from all cells higher in the chart before its own outside probability is used.

The contributions to the rule expected counts are computed as

$$c(\rho.r) += \frac{P(\rho.r)\alpha_{ijkl}\prod_{i=1}^{\rho.n}\beta_{\rho.bp_i}}{\beta_{1,M,1,N}}. \quad (9)$$

Finally, rule probabilities $P(r)$ are obtained by normalizing expected counts in the 'M' step.

To improve the grammar coverage, the ruleset is extended by the following rules providing "backoff" parses and scoring for the SCFG rules:

(10) $\langle X_1, X_1 f\rangle$, $\langle X_1, f X_1\rangle$, $\langle X_1 e, X_1\rangle$, $\langle e X_1, X_1\rangle$,

(11) $\langle X_1 X_2, X_2 X_1\rangle$.

Rules (10) enable insertions and deletions, while rule (11) allows for aligning swapped constituents in addition to the standard glue rule.

3 Proposing new rules with rule arithmetic

The main idea of this work is to propose new rules independently of the bilingual word alignments. We parse each sentence pair using the baseline ruleset extended by the new rule types (10) and (11). Then we select the *most promising* rule usages and combine each two of them using the *rule arithmetic* to propose new rules. We put the new rules into a temporary pool, and parse and compute probabilities and expected counts again, this time we use rules from the baseline and from the temporary pool. Finally, we dump expected counts for proposed rules, and empty the temporary pool. This way we can try to propose many rules for each sentence pair, and to filter them later using accumulated expected counts from the EM.

The term *most promising* is purposefully vague — to cover all possible approaches to filtering rule usages. In our implementation, we are limited by space and time, and we have to prune the number of rules that we can combine. We use expected counts as the main scoring criterion. When computing the contributions to expected counts from particular rule usages as described by (9), we remember the n-best contributors, and use them as candidates after the expected counts for the given sentence pair have been estimated.

The *rule arithmetic* combines existing rules using *addition* operation to create new rules. The idea is shown in Example 12.

(12) Addition

$\langle 5,13,5,11,13,13\rangle$ $\langle 4,10,6,10,5,5\rangle$ $X \to \langle X_1$ zu X_2, to X_2 $X_1\rangle$
$\langle 5,11,6,11,0,0\rangle$ $\langle 6,10,7,10,0,0\rangle$ $X \to \langle$diese X_1, the $X_1\rangle$

1:	...	4	5	6	...	11	12	13	3	4	5	6	7	...	10
2:	...	0	-1	-1	...	-1	zu	-2	0	to	-2	-1	-1	...	-1
3:	...	0	diese	-3	...	-3	0	0	0	0	0	the	-3	...	-3
4:	...	0	diese	-3	...	-3	zu	-2	0	to	-2	the	-3	...	-3

5: $\langle 5,13,6,11,13,13\rangle$ $\langle 4,10,7,10,5,5\rangle$ $X \to \langle$diese X_1 zu X_2, to X_2 the $X_1\rangle$

First, create span projections for both source and target sides of both rules. Use symbol 0 for all unspanned positions, copy terminal symbols as they are, and use symbols -1, -2, -3, and -4 to transcribe X_1 and X_2 from the first rule, and X_1 and X_2 from the second rule. Repeat the non-terminal symbol on all spanned positions. In Example 12 line 1 shows the positions in the sentence, lines 2 and 3 show the rule span projections of the two rules.

Second, merge source span projections (line 4), record mappings of non-terminal symbols. We require that merged projections are *continuous*. We allow substituting non-terminal symbols by terminals, but we require that the whole span of the non-terminal is fully replaced. In other words, shortenings of non-terminal spans are not allowed.

Third, collect new rule. The merged rule usages (lines 5) are generalized into rules, so that they are not limited to the particular span for which they were originally proposed.

The rule arithmetic can combine all types of rules – phrase pairs, abstract rules, glues, swaps, insertions and deletions. However, we require that

at least one of the rules is either a phrase pair or an abstract rule.

4 Proposing directly from chart

One of the issues observed while proposing new rules with the rule arithmetic is the selection of the best candidates. The number of all candidates that can be combined depends on the length of the sentence pair and on the number of competing parsing hypotheses. Using a fixed size of the n-best can constitute a risk of selecting bad candidates from shorter sentences. On the other hand, the spans of the best candidates extracted from long sentences can be far from each other, so that most combinations are not valid rules (e.g., the combination of two discontinuous phrasal rules is not defined).

In our new approach we propose new rules directly from the bilingual chart, relying on the inside and outside probabilities computed after the parsing of the sentence pair. The method has two steps. In the first step we identify best matching parallel sequences; in the second step we propose "holes" for non-terminals.

4.1 Identifying best matching sequences

To identify the best matching sequences, we score all sequences (e_i^j, f_k^l) by a scoring function:

$$score_{ijkl} = \frac{\alpha_{ijkl}\beta_{ijkl}}{\beta_{1,M,1,N}} Lex(i,j,k,l), \quad (13)$$

where the lexical score is defined as:

$$Lex(i,j,k,l) = \sum_{j'=1}^{N} \prod_{i'=0}^{M} t(f_{j'}|e_{i'})\delta_{ijkli'j'} \quad (14)$$

The t is the lexical probability from the word-to-word translation table, and $\delta_{ijkli'j'}$ is defined as δ_{ins} if $i' \in \langle i,j \rangle$ and $j' \in \langle k,l \rangle$, and as δ_{out} if $i' \notin \langle i,j \rangle$ and $j' \notin \langle k,l \rangle$, and as 0 elsewhere. The purpose of this function is to score only the pairs of words that are both either from within the sequence or from outside the sequence. Usually $0 \leq \delta_{out} \leq \delta_{ins}$ to put more weight on words within the parallel sequence.

The scoring function is a combination of expected counts contribution of a sequence (e_i^j, f_k^l) estimated from the chart with the IBM Model 1 lexical score.

Since only the sequences spanned by filled chart cells can have non-zero expected counts, we can select the n-best matching sequences relatively efficiently.

4.2 Proposing non-terminal positions

Similar approach can be used to propose best positions for non-terminals. We score every combination of non-terminal positions. The expected counts can be estimated using Eq. 9. Since we are proposing new rules, the probability $P(r)$ used in that equation is not defined. Again, we can use Model 1 score instead, and use the following scoring function:

$$s_{ijkl}(bp_1, bp_2) = \frac{Lex(i,j,k,l,bp_1,bp_2)\alpha_{ijkl}\beta_{bp_1}\beta_{bp_2}}{\beta_{1,M,1,N}}, \quad (15)$$

$Lex(i,j,k,l,bp_1,bp_2)$ is defined as in Eq. 14. This time using $0 \leq \delta_{out} \leq \delta_{NT1} = \delta_{NT2} \leq \delta_{term}$, restricting the IBM Model 1 to score only word pairs that both belong either to the terminals of the proposed rule, or to the sequences spanned by the same non-terminal, or outside of the rule span. The scoring function for rules with one non-terminal is just a special case of 15.

Again, the candidates can be scored efficiently, taking into account only those combinations of non-terminal spans that correspond to filled cells in the chart.

The proposed method is again independent of bilingual alignment, but at the same time utilizes the information obtained from the bilingual chart parsing.

5 Experiments

We carried out experiments on two language pairs, German-English and Farsi-English.

The **German-English** data is a subset (297k sentence pairs) of the Europarl (Koehn, 2005) corpus. Since we are focused on speech-to-speech translation, the punctuation was removed, and the text was lowercased. The dev set and test set contain each 1k sentence pairs with one reference.

The word alignments were trained by GIZA++ toolkit (Och and Ney, 2000). Phrase pairs were

extracted using grow-diag-final (Koehn et al., 2007). The baseline ruleset was obtained as in (Chiang, 2007). The maximum phrase length for rule extraction was set to 10, the minimum required non-terminal span was 2.

Additional rules for insertion, deletion, and swap were added to improve the parsability of the data, and to help EM training and rule arithmetic. However, these rules are not used by the decoder, since they would degrade the performance.

New rules were proposed after the first iteration of EM[1], either by rule arithmetic or directly from the chart.

Only non-terminal rules proposed by the rule arithmetic from at least two different sentence pairs and ranked (by expected counts $c(r)$) in the top 100k were used. Figure 4 presents a sample of the new rules.

New rules were also proposed directly from the chart, using the approach in Sec. 4. 5% of best matching parallel sequences, and 5 best scoring rules were selected from each parallel sequence. Non-terminal rules from the 200k-best rank were added to the model. Figure 5 presents a sample of the new rules.

Finally, one more iteration of EM was used to adjust the probabilities of the new and baseline rules. These probabilities were used as features in the decoding.

The performance of rule arithmetic was also verified on **Farsi-English** translation. The training corpus contains conversational spoken data from the DARPA TransTac program extended by movie subtitles and online dictionaries downloaded from the web (297k sentence pairs). The punctuation was removed, and the text was lowercased. The dev set is 1,420 sentence pairs held out from the training data, with one reference. The test set provided by NIST contains 470 sentences with 4 references. The sentences are about 30% longer and more difficult.

The training pipeline was the same as for the German-English experiments. 122k new non-terminal rules were proposed using the rule arithmetic.

[1]Since our initial experiments did not show any significant gain from proposing rules after additional (lengthy) iterations of EM.

The feature weights were tuned on the dev set for each translation model separately. The translation quality was measured automatically by BLEU score (Papineni et al., 2001).

6 Discussion of results

The BLEU score results are shown in the Table 3. The cumulative gain of rule arithmetic and EM (RA + EM-i0) is 1 BLEU point for German-English translation and 2 BLEU points for Farsi-English. The cumulative gain of rules proposed from the chart (DC + EM-i0) is 0.2 BLEU points for German-English. For comparison of effects of various components of our method, we also show scores after the first five iterations of EM (EM-i0–EM-i4) without adding any new rules, just using EM-trained probabilities as feature weights, and also scores for new rules added into the baseline without adjusting their costs by EM (RA).

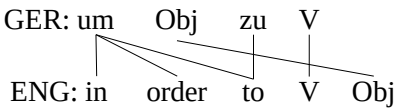
The qualities of proposed rules are discussed in this section.

6.1 German-English rules from rule arithmetic

The Figure 4 presents a sample of new rules proposed during this experiment. The table is divided into three parts, presenting rules from the top, middle, and bottom of the 100K list. The quality of the rules is high even in the middle part of the table, the tail part is worse.

We were surprised by seeing short rules consisting of frequent words. For example $\langle$um X_1, in order $X_1\rangle$. When looking into word-level alignments, we realized that these rules following the pattern 16 prevent the baseline approach from extracting the rule.

(16)

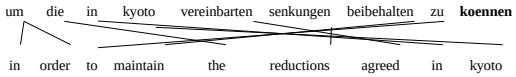


Similarly many other rules match the pattern of beginning of a subordinated clause, such as *that is why*, or insertions, such as *of course*, which both have to be strictly followed by VSO construction in German, in contrast to the SVO word order in English.

We also studied the cases of rule arithmetic correcting for systematic word alignment errors. For

example the new rule $\langle X_1$ zu koennen, to $X_1\rangle$ was learned from the sentence

(17)



The English translation often uses a different modality, thus the modal verb *koennen* is always aligned with null. Since unaligned words are usually not allowed at the edges of sub-phrases generalized into non-terminals (Chiang, 2007), this rule cannot be learned by the baseline.

We observe that many new proposed rules correspond to patterns with a non-terminal spanning one word. For example $\langle$um X_1 zu X_2, to X_2 $X_1\rangle$ corresponds to the same pattern 16, where X_2 spans one verb. The line *baseline min1* in the Table 3 shows 0.3 BLEU improvement of a model trained without the minimum non-terminal span requirement. However, this improvement comes at a cost of more than four times increased model size, as shown in Table 2. We observe that using the minimum span requirement while learning from bitext alignments combined with rule arithmetic that can learn the most reliable rules spanning one word yields better performance in speed, memory, and precision.

We can also study the new rules quantitatively. We want to know how the rules proposed by the rule arithmetic are used in decoding. We traced the translation of the 1,000 test set sentences to mark the rules that were used to generate the best scoring hypotheses.

The stats are presented in the Table 1. The chance that a new rules will be used in the test set decoding (0.86%) is more than 7 times higher than that of all rules (0.12%). Encouraging evidence is that while the rule arithmetic rules constitute only 1.87% of total rules, they present 9.17% of rules used in the decoding.

The Figure 1 lists the most frequently used new rules in the decoding. We can see many rules with 2 non-terminals that model complex verb forms ($\langle$wird X_1 haben,will have $X_1\rangle$), reordering in clauses ($\langle$um X_1 zu gewaehrleisten, to ensure $X_1\rangle$), or reordering of verbs from the second position in German to SVO in English ($\langle$heute X_1 wir X_2, today we X_1 $X_2\rangle$).

Model	#phrases	#rules
Ger-Eng baseline	8.5M	5.3M
Ger-Eng baseline min1	8.5M	23.M

Table 2: Model sizes.

We also studied the correlation between the rank of the proposed rules (ranked by expected counts) and the hit rate during the decoding. The Figure 2 measures the hit rate for each of 1,000 best ranking rules, and should be read as follows: the rules ranking 0 to 999 were used 70 times, the hit rate decreases as the rank grows so that there were no hits for rules ranking 90k and more. The rank is a good indicator of the usefulness of new rules.

We hypothesize that the new rules are capable of combining partial solutions to form hypotheses with better word order, or better complex verb forms so that these hypotheses are better scored and are parts of the winning solutions more often.

6.2 German-English rules proposed directly from the chart

We also studied why the rules proposed directly from the bilingual chart yield smaller improvement than the rule arithmetic. The number of new rules used in the decoding (1,541) is even higher than that of the rule arithmetic, and it constitutes 21.23% of all cases. The two experiments were

#hits	Ger	Eng

2	es muss X_1 werden	it must be X_1

Figure 1: Examples of the most frequently h rules during the decoding.

tuned separately, so that they used different glu rule weights. That is why we observe the differ ence in the number of glues (and the number c total rules) in the Table 1. We do not observe an significant correlation between the rank of the rul and the hit rate. The Figure 3 shows that the first 10k-ranked rules are hit several times, and then the hit rate stays flat.

We offer an explanation based on our observations of rules used for the decoding. The rules proposed directly from the chart contain a big portion of content words. These rules do not capture any important differences between the structures of the two languages that could not be handled by phrasal rules as well. For example, the rule ⟨die neuen vorschriften sollen X_1,the new rules are X_1⟩ is correct, but a combination of a baseline phrasal rule and glue will produce the same result.

We also see many rules with non-terminals spanning one word. For example, the sequence

(18) die europaeische kommission—the european commission

will produce the rule

(19) ⟨die X_1 kommission, the X_1 commission⟩.

Although the sequence and the rule are high scored by 13 and 15, we intuitively feel that gen-

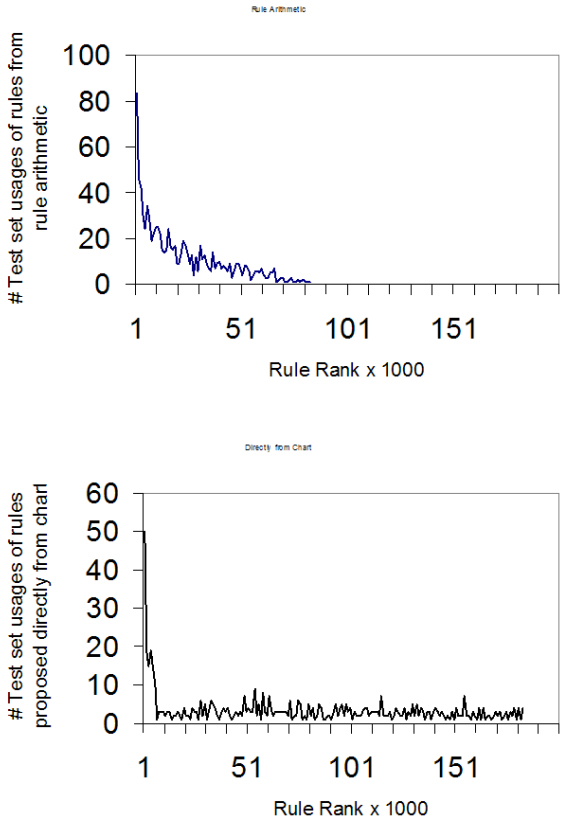

Figure 3: Usage of new rules (DC).

eralizing the word *european* is not very helpful in this context.

The rule arithmetic could propose the rule 19 as

(20) ⟨die X_1, the X_1⟩ + ⟨kommission, commission⟩,

but since the candidates for combination are selected as rules with the highest expected counts (Sec. 3), the rules 20 will most likely loose to the phrase pair 18 and will not be selected.

To conclude our comparison, we observe that both methods produce reliable rules that are often reused in decoding. Nevertheless, since the rule arithmetic combines the most successful rules from each parallel parse, the resulting rules enable structural transformations that could not be handled by baseline rules.

6.3 Farsi-English rules from the rule arithmetic

Although we have only limited resources to qualitatively analyze the Farsi-English experiments, we noticed that there are two major groups of new rules.

The first group corresponds to the fact that Farsi does not have definite article and allows pro-drop. We observe many new rules that could not be learned from word alignments, since some definite articles or pronouns in English were aligned to null (and unaligned words are not allowed at the edges of phrases). However, if the chart contains an insertion (of the determiner or pronoun) with a high expected count, the rule arithmetic may propose new rule by combining it with other rules.

The second group contains rules that help word reordering. We observe rules moving verbs from the S PP O V in Farsi into SVO in English as well as rules reordering wh-clauses.

Most of the rules traced during the test set decoding belong to the second group. Figure 1 shows that the number of new rules hit during the decoding is smaller compared to the German-English experiments. On the other hand, the rules have smaller number of terminals so that we assume that the positive effect of these rules comes from the reordering of non-terminals.

7 Conclusion

In this work, we studied two new methods for learning hierarchical MT rules: the rule arithmetic and proposing directly from the parse forest. We discussed systematic patterns where the rule arithmetic outperforms alignment-based approaches and verified its significant improvement on two different language pairs (German-English and Farsi-English). We also hypothesized why the second method – proposing rules directly from the chart – improves the baseline less than the rule arithmetic.

Abstract

In this paper we look at the problem of cleansing noisy text using a statistical machine translation model. Noisy text is produced in informal communications such as Short Message Service (SMS), Twitter and chat. A typical Statistical Machine Translation system is trained on parallel text comprising noisy and clean sentences. In this paper we propose an unsupervised method for the translation of noisy text to clean text. Our method has two steps. For a given noisy sentence, a weighted list of possible clean tokens for each noisy token are obtained. The clean sentence is then obtained by maximizing the product of the weighted lists and the language model scores.

1 Introduction

Noisy unstructured text data is found in informal settings such as Short Message Service (SMS), online chat, email, social message boards, newsgroup postings, blogs, wikis and web pages. Such text may contain spelling errors, abbreviations, non-standard terminology, missing punctuation, misleading case information, as well as false starts, repetitions, and special characters.

We define noise in text as any kind of difference between the surface form of a coded representation of the text and the correct text. The SMS "u kno whn is d last train of delhi metro" is noisy because several of the words are not spelled correctly and there are grammar mistakes. Obviously the person who wrote this message intended to write exactly what is there in the SMS. But still it is considered noisy because the message is coded using non-standard spellings and grammar.

Current statistical machine translation (SMT) systems rely on large parallel and monolingual training corpora to produce high quality translations (Brown et al., 1993). Most of the large parallel corpora available comprise newswire data that include well formed sentences. Even when web sources are used to train a SMT system, noisy portions of the corpora are eliminated (Imamura et al., 2003) (Imamura and Sumita, 2002) (Khadivi and Ney, 2005). This is because it is known that noise in parallel corpora results in incorrect training of models thus degrading the performance.

We are not aware of sufficiently large parallel datasets comprising noisy and clean sentences. In fact, even dictionaries comprising of noisy to clean mappings in one language are very limited in size.

With the increase in noisy text data generated in various social communication media, cleansing of such text has become necessary. The lack of noisy parallel datasets means that this problem cannot be tackled in the traditional SMT way, where translation models are learned based on the parallel dataset. Consider the problem of translating a noisy English sentence e to a clean English sentence h. SMT imagines that e was originally conceived in clean English which when transmitted over the noisy channel got corrupted and became a noisy English sentence. The objective of SMT is to recover the original clean sentence.

Coling 2008: Poster Volume, pages 189–196,
Beijing, August 2010

The goal of this paper is to analyze how noise can be tackled. We present techniques to translate noisy text sentences e to clean text sentences h. We show that it is possible to clean noisy text in an unsupervised fashion by incorporating steps to construct ranked lists of possible clean English tokens and then searching for the best clean sentence. Of course as we will show for a given noisy sentence, several clean sentences are possible. We exploit the statistical machine learning paradigm to let the decoder pick the best alternative from these possible clean options to give the final translation for a given noisy sentence.

The rest of the paper is organized as follows. In section 2 we state our contributions and give an overview of our approach. In Section 3 we describe the theory behind clean noisy text using MT. In Section 4 we explain how we use a weighing function and a plain text dictionary of clean tokens to guess possible clean English language tokens. Section 5 describes our system along with our results. We have given an analysis of the kind of noise present in our data set in section 5.2

2 Our Approach

In this paper we describe an unsupervised method to clean noisy text. We formulate the text cleansing problem in the machine translation framework using translation model 1 (Brown et al., 1993). We clean the text using a pseudo-translation model of clean and noisy words along with a language model trained using a large monolingual corpus. We use a decoder to search for the best clean sentence for a noisy sentence using these models.

We generate scores for the pseudo translation model using a weighing function for each token in an SMS and use these scores along with language model probabilities to hypothesize the best clean sentence for a given noisy SMS. Our approach can be summarized in the following steps:

- Tokenize noisy SMS S into n tokens s_1, s_2 ... s_n. For each SMS token s_i create a weighted list based on a weighing function. These lists along with their scores corresponds to the translation probabilities of the SMT translation model.
- Use the lists generated in the step above along with clean text language model scores, in a decoder to hypothesize the best clean sentence
- At the end of the search choose the highest scoring sentence as the clean translation of the noisy sentence

In the above approach we do not learn the translation model but emulate the translation model during decoding by analyzing the noise of the tokens in the input sentence.

3 Noisy sentence translation

Statistical Translation models were invented by Brown, et al (Brown et al., 1993) and are based on the source-channel paradigm of communication theory. Consider the problem of translating a noisy sentence e to a clean sentence h. We imagine that e was originally conceived cleanly which when transmitted over the noisy communication channel got corrupted and became a noisy sentence. The goal is to get back the original clean sentence from the noisy sentence. This can be expressed mathematically as

$$\hat{h} = arg\max_{h} Pr(h|e)$$

By Bayes' Theorem

$$\hat{h} = arg\max_{h} Pr(e|h)Pr(h)$$

Conceptually, the probability distribution $P(e|h)$ is a table which associates a probability score with every possible pair of clean and noisy sentences (e, h). Every noisy sentence e is a candidate translation of a given clean sentence h. The goodness of the translation $h \Rightarrow e$ is given by the probability score of the pair (e, h). Similarly, $Pr(h)$ is a table which associates a probability score with every possible clean sentence h and measures how well formed the sentence h is.

It is impractical to construct these tables exactly by examining individual sentences (and sentence pairs) since the number of conceivable sentences in any language is countably infinite. Therefore, the challenge in Statistical Machine Translation is to construct approximations to the probability

distributions $P(e|h)$ and $Pr(h)$ that give an acceptable quality of translation. In the next section we describe a model which is used to approximate $P(e|h)$.

3.1 IBM Translation Model 2

IBM translation model 2 is a generative model, i.e., it describes how a noisy sentence e could be stochastically generated given a clean sentence h. It works as follows:

- Given a clean sentence h of length l, choose the length (m) for the noisy sentence from a distribution $\epsilon(m|l)$.
- For each position $j = 1, 2, \ldots m$ in the noisy string, choose a position a_j in the clean string from a distribution $a(a_j|j, l, m)$. The mapping $\mathbf{a} = (a_1, a_2, \ldots, a_m)$ is known as alignment between the noisy sentence e and the clean sentence h. An alignment between e and h tells which word of e is the corrupted version of the corresponding word of h.
- For each $j = 1, 2, \ldots m$ in the noisy string, choose an noisy word e_j according to the distribution $t(e_j|h_{a_j})$.

It follows from the generative model that probability of generating $e = e_1 e_2 \ldots e_m$ given $h = h_1 h_2 \ldots h_l$ with alignment $\mathbf{a} = (a_1, a_2, \ldots, a_m)$ is

$$Pr(e, a|h) = \epsilon(m|l) \prod_{j=1}^{m} t(e_j|h_{a_j}) a(a_j|j, m, l).$$

It can be easily seen that a sentence e could be produced from h employing many alignments and therefore, the probability of generating e given h is the sum of the probabilities of generating e given h under all possible alignments a, i.e., $Pr(e|h) = \sum_a Pr(e, a|h)$. Therefore,

$$Pr(e|h) =$$

$$\epsilon(m|l) \sum_{a_1=0}^{l} .. \sum_{a_m=0}^{l} \prod_{j=1}^{m} t(e_j|h_{a_j}) a(a_j|j, m, l).$$

The above expression can be rewritten as follows:

$$Pr(e|h) = \epsilon(m|l) \prod_{j=1}^{m} \sum_{i=0}^{l} t(e_j|h_i) a(i|j, m, l).$$

Typical statistical machine translation systems use large parallel corpora to learn the translation probabilities (Brown et al., 1993). Traditionally such corpora have consisted of news articles and other well written articles. Therefore in theory $P(e|h)$ should be constructed by examining sentence pairs of clean and noisy sentences. There exists some work to remove noise from SMS (Choudhury et al., 2007) (Byun et al., 2008) (Aw et al., 2006) (Neef et al., 2007) (Kobus et al., 2008). However, all of these techniques require an aligned corpus of SMS and conventional language for training.

Aligned parallel corpora for noisy sentence is difficult to obtain. This lack of data for a language and the domain dependence of noise makes it impractical to construct corpus from which $P(e|h)$ can be learnt automatically. This leads to difficulty in learning $P(e|h)$. Fortunately the alignment between clean and noisy sentences are monotonic in nature hence we assume a uniform distribution for $a(i|j, m, l)$ held fixed at $(l+1)^{-1}$. This is equivalent to model 1 of IBM translation model. The translation models $t(e_j|h_{a_j})$ can be thought of as a ranked list of noisy words given a clean word. In section 4.2 we show how this ranked list can be constructed in an unsupervised fashion.

3.2 Language Model

The problem of estimating the sentence formation distribution $Pr(h)$ is known as the language modeling problem. The language modeling problem is well studied in literature particularly in the context of speech recognition. Typically, the probability of a n-word sentence $h = h_1 h_2 \ldots h_n$ is modeled as $Pr(h) = Pr(h_1|H_1)Pr(h_2|H_2) \ldots Pr(h_n|H_n)$, where H_i is the *history* of the ith word h_i. One of the most popular language models is the n-gram model (Brown et al., 1993) where the history of a word consists o f the word and the previous $n-1$ words in the sentence, i.e., $H_i = h_i h_{i-1} \ldots h_{i-n+1}$. In our application we use a smoothed trigram model.

3.3 Decoding

The problem of searching for a sentence h which minimizes the product of translation model prob-

ability and the language model probability is known as the decoding problem. The decoding problem has been proved to be NP-complete even when the translation model is IBM model 1 and the language model is bi-gram (K Knight., 1999). Effective suboptimal search schemes have been proposed (F. Jelinek, 1969), (C. Tillman et al., 1997).

4 Pseudo Translation Model

In order to be able to exploit the SMT paradigm we first construct a pseudo translation model. The first step in this direction is to create noisy token to clean token mapping. In order to process the noisy input we first have to map noisy tokens in noisy sentence, S^e, to the possible correct lexical representations. We use a similarity measure to map the noisy tokens to their clean lexical representations .

4.1 Similarity Measure

For a term $t_e \in \mathcal{D}^e$, where $\mathcal{D}^e$ is a dictionary of possible clean tokens, and token s_i of the noisy input S^e, the similarity measure $\gamma(t_e, s_i)$ between them is

$$\gamma(t_e, s_i) = \begin{cases} \frac{LCSRatio(t_e,s_i)}{EditDistance_{SMS}(t_e,s_i)} & \text{if } t_e \text{ and } s_i \text{ share same starting character} \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

where $LCSRatio(t_e, s_i) = \frac{length(LCS(t_e,s_i))}{length(t_e)}$ and $LCS(t_e, s_i)$ is the *Longest common subsequence* between t_e and s_i. The intuition behind this measure is that people typically type the first few characters of a word in an SMS correctly. This way we limit the possible variants for a particular noisy token.

The *Longest Common Subsequence Ratio* (LCSRatio) (Melamed et al., 1999) of two strings is the ratio of the length of their LCS and the length of the longer string. Since in the SMS scenario, the dictionary term will always be longer than the SMS token, the denominator of LCSR is taken as the length of the dictionary term.

The $EditDistance_{SMS}$ (Figure 1) compares the Consonant Skeletons (Prochasson et al., 2007) of the dictionary term and the SMS token. If the Levenshtein distance between consonant skeletons is small then $\gamma(t_e, s_i)$ will be high. The intuition behind using $EditDistance_{SMS}$ can be explained through an example. Consider an SMS token "gud" whose most likely correct form is "good". The two dictionary terms "good" and "guided" have the same LCSRatio of 0.5 w.r.t "gud", but the $EditDistance_{SMS}$ of "good" is 1 which is less than that of "guided", which has $EditDistance_{SMS}$ of 2 w.r.t "gud". As a result the similarity measure between "gud" and "good" will be higher than that of "gud" and "guided". Higher the *LCSRatio* and lower the $EditDistance_{SMS}$, higher will be the similarity measure. Hence, for a given SMS token "byk", the similarity measure of word "bike" is higher than that of "break".

In the next section we show how we use this similarity measure to construct ranked lists. Ranked lists of clean tokens have also been used in FAQ retrieval based on noisy queries (Kothari et al., 2009).

Procedure $EditDistance_{SMS}(t_e, s_i)$
Begin
  return $LevenshteinDistance(CS(s_i), CS(t_e)) + 1$
End

Procedure *CS (t): // Consonant Skeleton Generation*
Begin
  Step 1. remove consecutive repeated characters in t
    // $(fall \rightarrow fal)$
  Step 2. remove all vowels in t
    //$(painting \rightarrow pntng, threat \rightarrow thrt)$
  return t
End

Figure 1: $EditDistance_{SMS}$

4.2 List Creation

For a given noisy input string S^e, we tokenize it on white space and replace any occurrence of digits to their string based form (e.g. 4get, 2day) to get a series of n tokens $s_1, s_2, \ldots, s_n$. A list L_i^e is created for each token s_i using terms in a dic-

hv u cmplted ure prj rprt
d ddline fr sbmission of d rprt hs bn xtnded
i wil be lte by 20 mns
d docs shd rech u in 2 days
thnk u for cmg 2 d prty

Figure 2: Sample SMS queries

tionary D^e consisting of clean english words. A term t_e from D^e is included in L_i^e if it satisfies the threshold condition

$$\gamma(t_e, s_i) > \phi \quad (2)$$

Heuristics are applied to boost scores of some words based on positional properties of characters in noisy and clean tokens. The scores of the following types of tokens are boosted:

1. Tokens that are a substring of a dictionary words from the first character.

2. Tokens having the same first and last character as a dictionary word.

3. Token that are dictionary words themselves (clean text).

The threshold value ϕ is determined experimentally. Thus we select only the top scoring possible clean language tokens to construct the sentence.

Once the list are constructed the similarity measure along with the language model scores is used by the decoding algorithm to find the best possible English sentence. It is to be noted that these lists are constructed at decoding time since they depend on the noisy surface forms of words in the input sentence.

5 Experiments

To evaluate our system we used a set of 800 noisy English SMSes sourced from the publicly available National University of Singapore SMS corpus[1] and a collection of SMSes available from the Indian Institute of Technology, Kharagpur. The SMSes are a collection of day-to-day SMS exchanges between different users. We manually

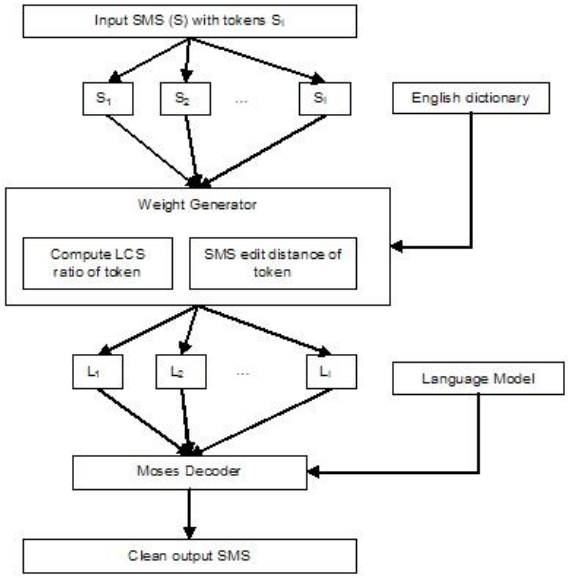

Figure 3: System implementation

	BLEU scores	1-gram	2-gram	3-gram	4-gram
Noisy text	40.96	63.7	45.1	34.5	28.3
Cleaned text	53.90	77.5	58.7	47.4	39.5

Table 1: BLEU scores

generated a cleaned english version of our test set to use as a reference.

The noisy SMS tokens were used to generate clean text candidates as described in section 4.2. The dictionary D^e used for our experiments was a plain text list of 25,000 English words. We created a tri-gram language model using a collection of 100,000 clean text documents. The documents were a collection of articles on news, sporting events, literature, history etc. For decoding we used Moses[2], which is an open source decoder for SMT (Hoang et al., 2008), (Koehn et al., 2007). The noisy SMS along with clean candidate token lists, for each SMS token and language model probabilities were used by Moses to hypothesize the best clean english output for a given noisy SMS. The language model and translation models weights used by Moses during the decoding phase, were adjusted manually after some experimentation.

We used BLEU (Bilingual evaluation understudy) and Word error rate (WER) to evaluate the performance of our system. BLEU is used to

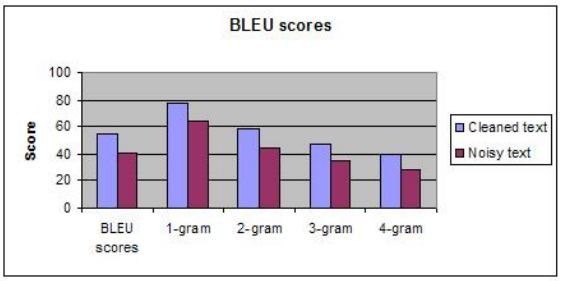

Figure 4: Comparison of BLEU scores

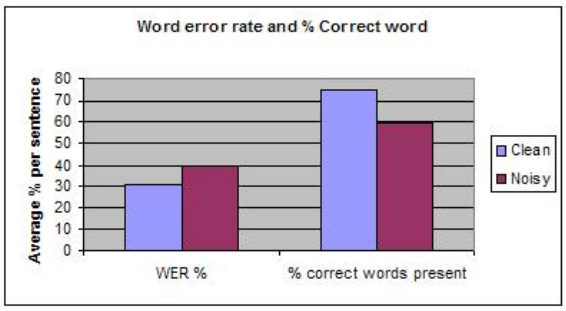

Figure 5: Word error rates

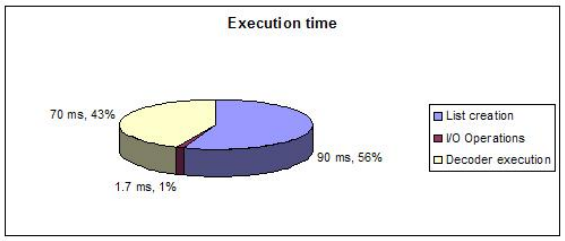

Figure 6: Execution time slices

establish similarity between a system translated and human generated reference text. A noisy SMS ideally has only one possible clean translation and all human evaluators are likely to provide the same translation. Thus, BLEU which makes use of n-gram comparisons between reference and system generated text, is very useful to measure the accuracy of our system. As shown in Fig 4 , our system reported significantly higher BLEU scores than unprocessed noisy text.

The word error rate is defined as

$$WER = \frac{S + D + I}{N} \quad (3)$$

where S is the number of substitutions, D is the number of the deletions, I is the number of the insertions and N is the number of words in the reference The WER can be thought of as an execution of the Levenstein Edit distance algorithm at the token level instead of character level.

Fig 5 shows a comparison of the WER. Sentences generated from our system had 10 % lower WER as compared to the unprocessed noisy sentences. In addition, the sentences generated by our system match a higher number of tokens (words) with the reference sentences, as compared to the noisy sentences.

5.1 System performance

Unlike standard MT system when $P(e|h)$ is precomputed during the training time, list generation in our system is dynamic because it depends on the noisy words present in the input sentence. In this section we evaluate the computation time for list generation along with the decoding time for finding the best list. We used an Intel Core 2 Duo 2.2 GHz processor with 3 GB DDR2 RAM to implement our system. As shown in Fig 6 the additional computation involving list creation etc takes up 56% (90 milliseconds) of total translation time. 43% of the total execution time is taken by the decoder, while I/O operations take only 1% of the total execution time. The decoder execution time slices reported above exclude the time taken to load the language model. Moses took approximately 10 seconds to load our language model.

5.2 Measuring noise level in SMS queries

The noise in the collected SMS corpus can be categorized as follows

1. Removal of characters : The commonly observed patterns include deletion of vowels (as in “msg” for “message”), deletion of repeated character (as in ”happy” for “hapy”) and truncation (as in “tue” for “tuesday”)

Type of Noise	% of Total Noisy Tokens
Deletion of Characters	48%
Phonetic Substitution	33%
Abbreviations	5%
Dialectical Usage	4%
Deletion of Words	1.2%

Table 2: Measure of Types of SMS Noise

	Clean (Reference) text	Noisy text	Output text
Perplexity	19.61	34.56	21.77

Table 3: Perplexity for Reference, Noisy Cleaned SMS

2. Phonetic substitution: For example, “2” for “to” or “too”, “lyf”’ for “life”, “lite” for “light” etc.

3. Abbreviation: Some frequently used abbreviations are “tb” for “text back”, “lol” for “laughs out loud”, “AFAICT” for “as far as i can tell” etc.

4. Dialectal and informal usage: Often multiple words are combined into a single token following certain dialectal conventions. For example, “gonna” is used for “going to”, “aint” is used for “are not”, etc.

5. Deletion of words: Function words (e.g. articles) and pronouns are commonly deleted. “I am reading the book” for example may be typed as “readin bk”.

Table 2 lists statistics on these noise types from 101 SMSes selected at random from our data set. The average length of these SMSes was 13 words. Out of the total number of words in the SMSes, 52% were non standard words. Table 2 lists the statistics for the types of noise present in these non standard words.

Measuring character level perplexity can be another way of estimating noise in the SMS language.The perplexity of a LM on a corpus gives an indication of the average number of bits needed per n-gram to encode the corpus. Noise results in the introduction of many previously unseen n-grams in the corpus. Higher number of bits are needed to encode these improbable n-grams which results in increased perplexity.

We built a character-level language model (LM) using a document collection (vocabulary size is 20K) and computed the perplexity of the language model on the noisy and the cleaned SMS test-set and the SMS reference data.

From Table 3 we can see the difference in perplexity for noisy and clean SMS data. Large perplexity values for the SMS dataset indicates a high level of noise. The perplexity evaluation indicates that our method is able to remove noise from the input queries as given by the perplexity and is close to the human correct reference corpus whose perplexity is 19.61.

6 Conclusion

We have presented an inexpensive, unsupervised method to clean noisy text. It does not require the use of a noisy to clean language parallel corpus for training. We show how a simple weighing function based on observed heuristics and a vocabulary file can be used to shortlist clean tokens. These tokens and their weights are used along with language model scores, by a decoder to select the best clean language sentence.

yvon@limsi.fr

Abstract

We present a new reordering model estimated as a standard n-gram language model with units built from morpho-syntactic information of the source and target languages. It can be seen as a model that translates the morpho-syntactic structure of the input sentence, in contrast to standard translation models which take care of the surface word forms. We take advantage from the fact that such units are less sparse than standard translation units to increase the size of bilingual context that is considered during the translation process, thus effectively accounting for mid-range reorderings. Empirical results on French-English and German-English translation tasks show that our model achieves higher translation accuracy levels than those obtained with the widely used lexicalized reordering model.

1 Introduction

Word ordering is one of the major issues in statistical machine translation (SMT), due to the many word order peculiarities of each language. It is widely accepted that there is a need for structural information to account for such differences. Structural information, such as Part-of-speech (POS) tags, chunks or constituency/dependency parse trees, offers a greater potential to learn generalizations about relationships between languages than models based on word surface forms, because such "surfacist" models fail to infer generalizations from the training data.

The word ordering problem is typically decomposed in a number of related problems which can be further explained by a variety of linguistic phenomena. Accordingly, we can sort out the reordering problems into three categories based on the kind of linguistic units involved and/or the typical distortion distance they imply. Roughly speaking, we face *short-range* reorderings when single words are reordered within a relatively small window distance. It consist of the easiest case as typically, the use of phrases (in the sense of translation units of the phrase-based approach to SMT) is believed to adequately perform such reorderings. *Mid-range* reorderings involve reorderings between two or more phrases (translation units) which are closely positioned, typically within a window of about 6 words. Many alternatives have been proposed to tackle mid-range reorderings through the introduction of linguistic information in MT systems. To the best of our knowledge, the authors of (Xia and McCord, 2004) were the first to address this problem in the statistical MT paradigm. They automatically build a set of linguistically grounded rewrite rules, aimed at reordering the source sentence so as to match the word order of the target side. Similarly, (Collins, et al 2005) and (Popovic and Ney, 2006) reorder the source sentence using a small set of hand-crafted rules for German-English translation. (Crego and Mariño, 2007) show that the ordering problem can be more accurately solved by building a source-sentence word lattice containing the most promising reordering hypotheses, allowing the decoder to decide for the best word order hypothesis. Word lattices are built by means of rewrite rules operating on POS tags; such rules are automatically extracted from the training bi-text. (Zhang, et al 2007) introduce shallow parse (chunk) information to reorder the source sentence, aiming at extending the scope of their rewrite rules, encoding reordering hypotheses in the form of a confusion network that is then passed to the decoder. These studies tackle mid-range reorderings by predicting more or less accurate reordering hypotheses. However, none

Coling 2008: Poster Volume, pages 197–205,
Beijing, August 2010

of them introduce a reordering model to be used in decoding time. Nowadays, most of SMT systems implement the well known *lexicalized reordering* model (Tillman, 2004). Basically, for each translation unit it estimates the probability of being translated *monotone*, *swapped* or placed *discontiguous* with respect to its previous translation unit. Integrated within the *Moses* (Koehn, et al 2007) decoder, the model achieves state-of-the-art results for many translation tasks. One of the main reasons that explains the success of the model is that it considers information of the source- and target-side surface forms, while the above mentionned approaches attempt to hypothesize reorderings relying only on the information contained on the source-side words.

Finally, *long-range* reorderings imply reorderings in the structure of the sentence. Such reorderings are necessary to model the translation for pairs like Arabic-English, as English typically follows the SVO order, while Arabic sentences have different structures. Even if several attempts exist which follow the above idea of making the ordering of the source sentence similar to the target sentence before decoding (Niehues and Kolss, 2009), long-range reorderings are typically better addressed by syntax-based and hierarchical (Chiang, 2007) models. In (Zollmann et al., 2008), an interesting comparison between phrase-based, hierarchical and syntax-augmented models is carried out, concluding that hierarchical and syntax-based models slightly outperform phrase-based models under large data conditions and for sufficiently non-monotonic language pairs.

Encouraged by the work reported in (Hoang and Koehn, 2009), we tackle the mid-range reordering problem in SMT by introducing a n-gram language model of bilingual units built from POS information. The rationale behind such a model is double: on the one hand we aim at introducing morpho-syntactic information into the reordering model, as we believe it plays an important role for predicting systematic word ordering differences between language pairs; at the same time that it drastically reduces the sparseness problem of standard translation units built from surface forms. On the other hand, n-gram language modeling is a robust approach, that enables to account for arbitrary large sequences of units. Hence, the proposed model takes care of the translation adequacy of the structural information present in translation hypotheses, here introduced in the form of POS tags. We also show how the new model compares to a widely used *lexicalized reordering* model, which we have also implemented in our particular bilingual n-gram approach to SMT, as well as to the widely known *Moses* SMT decoder, a state-of-the-art decoder performing lexicalized reordering.

The remaining of this paper is as follows. In Section 2 we briefly describe the bilingual n-gram SMT system. Section 3 details the bilingual n-gram reordering model, the main contribution of this paper, and introduces additional well known reordering models. In Section 4, we analyze the reordering needs of the language pairs considered in this work and we carry out evaluation experiments. Finally, we conclude and outline further work in Section 5.

2 Bilingual n-gram SMT

Our SMT system defines a translation hypothesis t given a source sentence s, as the sentence which maximizes a linear combination of feature functions:

$$\hat{t}_1^I = \arg\max_{t_1^I} \left\{ \sum_{m=1}^{M} \lambda_m h_m(s_1^J, t_1^I) \right\} \quad (1)$$

where λ_m is the weight associated with the feature $h_m(s,t)$. The main feature is the log-score of the translation model based on bilingual n-grams. This model constitutes a language model of a particular *bi-language* composed of bilingual units which are typically referred to as *tuples* (Mariño et al., 2006). In this way, the translation model probabilities at the sentence level are approximated by using n-grams of tuples:

$$p(s_1^J, t_1^I) = \prod_{k=1}^{K} p((s,t)_k | (s,t)_{k-1} \ldots (s,t)_{k-n+1})$$

where s refers to source t to target and $(s,t)_k$ to the k^{th} tuple of the given bilingual sentence pairs, s_1^J and t_1^I. It is important to notice that, since both languages are linked up in tuples, the context

information provided by this translation model is bilingual. As for any standard n-gram language model, our translation model is estimated over a training corpus composed of sentences of the language being modeled, in this case, sentences of the *bi-language* previously introduced. Translation units consist of the core elements of any SMT system. In our case, tuples are extracted from a word aligned corpus in such a way that a unique segmentation of the bilingual corpus is achieved, allowing to estimate the n-gram model. Figure 1 presents a simple example illustrating the unique tuple segmentation for a given word-aligned pair of sentences (top).

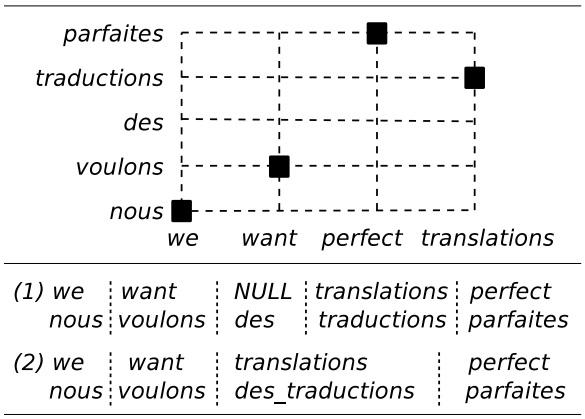

Figure 1: *Tuple extraction from an aligned sentence pair.*

The resulting sequence of tuples *(1)* is further refined to avoid *NULL* words in source side of the tuples *(2)*. Once the whole bilingual training data is segmented into tuples, n-gram language model probabilities can be estimated. Notice from the example that the English source words *perfect* and *translations* have been reordered in the final tuple segmentation, while the French target words are kept in their original order. During decoding, sentences to be translated are encoded in the form of word lattices containing the most promising reordering hypotheses, so as to reproduce the word order modifications introduced during the tuple extraction process. Hence, at decoding time, only those reordering hypotheses encoded in the word lattice are examined. Reordering hypotheses are introduced following a set of reordering rules automatically learned from the bi-text corpus word alignments.

Following on the previous example, the rule *perfect translations* $\rightsquigarrow$ *translations perfect* produces the swap of the English words that is observed for the French and English pair. Typically, POS information is used to increase the generalization power of such rules. Hence, rewrite rules are built using POS instead of surface word forms. See (Crego and Mariño, 2007) for details on tuples extraction and reordering rules.

3 Reordering Models

In this section, we detail three different reordering models implemented in our SMT system. As previously outlined, the purpose of reordering models is to accurately learn generalizations for the word order modifications introduced on the source side during the tuple extraction process.

3.1 Source n-gram Language Model

We employ a n-gram language model estimated over the source words of the training corpus after being reordered in the tuple extraction process. Therefore, the model scores a given source-side reordering hypothesis according to the reorderings performed in the training sentences.

POS tags are used instead of surface forms in order to improve generalization and to reduce sparseness. The model is estimated as any standard n-gram language model, described by the following equation:

$$p(s_1^J, t_1^I) = \prod_{j=1}^{J} p(s_j^t | s_{j-1}^t, \ldots, s_{j-n+1}^t) \quad (2)$$

where s_j^t relates to the POS tag used for the j^{th} source word.

The main drawback of this model is the lack of knowledge of the hypotheses on the target-side. The probability assigned to a sequence of source words is only conditioned to the sequence of source words.

3.2 Lexicalized Reordering Model

A broadly used reordering model for phrase-based systems is lexicalized reordering (Tillman, 2004). It introduces a probability distribution for each phrase pair that indicates the likelihood of being

translated *monotone*, *swapped* or placed *discontiguous* to its previous phrase. The ordering of the next phrase with respect to the current phrase is typically also modeled. In our implementation, we modified the three orientation types and consider: a *consecutive* type, where the original monotone and swap orientations are lumped together, a *forward* type, specifying discontiguous forward orientation, and a *backward* type, specifying discontiguous backward orientation. Empirical results showed that in our case, the new orientations slightly outperform the original ones. This may be explained by the fact that the model is applied over tuples instead of phrases.

Counts of these three types are updated for each unit collected during the training process. Given these counts, we can learn probability distributions of the form $p_r(orientation|(st))$ where $orientation \in \{c, f, b\}$ (consecutive, forward and backward) and (st) is a translation unit. Counts are typically smoothed for the estimation of the probability distribution. A major weakness of the lexicalized reordering model is due to the fact that it does not considers phrase neighboring, *i.e.* a single probability is learned for each phrase pair without considering its context. An additional concern is the problem of sparse data: translation units may occur only a few times in the training data, making it hard to estimate reliable probability distributions.

3.3 Linguistically Informed Bilingual n-gram Language Model

The bilingual n-gram LM is estimated as a standard n-gram LM over translation units built from POS tags represented as:

$$p(s_1^J, t_1^I) = \prod_{k=1}^{K} p((st)_k^t | (st)_{k-1}^t \dots (st)_{k-n+1}^t)$$

where $(st)_k^t$ relates to the k^{th} translation unit, $(st)_k$, built from POS tags instead of words.

This model aims at alleviating the drawbacks of the previous two reordering models. On the one hand it takes into account bilingual information to model reordering. On the other hand it considers the phrase neighboring when estimating the reordering probability of a given translation unit. Figure 2 shows the sequence of translation units built from POS tags, used in our previous example.

PP	*VBP*	*NNS*	*JJ*
PRO:PER	*VER:pres*	*PRP:det_NOM*	*ADJ*

Figure 2: *Sequence of POS-tagged units used to estimate the bilingual n-gram LM.*

POS-tagged units used in our model are expected to be much less sparse than those built from surface forms, allowing to estimate higher order language models. Therefore, larger bilingual context are introduced in the translation process. This model can also be seen as a translation model of the sentence structure. It models the adequacy of translating sequences of source POS tags into target POS tags.

Note that the model is not limited to using POS information. Rather, many other information sources could be used (supertags, additional morphology features, *etc.*), allowing to model different translation properties. However, we must take into account that the degree of sparsity of the model units, which is directly related to the information they contain, affects the level of bilingual context finally introduced in the translation process. Since more informed units may yield more accurate predictions, more informed units may also force the model to fall to lower n-grams. Hence, the degree of accuracy and generalization power of the model units must be carefully balanced to allow good reordering predictions for contexts as large as possible.

As any standard language model, smoothing is needed. Empirical results showed that Kneser-Ney smoothing (Kneser and Ney, 1995) achieved the best performance among other options (measured in terms of translation accuracy).

3.4 Decoding Issues

A straightforward implementation of the three models is carried out by extending the log-linear combination of equation (1) with the new features. Note that no additional decoding complexity is introduced in the baseline decoding implementation. Considering the bilingual n-gram language model, the decoder must know the POS tags for

each tuple. However, each tuple may be tagged differently, as words with same surface form may have different POS tags.

We have implemented two solutions for this situation. Firstly, we assume that each tuple has a single POS-tagged version. Accordingly, we select a single POS-tagged version out of the multiple choices (the most frequent). Secondly, all POS-tagged versions of each tuple are allowed. The second choice implies using more accurate POS-tagged tuples to model reordering, however, it overpopulates the search space with spurious hypotheses, as multiple identical units (with different POS tags) are considered.

Our first empirical findings showed no differences in translation accuracy for both configurations. Hence, in the remaining of this paper we only consider the first solution (a single POS-tagged version of each tuple). The training corpus composed of tagged units out of which our new model is estimated is accordingly modified to contain only those tagged units considered in decoding. Note that most of the ambiguity present in word tagging is resolved by the fact that translation units may contain multiple source and target side words.

4 Evaluation Framework

In this section, we perform evaluation experiments of our novel reordering model. First, we give details of the corpora and baseline system employed in our experiments and analyze the reordering needs of the translation tasks, French-English and German-English (in both directions). Finally, we evaluate the performance of our model and contrast results with other reordering models and translation systems.

4.1 Corpora

We have used the fifth version of the *EPPS* and the *News Commentary* corpora made available in the context of the *Fifth ACL Workshop on Statistical Machine Translation*. Table 1 presents the basic statistics for the training and test data sets. Our test sets correspond to *news-test2008* and *newstest2009* file sets, hereinafter referred to as *Tune* and *Test* respectively.

French, German and English Part-of-speech tags are computed by means of the *TreeTagger* [1] toolkit. Additional German tags are obtained using the *RFTagger* [2] toolkit, which annotates text with fine-grained part-of-speech tags (Schmid and Laws, 2008) with a vocabulary of more than 700 tags containing rich morpho-syntactic information (gender, number, case, tense, *etc.*).

Lang.	*Sent.*	*Words*	*Voc.*	*OOV*	*Refs*

4.2 System Details

After preprocessing the corpora with standard tokenization tools, word-to-word alignments are performed in both directions, source-to-target and target-to-source. In our system implementation, the *GIZA++* toolkit[3] is used to compute the word alignments. Then, the *grow-diag-final-and* (Koehn et al., 2005) heuristic is used to obtain the alignments from which tuples are extracted.

In addition to the tuple n-gram translation model, our SMT system implements six additional feature functions which are linearly com-

[1] www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger
[2] www.ims.uni-stuttgart.de/projekte/corplex/RFTagger
[3] http://www.fjoch.com/GIZA++.html

bined following a discriminative modeling framework (Och and Ney, 2002): a *target-language model* which provides information about the target language structure and fluency; two *lexicon models*, which constitute complementary translation models computed for each given tuple; a 'weak' distance-based *distortion model*; and finally a *word-bonus model* and a *tuple-bonus model* which are used in order to compensate for the system preference for short translations.

All language models used in this work are estimated using the *SRI language modeling* toolkit[4]. According to our experience, Kneser-Ney smoothing (Kneser and Ney, 1995) and interpolation of lower and higher n-grams options are used as they typically achieve the best performance. Optimization work is carried out by means of the widely used *MERT* toolkit[5] which has been slightly modified to perform optimizations embedding our decoder. The *BLEU* (Papineni et al., 2002) score is used as objective function for MERT and to evaluate test performance.

4.3 Reordering in German-English and French-English Translation

Two factors are found to greatly impact the overall translation performance: the morphological mismatch between languages, and their reordering needs. The vocabulary size is strongly influenced by the number of word forms for number, case, tense, mood, *etc.*, while reordering needs refer to the difference in their syntactic structure. In this work, we are primarily interested on the reordering needs of each language pair. Figure 3 displays a quantitative analysis of the reordering needs for the language pairs under study.

Figure 3 displays the ($\%$) distribution of the reordered sequences, according to their size, observed for the training bi-texts of both translation tasks. Word alignments are used to determine reorderings. A reordering sequence can also be seen as the sequence of words implied in a reordering rule. Hence, we used the reordering rules extracted from the training corpus to account for reordering sequences. Coming back to the example of Figure 1, a single reordering sequence is found, which considers the source words *perfect translations*.

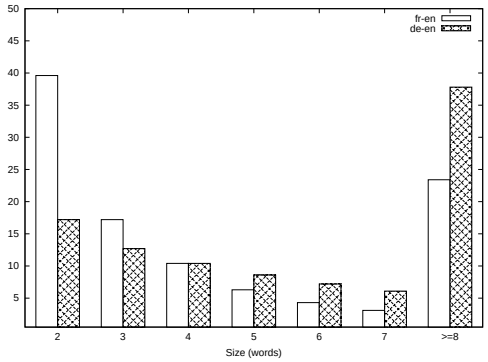

Figure 3: *Size (in words) of reorderings (%) observed in training bi-texts.*

As can be seen, the French-English and German-English pairs follow a different distribution of reorderings according to their size. A lower number of short-range reorderings are observed for the German-English task while a higher number of long-range reorderings. Considering mid-range reorderings (from 5 to 7 words), the French-English pair shows a lower percentage ($\sim 14\%$) than the German-English ($\sim 22\%$). A similar performance is expected when considering the opposite translation directions. Note that reorderings are extracted from word-alignments, an automatic process which is far notoriously error-prone. The above statistics must be accordingly considered.

4.4 Results

Translation accuracy (BLEU) results are given in table 2 for the same *baseline* system performing different reordering models: source 6-gram LM (**sLM**); lexicalized reordering (**lex**); bilingual 6-gram LM (**bLM**) assuming a single POS-tagged version of each tuple. In the case of the German-English translation task we also report results for the bilingual 5-gram LM built from POS tags obtained from *RFTagger* containing a richer vocabulary tag set (**b$^+$LM**). For comparison purposes, we also show the scores obtained by the **Moses** phrase-based system performing lexicalized reordering. Models of both systems are built sharing the same training data and word alignments.

[4]http://www.speech.sri.com/projects/srilm/

[5]http://www.statmt.org/moses/

The worst results are obtained by the **sLM** model. The fact that it only considers source-language information results clearly relevant to accurately model reordering. A very similar performance is shown by our bilingual n-gram system and Moses under lexicalized reordering (**bLM** and **Moses**), slightly lower results are obtained by the n-gram system under French-English translation.

Config	*Fr⇝En*	*En⇝Fr*	*De⇝En*	*En⇝De*
sLM	22.32	21.97	17.11	12.23
lex	22.46	22.09	17.31	12.38
bLM	**23.03**	**22.32**	17.37	12.58
b$^+$LM	–	–	**17.57**	**12.92**
Moses	22.81	**22.33**	17.22	12.45

Table 2: *Translation accuracy (BLEU) results.*

When moving from **lex** to **bLM**, our system increases its accuracy results for both tasks and translation directions. In this case, results are slightly higher than those obtained by Moses (same results for English-to-French). Finally, results for translations performed with the bilingual n-gram reordering model built from rich German POS tags (**b$^+$LM**) achieve the highest accuracy results for both directions of the German-English task. Even though results are consistent for all translation tasks and directions they fall within the statistical confidence margin. Add ± 2.36 to French-English results and ± 1.25 to German-English results for a 95% confidence level. Very similar results were obtained when estimating our model for orders from 5 to 7.

In order to better understand the impact of the proposed reordering model, we have measured the accuracy of the reordering task. Hence, isolating the reordering problem from the more general translation problem. We use BLEU to account the n-gram matching between the sequence of source words aligned to the 1-best translation hypothesis, *i.e.* the permutation of the source words output by the decoder, and the permutation of source words that monotonizes the word alignments with respect to the target reference. Note that in order to obtain the word alignments of the test sets we re-aligned the entire corpus after including the test set. Table 3 shows the BLEU results of the reordering task. Bigram, trigram and 4gram precision scores are also given.

Pair	*Config*	*BLEU (2g/3g/4g)*
Fr⇝En	*lex*	71.69 $(75.0/63.4/55.6)$
	bLM	71.98 $(75.3/63.7/56.0)$
En⇝Fr	*lex*	72.92 $(75.5/65.0/57.6)$
	bLM	73.25 $(75.8/65.4/58.1)$
De⇝En	*lex*	62.12 $(67.3/52.1/42.5)$
	b$^+$LM	63.29 $(68.3/53.5/44.0)$
En⇝De	*lex*	62.72 $(67.9/52.8/43.1)$
	b$^+$LM	63.36 $(68.6/53.6/43.8)$

Table 3: *Reordering accuracy (BLEU) results.*

As can be seen, the bilingual n-gram reordering model shows higher results for both translation tasks and directions than lexicalized reordering, specially for German-English translation. Our model also obtains higher values of n-gram precision for all values of n.

Next, we validate the introduction of additional bilingual context in the translation process. Figure 4 shows the average size of the translation unit n-grams used for the test set according to different models (German-English), the surface form 3-gram language model (main translation model), and the new reordering model when built from the reduced POS tagset (POS) and using the rich POS tagset (POS$^+$).

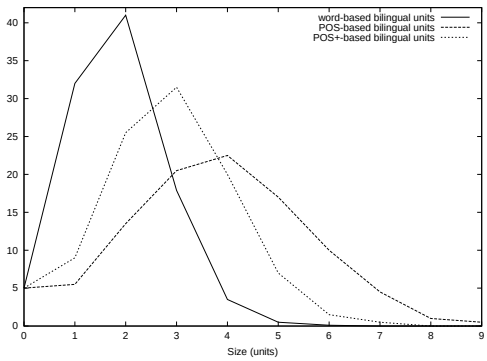

Figure 4: *Size of translation unit n-grams (%) seen in test for different n-gram models.*

As expected, translation units built from the reduced POS tagset are less sparse, enabling us to

introduce larger n-grams in the translation process. However, the fact that they achieve lower translation accuracy scores (see Table 2) indicates that the probabilities associated to these large n-grams are less accurate. It can also be seen that the model built from the rich POS tagset uses a higher number of large n-grams than the language model built from surface forms.

The availability of mid-range n-grams validates the introduction of additional bilingual context achieved by the new model, leading to effectively modeling mid-range reorderings. Notice additionally that considering the language model built from surface forms, only a few 4-grams of the test set are seen in the training set, which explains the small reduction in performance observed when translating with a bilingual 4-gram language model (internal results). Similarly, the results shown in Figure 4 validates the choice of using bilingual 5-grams for b^+LM and 6-grams for bLM.

Finally, we evaluate the mismatch between the reorderings collected on the training data, and those output by the decoder. Table 4 shows the percentage of reordered sequences found for the 1-best translation hypothesis of the test set according to their size. The French-to-English and German-to-English tasks are considered.

Pair	Config	2	3	4	5	6	7	≥ 8
Fr⇝En	*lex*	58	23	10	5	2	1	1
	bLM	57	23	11	4	2.5	1.5	1
De⇝En	*lex*	33	24	22	14	5	1.5	0.5
	b$^+$LM	35	25	19	13	5	2.5	0.5

Table 4: *Size (%) of the reordered sequences observed when translating the test set.*

Very similar distributions are observed for both reordering models. In parallel, distributions are also comparable to those presented in Figure 3 for reorderings collected from the training bi-text, with the exception of long-range and very short-range reorderings. This may be explained by the fact that system models, in special the distortion penalty model, typically prefer monotonic translations, while the system lacks a model to support large-range reorderings.

5 Conclusions and Further Work

We have presented a new reordering model based on bilingual n-grams with units built from linguistic information, aiming at modeling the structural adequacy of translations. We compared our new reordering model to the widely used lexicalized reordering model when implemented in our bilingual n-gram system as well as using *Moses*, a state-of-the-art phrase-based SMT system.

Our model obtained slightly higher translation accuracy (BLEU) results. We also analysed the quality of the reorderings output by our system when performing the new reordering model, which also outperformed the quality of those output by the system performing lexicalized reordering. The back-off procedure used by standard language models allows to dynamically adapt the scope of the context used. Therefore, in the case of our reordering model, back-off allows to consider always as much bilingual context (n-grams) as possible. The new model was straightforward implemented in our bilingual n-gram system by extending the log-linear combination implemented by our decoder. No additional decoding complexity was introduced in the baseline decoding implementation.

Finally, we showed that mid-range reorderings are present in French-English and German-English translations and that our reordering model effectively tackles such reorderings. However, we saw that long-range reorderings, also present in these tasks, are yet to be addressed.

We plan to further investigate the use of different structural information, such as supertags, and tags conveying different levels of morphology information (gender, number, tense, mood, *etc.*) for different language pairs.

Abstract

Traditionally Sanskrit is written without blank, sentences can make thousands of characters without any separation. A critical edition takes into account all the different known versions of the same text in order to show the differences between any two distinct versions, in term of words missing, changed or omitted. This paper describes the Sanskrit characteristics that make text comparisons different from other languages, and will present different methods of comparison of Sanskrit texts which can be used for the elaboration of computer assisted critical edition of Sanskrit texts. It describes two sets of methods used to obtain the alignments needed. The first set is using the L.C.S., the second one the global alignment algorithm. One of the methods of the second set uses a classical technique in the field of artificial intelligence, the A* algorithm to obtain the suitable alignment. We conclude by comparing our different results in term of adequacy as well as complexity.

1 Introduction

A critical edition is an edition that takes into account all the different known versions of the same text. If the text is mainly known through a great number of manuscripts that include non trivial differences, the critical edition often looks rather daunting for readers unfamiliar with the subject: the edition is then formed mainly by footnotes that enlighten the differences between manuscripts, while the main text (that of the edition) is rather short, sometimes a few lines on a page. The differences between the texts are usually described in term of words (sometime sentences) missing, added or changed in a specific manuscript. This reminds us the edit distance but in term of words instead of characters. The text of the edition is established by the editor according to his own knowledge of the text. It can be a particular manuscript or a "mean" text built according to some specific criteria. Building a critical edition by comparing texts two by two, especially manuscript ones, is a task which is certainly long and, sometimes, tedious. This is why, for a long time, computer programs have been helping philologists in their work (see O'Hara (1993) or Monroy (2002) for example), but most of them are dedicated to texts written in Latin (sometimes Greek) scripts.

In this paper we will focus on the problems involved by a critical edition of manuscripts written in Sanskrit. Our approach will be illustrated by texts that are extracted from manuscripts of the "Banaras gloss", *kāśikāvṛtti*.

The Banaras gloss was written around the 7th century A.D., and is one of the most famous commentary on the Pāṇini's grammar, which is known as the first **generative** grammar ever written, and was written around the fifth century B.C. as a set of rules. These rules cannot be understood without the explanation provided by a commentary such as the *kāśikāvṛtti*. This collection was chosen, because it is one of the largest collection of Sanskrit manuscripts (about hundred different ones) of the same text actually known.

* This work is supported by the EEC FP7 project IDEAS

Coling 2008: Poster Volume, pages 206–213,
Beijing, August 2010

In what follows we will first describe the characteristics of Sanskrit that matter for text comparison algorithms, we will then show that such a comparison requires the use of a lemmatized text as the main text. The use of a lemmatized text induces the need of a lexical preprocessing. Once the lexical preprocessing is achieved, we can proceed to the comparison, where we develop two kinds of approach, one based on the LCS, which was used to solved this problem, the other one related to sequence alignment. In both cases the results are compared in terms of adequacy as well as complexity. We then conclude and examine the perspective of further work.

2 How to compare Sanskrit manuscripts

One of the main characteristics of Sanskrit is that it is not linked to a specific script. But here we will provide all our examples using the *Devanāgarī* script, which is nowadays the most used. The script has a 48 letters alphabet. Due to the long English presence in India, a tradition of writing Sanskrit with the Latin alphabet (a transliteration) has been established for a long time. These transliteration schemes were originally carried out to be used with traditional printing. It was adapted for computers by Frans Velthuis (Velthuis, 1991), more specifically to be used with TEX. According to the Velthuis transliteration scheme, each Sanskrit letter is written using one, two or three Latin characters; notice that according to most transliteration schemes, upper case and lower case Roman characters have a very different meaning.

In ancient manuscripts, Sanskrit is written without spaces, and this is an important graphical specificity, because it increases greatly the complexity of text comparison algorithms. On the other hand, each critical edition deals with the notion of word. Since electronic Sanskrit lexicons such as the one built by Huet (2006; 2004) do not cope with grammatical texts, we must find a way to identify each Sanskrit word within a character string, without the help of either a lexicon or of spaces to separate the words.

The reader interested in a deeper approach of the Sanskrit characteristics which matters for a computer comparison can look in Csernel and Patte (2009).

The solution comes from the lemmatization of one of the two texts of the comparison: the text of the edition. The lemmatized text is prepared **by hand** by the editor. We call it a *padapāṭha*, according to a mode of recitation where syllables are separated. From this lemmatized text, we will build the text of the edition, that we call a *saṃhitapāṭha*, according to a mode of recitation where the text is said continuously. The transformation of the *padapāṭha* into the *saṃhitapāṭha* is not straightforward because of the existence of *sandhi* rules.

What is called *sandhi* — from the Sanskrit: liaison — is a set of phonetic rules which apply to the morpheme junctions inside a word or to the junction of words in a sentence. These rules are perfectly codified in Pāṇini's grammar. Roughly speaking the Sanskrit reflects (via the *sandhi*) in the writing the liaison(s) which are made by a human speaker. A text with separators (such as spaces) between words, can look rather different (the letter string can change greatly) from a text where no separator is found (see the example of *padapāṭha* on next page).

The processing is done in three steps, but only two of them will be considered in this paper:

- **First step**: The *padapāṭha* is transformed into a virtual *saṃhitapāṭha* in order to make feasible a comparison with a manuscript. The transformation consists in removing all the separations between words and then in applying the *sandhi*. This virtual *saṃhitapāṭha* which will form the text of the edition, is compared with each manuscript. As a sub product of this lexical treatment, the places where the separation between words occur will be kept into a table which will be used in further treatments.

- **Second step:** An alignment of a manuscript and the virtual *saṃhitapāṭha*. We describe three different methods to obtain these alignments. The aim is to identify, as precisely as possible, the words in the manuscript, using the *padapāṭha* as a pattern. Once the words of the manuscript have been determined, we can see through the alignment those which have been added, modified or suppressed.

- **Third step:**: Display the results in a comprehensive way for the editor.

The comparison is done paragraph by paragraph, according to the paragraphs made in the *padapāṭha* during its elaboration by the editor. Each of the obtained alignments, together with the lemmatized text (i.e. *padapāṭha*), suggests an identification of the words of the manuscript.

3 The lexical preprocessing

The goal of this step is to transform both the *padapāṭha* and the manuscript in order to make them comparable. This treatment will mainly consist in transforming the *padapāṭha* into a *saṃhitapāṭha* by applying the *sandhi*.

At the end of the lexical treatment the texts are transmitted to the comparison module in an internal encoding.

This allows us to ensure the comparison whatever the text encoding.

An example of *padapāṭha*:

```
vi^ud^panna_ruupa_siddhi+v.rtti+iya.mkaa"sikaa_naama
```

We can see that words are separated by three different lemmatization signs: +, _, ^ which indicate respectively the presence of an inflected item, the component of a compound word, the presence of a prefix.

The previous *padapāṭha* becomes the following *saṃhitapāṭha*:

```
vyutpannaruupasiddhirv.rttiriya.mkaa"sikaanaama
```

after the transformation induced by the lexical pre-processing, the bold letters represent the letters (and the lemmatization signs) which have been transformed.

Notice that we were induced (for homogeneity reasons) to remove all the spaces from the manuscript before the comparison process. Thus no word of the manuscript can appear separately during that process.

The *sandhi* are perfectly determined by the Sanskrit grammar (see for example Renou (1996)). They induce a special kind of difficulties due to the fact that their construction can be, in certain cases, a two-step process. During the first step, a *sandhi* induces the introduction of a new letter (or a letter sequence). This new letter can induce, in the second step, the construction of another *sandhi*.

```
1d0                 Word 1 'tasmai' is :
< tasmai            - Missing
4c3,5               Word 2 '"srii' is :
< gurave            - Followed by
---                 Added word(s)
> gane             'ga.ne"saaya'
> "                 Word 3 'gurave' is :
> saaya             - Missing
```

`Ediff` with spaces L.C.S. based results without space

Table 1: different comparisons

4 The first trials

The very first trials on Sanskrit critical edition were conducted by Csernel and Patte (2009). Their first idea was to use `diff` (Myers (1986)) in order to obtain the differences between two Sanskrit sequences.

But they find the result quite disappointing. The classical `diff` command line provided no useful information at all.

They obtained a slightly better result with `Emacs ediff`, as shown in Table 1, left column: we can see which words are different. But as soon as they wanted to compare the same sequences without blank, they could not get a better result using `ediff` than using `diff`. This is why they started to implement an L.C.S. (Hirschberg, 1975) based algorithm. Its results appear in the right column of Table 1.

4.1 The L.C.S based algorithm

The L.C.S matrix associated with the previous result can be seen on figure 1 on next page.

On this figure the vertical text represents the *saṃhitapāṭha*, the horizontal text is associated with a manuscript. The horizontal bold dark lines have been provided by the *padapāṭha*, before it has been transformed into the *saṃhitapāṭha*.

The rectangles indicate how the correspondences have been done between the *saṃhitapāṭha* and the manuscript. One corresponds to a word missing (`tasmai`), two correspond to a word present in both strings: the words `s"rii` and `nama.h`, the last one corresponds to a word with a more ambiguous status, we can say either that

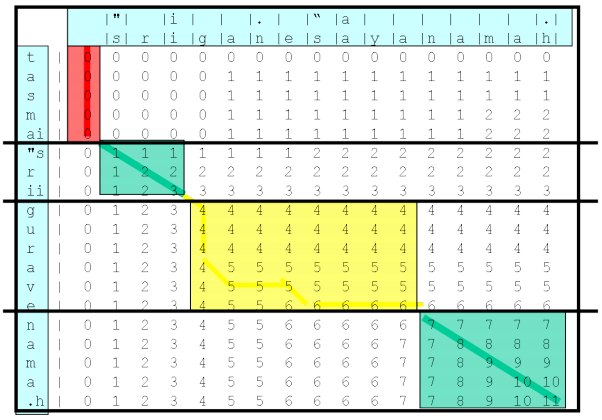

Figure 1: The L.C.S. Matrix

the word has been replaced or that one word is missing and another word has been added. We can see below the result in term of alignment where the double "|" represents a separation between two words.

t	a	s	m	ai		"s	r	ii		g	u	r	a	v	e	-	-	-	-		n	a	m	a	.h
-	-	-	-	-		"s	r	ii		g	-	-	a	.n	e	"s	aa	y	a		n	a	m	a	.h

the corresponding alignment

If the result appears quite obvious within this example, it is not always so easy, particularly when different paths within the matrix can lead to different alignments providing different results.

This induced them to put a lot of post treatments to improve their results, and, at the end, the method looked rather complicated. This is why we were induced to produce an aligment method based on the edit distance.

5 Alignment based on edit distance

We used two different methods to get the alignments formed by the matrix: the first one, based on the common sense, is the subject of this section. The second one, based on the IDA* algorithm is the subject of the next one.

The idea is to get anyone of the alignments between the *saṃhitapāṭha* and the *manuscript*, from the distance matrix, and then apply some simple transformations to get the right one.

The first goal is to minimize the number of incomplete words which appear in the alignment (mostly in the *manuscript*). The second goal is to improve the compactness of each letter sequence by moving in the same word the letters apart from the gaps.

In the following we consider that the distance matrix has been built from the top left to the bottom right, and that the alignment is built by keeping a path from the bottom right till the top left of the matrix.

In such case, if some words are missing in the *manuscript*, some letters can be misaligned (not with the proper word), but this misalignment can be easily corrected by shifting the orphan letters till the correct matching word.

5.1 Shifting the orphan letters

We will call an orphan letter a letter belonging to an incomplete word of the *manuscript* (generally) and being isolated. To obtain a proper alignment these letters must fit with the words to which they belong.

The sequence Seq 1 below gives a good example. The upper line of the table represents the *padapāṭha*, the second one the *manuscript*. In this table, the words `pratyaahaaraa` and `rtha.h` are missing in the *manuscript*. Consequently the letters `a.h` are misplaced, with the word `rtha.h`. The goal is to shift them to the right place with the word `upade"sa.h`. The result after shifting the letters appears in the sequence Seq 2 .

u	p	a	d	e	"s	a	.h	p	r	a	t	y	aa	h	aa	r	aa	r	th	a	.h
u	p	a	d	e	"s	-	-	-	-	-	-	-	-	-	-	-	-	-	-	a	.h

Seq 1

u	p	a	d	e	"s	a	.h	p	r	a	t	y	aa	h	aa	r	aa	r	th	a	.h
u	p	a	d	e	"s	a	.h	-	-	-	-	-	-	-	-	-	-	-	-	-	-

Seq 2

On the second example (Seq 3 & 4) we see on the left side of the table that the letter `a` must just be shifted from the beginning of `asiddhy` to the end of `saavarny` giving Seq 4.

s	aa	v	a	r	.n	y	a	p	r	a	s	y	d	dh	y
s	aa	v	a	r	.n	y	-	-	-	a	s	y	d	dh	y

Seq 3: the orphan letter

s	aa	v	a	r	.n	y	a	p	r	a	s	y	d	dh	y
s	aa	v	a	r	.n	y	a	-	-	-	s	y	d	dh	y

Seq 4: once shifted

But another kind of possible shift is the one linked to the presence of supplementary letters within the *manuscript* such as in Seq 5. The letters `a` and `nam` of the *padapāṭha* are shifted to the right end of the sequence `prayoj` such as shown in Seq 6.

p	r	a	y	o	j	-	-	-	-	a	-	-	-	-	n	a	m
p	r	a	y	o	j	a	n	a	m	s	a	.m	j	"n	aa	n	a	m

Seq 5: before shifting

	p	r	a	y	o	j	a	n	a	m	-	-	-	-	-	-	-	-
	p	r	a	y	o	j	a	n	a	m	s	a	.m	j	"n	aa	n	a	m

Seq 6: once shifted

5.2 The results

The results of the program are first displayed as a text file. They do not come directly from the alignment but from a further treatment, which eliminates some of the useless differences discovered, and transform the other ones into something more convenient for a human reader.

```
Paragraph 3 is Missing in File Asb2
 Word 11 'saara' is:
 - Substituted with 'saadhu' in Man. aa
 Word 17 'viv.rta' is:
 - Followed by Added word(s) 'grantha"saa'
in Manuscript A3
 Word 21 'viudpanna' is:
 - Substituted with 'vyutpannaa' in Man. A3
(P3) Word 32 'k.rtyam' is:
 - Substituted with 'karyam' in
Manuscript A3
 - Substituted with 'kaaryam' in
Manuscripts aa, am4, ba2
```

Such a result, if not fully perfect, has been validated as a correct base for further ameliorations.

6 Using A* for critical edition

In this section we explain the application of A* (Hart et al., 1968; Ikeda and Imai, 1994) to critical edition. We start defining a position for the problem, then we explain the cost function we have used and the admissible heuristic. We end with the search algorithm.

6.1 Positions

A position is a couple of indexes (`x,y`) that represents a position in the dynamic programming matrix. The starting position is at the bottom right of the matrix. The goal position is at the upper left of the matrix (0,0). There are at most three successors of a position: the upper position (`x,y-1`), the position on the left (`x-1,y`) and the position at the upper left (`x-1,y-1`).

Moving to the position at the upper left means aligning two characters in the sequences. Moving up means aligning a gap in the horizontal sequence with a letter in the vertical sequence. Moving to the left means aligning a gap in the vertical sequence with a letter in the horizontal sequence.

6.2 A cost function for the critical edition

It appeared at the end of the first trials of Csernel and Patte (2009) that we can consider the most important criteria concerning the text alignment to be an alignment concerning as few words as possible, and as a secondary criteria the highest possible compactness.

It can be formalized by a cost function which will contain

- the edit distance between the two strings.
- the number of sequences of gaps.
- the number of words in the *manuscript* containing at least a gap.

6.3 The admissible heuristic

We can observe that the edit distance contained in the dynamic programming matrix is always smaller than the score function we want to minimize since the score function is the edit distance increased by the number of gap sequences and the number of words containing gaps.

At any node in the tree, the minimum cost path that goes through that node will be greater than the cost of the path to the node (the `g` value) increased by the edit distance.

The edit distance contained in the dynamic programming matrix is an admissible heuristic for our problem.

6.4 The search algorithm

The search algorithm is the adaptation of IDA* (Korf, 1985) to the critical edition problem. It takes 7 parameters: `g` the cost of the path to the node, `y` and `x` the coordinates of the current position in the matrix, and four booleans that tell if a gap has already been seen in the same word of the *padapāṭha*, if a gap has already been seen in the same word of the *manuscript*, if the previous move is a gap in the *manuscript* or a move in the *padapāṭha*.

The search is successful if it has reached the upper left of the matrix (`x = 0` and `y = 0`, lines 3 and 4 of the pseudo code), and it fails if the minimal cost of the path going through the current node is greater than the threshold (lines 5-6). The search is also stopped if the position has already been searched during the same iteration, with the same threshold and a less or equal `g` (lines 7-8).

In other cases recursive calls are performed (lines 15, 22, 36 and 43).

The first case deals with the insertion of a gap in the *padapāṭha* (possible if `x` is strictly positive, lines 11-16). If this is the first gap in the word we do not add anything to the cost, since we don't care about the number of words containing gaps in the *padapāṭha*, if the previous move is not a gap in the *padapāṭha* then we add one to the cost (line 14) and the recursive call is made with a cost of $g + deltag + 1$ since inserting a gap also costs one.

The second case deals with alignment of the same letters (lines 17-23). In that case the recursive call is performed with the same `g` since it costs zero to align the same letters and that no gap is inserted.

The third case deals with the insertion of a gap in the *manuscript* (possible if y is strictly positive, lines 24-37). Then the cost is increased by one for the first gap in the word (line 28), by one for the first gap of a sequence of gaps (line 32), and by one since a gap is inserted.

The fourth case deals with the alignment of two different letters and increases the cost by one since aligning two different letters costs one and no gap is inserted (lines 38-45).

The pseudo code for the search algorithm is:

```
1  bool search (g, y, x, gapAlreadySeen,
                gapInMat,
2               previousIsGapInMat,
                previousIsGapInPad)
3    if y=0 and x=0
4     return true

5    if g + h(y,x) > threshold
6      return false

7    if position already searched with smaller g
8      return false

9    newSeen = gapAlreadySeen
10   newSeenMat = gapInMat

11   if x > 0
12     deltag = 0
13     if not previousIsGapInPad
         // cost of a sequence of gaps
         // in the Padapatha
14       deltag = deltag + 1
15     if search (g+deltag+1, y, x-1,
             true, gapInMat, false, true)
16       return true

17   if y > 0 and x > 0
18     if alignment of the same letters
19       if new word in the Padapatha
20         newSeen = false
21         newSeenMat = false
22       if search (g, y-1 , x-1, newSeen,
                  newSeenMat, false, false)
23         return true

24   if y > 0
25     deltag = 0;
26     if not gapInMat
27       // cost of each word containing
         // gaps in the Matrikapatha
28       deltag = 1
29       newSeenMat = true
30     if not previousIsGapInMat
31       // cost of a sequence of gaps in
         // the Matrikapatha
32       deltag = deltag + 1
33     if new word in the Padapatha
34       newSeen = false;
35       newSeenMat = false;
36     if search (g+deltag+1, y-1, x,
         newSeen, newSeenMat, true, false)
37       return true;

38   if y>0 and x>0
39     if alignment of different letters
40       if new word in the Padapatha
41         newSeen = false
42         newSeenMat = false
43       if search (g+1, y-1 , x-1, newSeen,
                    newSeenMat, false, false)
44         return true

45   return false
```

The search function is bounded by a threshold on the cost of the path. In order to find the shortest path, an iterative loop progressively increasing the cost is used.

7 Experiments and Conclusions

We have tested on our Sanskrit texts three different methods to align them: one based upon the L.C.S., the two other ones based on the edit distance. We have tested them on a set of 43 different manuscripts of a short text, the introduction of the *kāśikāvṛtti*: the *pratyāhārasūtraḥ*. A critical edition of this text exists (Bhate et al., 2009), and we have not seen obvious differences with our results.

The size of the *padapāṭha* related to this text is approximately 9500 characters. The time needed for the treatment is approximately 29 seconds for the L.C.S based one, 22 for the second method (with the shifts) and 185 seconds for the third one based on the IDA*algorithm (all mesured on a Pentium 4 (3.2mgz)).

The comparison between the first method and

the two others cannot be absolute, because the first one displays its results under a more synthetic form, and cannot display only the alignments. This form takes a little more time to be proceeded but less time to be written.

Comparing the different methods:

- The first trial (L.C.S.) was a very useful one, because it allows displaying significant results to Sanskrit philologists, and opens the possibility of further research. But it is too complicated compared with other approaches, and the different steps needed, though useful, do not provide the opportunity to make easily further improvements.

- The second approach gives the best results in term of time. It is conceptually quite simple, and not too difficult to implement in term of programming. And it gives place, because it has been simple to implement, for further improvements.

- What can we say then about the IDA* method, which is by far the longest to make the computation? That it is unmistakably not the best choice as a production method when computation time is a preoccupation (but the time overhead has nothing definitive), but it is for sure, for the person "who knows" the most flexible, and the easiest way to implement alignment methods, and to check an hypothesis. Using A* would probabbly be faster as the branching factor is small.

The use of edit distance based methods has been, by the simplifications and the ameliorations it provide for the comparison of the Sanskrit text a great improvement. Both methods will allow us to consider different coefficients for replacing the letters in the edit distance matrix and leads to further simplification of the pre-processing. The IDA* (or other A*) method, opens wide the doors for further experiments. Among these experiments one of the most interesting will consist in the modelling of an interaction between the information provided by the annotations contained in each manuscript (especially the presence of missing parts of the text) and the alignment.

It is difficult to provide a numerical evaluation of the different results, first because they are not provided under the same form, the first method is provided as a human readable text and the two other ones as sequence alignments, secondly because it is difficult (and we did not find it) to provide a criterion which differs from the function we optimize in the A* algorithm. Otherwise even if the differences between the two methods are rather tiny, the A* algorithm which optimizes by construction the criterion will be considered always as slightly better.

Another possible improvement is related to the fact that in Sanskrit, the order of the words is not necessary meaningful. Two sentences with the words appearing in two different orders can have the same meaning.

But there is a problem that none of these methods can solve, the problem induced by the absence of a word which has been used to build a *sandhi*. Once it disappeared the *sandhi* disappeared too, and a new *sandhi* can appear, then it looks like a real change of the text, but these modifications are perfectly justified in term of Sanskrit grammar and should not be notified in the critical edition. For example if we look at the following sequence:

"s	aa	s	t	r	a	p	r	a	v	.r	t	t	y	a	r	th	a	.h
"s	aa	s	t	r	aa	-	-	-	-	-	-	-	-	-	r	th	a	.h

- the word `"saastra` has been changed in `"saastr`**`aa`** (with a long `a` at the end).

- the word `prav.rtty` has disappeared.

- the word `artha.h` has been changed to `rtha.h`

In fact only the second point is valid. If we put the words `"saastra` and `artha.h` one after another in a Sanskrit text we get `"saastr`**`aa`**`rtha.h`. The two short `a` at the junction of the two words become a long `aa` (in bold) because of a *sandhi* rule. We have (until now) no precise idea on the way to solve this kind of problem, but we have the deep feeling that the answer will not be straightforward.

On the other hand we believe that the problems induced by the comparison of Sanskrit texts for

the construction of a critical edition, is an interesting family of problems. We hope that the solutions of these problems can be applied to other languages, and perhaps that it will also benefit to some other problems.

Abstract

In this paper, we present *hybrid decoding* — a novel statistical machine translation (SMT) decoding paradigm using multiple SMT systems. In our work, in addition to component SMT systems, system combination method is also employed in generating partial translation hypotheses throughout the decoding process, in which smaller hypotheses generated by each component decoder and hypotheses combination are used in the following decoding steps to generate larger hypotheses. Experimental results on NIST evaluation data sets for Chinese-to-English machine translation (MT) task show that our method can not only achieve significant improvements over individual decoders, but also bring substantial gains compared with a state-of-the-art word-level system combination method.

1 Introduction

In recent years, system combination for SMT has been known to be quite effective with translation consensus information built from multiple SMT systems. The combination approaches can be classified into two types. One is the combination with each system's outputs, which can be seen as full hypotheses combination. The other is the partial hypotheses (PHS) combination during the decoding phase.

A lot of impressive work has been done to improve the performance of the SMT systems by utilizing consensus statistics which come from single system or multiple systems. For example, Minimum Bayes Risk (MBR) (Kumar and Byrne, 2004) decoding over n-best list finds a translation that has lowest expected loss with all the other hypotheses, and it shows that improvement over the Maximum a Posteriori (MAP) decoding. Several word-based methods (Rosti et al., 2007a; Sim et al., 2007) have also been proposed. Usually, these methods take n-best list from different SMT systems as inputs, and construct a confusion network for second-pass decoding. There are also a lot of research work to advance the confusion network construction by finding better alignment between the skeleton and the other hypotheses (He et al., 2008; Ayan et al., 2008). Typically, all the approaches above only use full hypotheses but have no access to the PHS information.

Moreover, some dedicated efforts have been tried by manipulating PHS between multiple MT systems. Collaborative decoding (co-decoding) (Li et al., 2009) leverages translation consensus by exchanging partial translation results and reranking both full and partial hypotheses explored in decoding. However, no new PHS are generated compared to the individual decoding but only the ranking is affected. Liu et al. (2009) proposes joint decoding, a method that integrates multiple translation models in one decoder. Although joint decoding is able to generate new translations compared to single decoder, it has to use the PHS existed in one of its component decoder at each step. Different from their work, we propose a new perspective which leverages outputs from local word-level combination. This will potentially bring much benefit of performance since word-

*This work has been done while the first author was visiting Microsoft Research Asia.

Coling 2008: Poster Volume, pages 214–222,
Beijing, August 2010

level combination can produce more promising PHS.

The word-level system combination method is employed to generate partial translation hypotheses in our hybrid decoding framework. In this sense, full hypotheses word-level combination (FH-Comb) method(Rosti et al., 2007a; Sim et al., 2007; He et al., 2008; Ayan et al., 2008) can be considered as a special case of hybrid decoding, where their combinations are only performed on the largest hypotheses. Similar with FH-Comb, hybrid decoding also uses word alignment information. However, challenge exists in hybrid decoding as word alignment needs to be carefully conducted through the decoding process. Obviously, document-level word alignment methods such as GIZA++(Och and Ney, 2000) are quite time consuming and unpractical to be embedded into hybrid decoding. We propose a heuristic method that can conduct word alignment of partial hypotheses based on word alignment information of phrase pairs learnt automatically from the model training process. In this way, more PHS are generated and the search space is enlarged substantially, which brings better translation results.

The rest of the paper is organized as follows: Section 2 gives a formal description of hybrid decoding, including framework overview, word-level PHS combination and parameter estimation. We conduct experiments with different settings and make comparison between our method and baseline, as well as a state-of-the-art word-level system combination method in Section 3. Experimental results discussion is presented in Section 4. Section 5 concludes the paper.

2 Hybrid Decoding

2.1 Overview

Different system combination methods (Li et al., 2009; Liu et al., 2009) offer different frameworks to coordinate multiple SMT decoders. Hybrid decoding provides a new scheme to organize multiple decoders to work synchronously. As the decoding algorithms may differ in multiple decoders[1], hybrid decoding has some difficulty in integrating different decoding algorithms. Without loss of generality, we assume that bottom-up CKY-based decoding is adopted in each individual decoder, which is the same as co-decoding (Li et al., 2009) and joint decoding (Liu et al., 2009). Hybrid decoding collects n-best PHS of a source span[2] from multiple decoders, then results from word-level PHS combination of that span are given back to each decoder, mixed with the original PHS. After that, we re-rank the hybrid list and continue the decoding. In an example with two decoders, parts of the whole decoding process are illustrated in Figure 1 and can be summarized as follows:

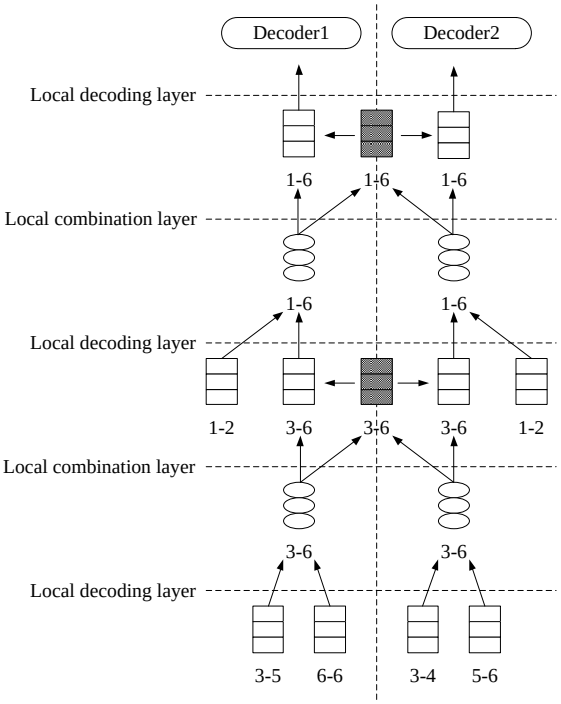

Figure 1: Hybrid decoding with two decoders, where the string "s-e" means the source span starts from position s and ends at position e. The blank rectangles represent the n-best partial translations of each decoder, and the shaded rectangles illustrate the n-best local combination outputs. The ovals denote bottom-up CKY-based decoding results.

[1]In the SMT area, some decoders use left-right decoding to generate the hypothesis and "Pharaoh" (Koehn et al., 2003) is one of them, while others adopt bottom-up decoding which is represented by "Hiero" (Chiang, 2007).

[2]The word "span" is used to represent translation unit in CKY-based decoders, which denotes one or more consecutive words in the source sentence.

1. *Individual decoding*. Each individual decoder should maintain the n-best PHS of each span from the bottom. After all the individual decoders finish translating the same span, they feed their own partial translations into a public container which can be used for word-level PHS combination, then get back the partial combination outputs for step 3.

2. *Local word-level combination*. After fed with PHS from multiple decoders, a confusion network is built and word-level combination for PHS is conducted. The obtained new partial translations are given back to each individual decoder to continue the decoding.

3. *Mix new PHS with the original ones*. The span in each individual decoder will receive the corresponding new PHS from the local combination outputs. The feature space of the new PHS is not exactly the same with that of the original ones. It has to be mapped in some way then the mixed hypotheses are reranked.

In the following sub-sections, we first present the background of word-level combination for PHS, then introduce hybrid decoding algorithm in detail, as well as the feature definition and parameter estimation.

2.2 Word-Level Combination for Partial Hypotheses

Most word-level system combination methods are based on confusion network decoding. In confusion network construction, one hypothesis has to be selected as the skeleton which determines the word order of the combination results. Other hypotheses are aligned against the skeleton. Either votes or some word confidence scores are assigned to each word in the network.

Most of the research on confusion network construction focuses on seeking better word alignment between the skeleton and the other hypotheses. So far, several word alignment procedures are used for SMT system combination, which mainly are GIZA++ alignments (Matusov et al., 2006), TER alignments (Sim et al., 2007) and IHMM alignments (He et al., 2008). Similar with general word-level system combination method, word-level PHS combination also uses word alignment information. However, in hybrid decoding, it is quite time-consuming and impractical to conduct word alignment like GIZA++ for each span. Fortunately, unit hypotheses word alignment can be obtained from the model training process, which is shown in Figure 2. We devise a heuristic approach for PHS alignment that leverages the translation derivations from the sub-phrases. The derivation information ultimately comes from the phrase table in phrase-based systems (Koehn et al., 2003; Xiong et al., 2006) or the rule table in syntactic-based systems (Chiang, 2007; Liu et al., 2007; Galley et al., 2006).

政治||| political ||| 0-0
政治 经济||| political and economic ||| 0-0 1-2
经济||| economic ||| 0-0
经济 利益||| economic interests ||| 0-0 1-1
政治 [X_1] ||| political and [X_1] ||| 0-0 1-2

Figure 2: The example of translation alignment from phrase-table and rule-table

The derivation is built in a phrase-based system as follows. For example, we have two phrase translations “我们 的 ||| our ||| 0-0 1-0” and “经济 利益 ||| economic interests ||| 0-0 1-1”, where string “m-n” means the m^{th} word in the source phrase is aligned to the n^{th} word in the target phrase. When combining the two phrases for generating “我们 的 经济 利益”, we obtain the translation hypothesis as “our economic interests” and also integrate the alignment fragment to get “0-0 1-0 2-1 3-2”. The case is similar in syntactic-based system for non-terminal substitution, which we will not discuss further here.

Next, we introduce the skeleton-to-hypothesis word alignment algorithm in detail. With the translation derivations, the skeleton-to-hypothesis ($sk2hy$) word alignment can be performed based on the source-to-skeleton ($so2sk$) and source-to-hypothesis ($so2hy$) word alignment as they share the same source sentence. The basic idea is to construct the $sk2hy$ word alignment with the *minimum correspondence subsets* (MCS). A MCS is defined as a triple $< SK, HY, SO >$ where the

SK is the subset of skeleton words, HY is the subset of the hypothesis words, and SO is the minimum source word set that all target words in both SK and HY are aligned to. Figure 3 shows the algorithm for skeleton-to-hypothesis alignment. Most of the pseudo-code is self-explained except for some subroutines, which are listed in Table 1.

```
1:  procedure SKEHYPALIGN(so2sk, so2hy)
2:      repeat
3:          Fetch out a source word to SO
4:          SO_1 = SO_2 = SO
5:          repeat
6:              SO=UNION(SO_1, SO_2)
7:              SK=GETALIGN(SO, so2sk)
8:              HY=GETALIGN(SO, so2hy)
9:              SO_1=GETALIGN(SK, so2sk)
10:             SO_2=GETALIGN(HY, so2hy)
11:         until |SO_1| == |SO_2| == |SO|
12:         sim_max = -infinity
13:         for all sk ∈ SK do
14:             for all hy ∈ HY do
15:                 sim =SIM(sk, hy)
16:                 if sim ≥ sim_max then
17:                     sim_max = sim
18:                     sk_max = sk
19:                     hy_max = hy
20:                 end if
21:             end for
22:         end for
23:         ADDALIGN(sk_max, hy_max)
24:     until all the source words are fetched out
25: end procedure
```

Figure 3: Algorithm for skeleton-to-hypothesis alignment

SIM(w_1,w_2)	similarity between w_1 and w_2, we use edit distance here
ADDALIGN(w_1,w_2)	align w_1 with w_2

Table 1: Description for subroutines

Due to the variety of the word order in n-best outputs, skeleton selection becomes essential in confusion network construction. The simplest way is to use the top-1 PHS from any individual decoder with the best performance under some criteria. However, this cannot always lead to better performance on some evaluation metrics (Rosti et al., 2007a). An alternative would be MBR method with some loss function such as TER (Snover et al., 2006) or BLEU (Papineni et al., 2002). We show the experimental results of two skeleton selection methods for PHS combination in Section 3.

2.3 Hybrid Decoding Model

For a given source sentence f, any individual decoder in hybrid decoding finds the best translation e^* among the possible translation hypotheses $\Phi(f)$ in terms of a ranking function F:

$$e^* = \text{argmax}_{e \in \Phi(f)} F(e) \quad (1)$$

Suppose we have n individual decoders. The ranking function F_n of the n^{th} decoder can be written as:

$$F_n(e) = \sum_{i=1}^{m} \lambda_{n,i} h_{n,i}(f, e) \quad (2)$$

where each $h_{n,i}(f, e)$ is a feature function of the n^{th} decoder, and $\lambda_{n,i}$ is the corresponding feature weight. m is the number of features in each decoder.

The final result of hybrid decoder is the top-1 translation from the confusion network, which is constructed on multiple decoders with the last layer's output of CKY-based decoding.

2.4 Hybrid Decoding Algorithm

The hybrid decoder acts as a control unit which controls the synchronization of multiple individual decoders. The algorithm is fully demonstrated in Figure 4. The hybrid decoder pushes the same span f_i^j to different decoders and gets back the n-best PHS (lines 2-6). When the span's length is too small, both word alignment and partial combination results are not accurate. We predefine a fixed threshold δ which is used for determining the start-up of combination (line 7). When the length condition holds, the n-best PHS of each individual

decoder are stored in container G (lines 8). Confusion network is constructed and new PHS can be extracted from it and are further mixed and sorted with the original ones (lines 11-15).

```
1:  procedure HYBRIDDECODING(f_1^n, D)
2:      for l ← 1...n do
3:          for all i, j s.t. j − i = l do
4:              G ← ∅
5:              for all d ∈ D do
6:                  nbest =DECODING(d, i, j)
7:                  if j − i ≥ δ then
8:                      ADD(G, nbest)
9:                  end if
10:             end for
11:             cn =CONNETBUILD(G)
12:             nbest′ =GETPARHYP(cn)
13:             for all d ∈ D do
14:                 MIXSORT(nbest_d, nbest′)
15:             end for
16:         end for
17:     end for
18: end procedure
```

Figure 4: Hybrid decoding algorithm

2.5 Hybrid Decoding Features

Next we present the PHS word-level combination feature functions for hybrid decoding. Following (Rosti et al., 2007b), four features are utilized to model the PHS as:

Word Confidence Feature $h_{wc}(e)$
The word confidence feature is computed as $h_{wc}(e) = \sum_{i=1}^{n} \mu_i c_{iw}$, where n is the number of the systems, μ_i is the system confidence of system i, and c_{iw} is the word confidence of word w in system i.

Word Penalty Feature $h_{wp}(e)$
Word penalty feature is the number of words in the partial hypothesis (PH).

Null Penalty Feature $h_{np}(e)$
For null penalty feature, we mean the number of NULL links along the PH when extracted from the confusion network.

Language Model Feature $h_{lm}(e)$
Different from the above three combination features, which can be obtained during the confusion network construction or hypotheses extraction, the language model feature cannot be summed up on the fly. Instead, it must be re-computed when building each new PH.

2.6 Feature Space Mapping

The features used in hybrid decoding can be classified into two categories: features for individual decoders (FID) and features for PHS word-level combination (FComb), and they are independent. When mixing the new PHS with the original ones of individual decoders, FComb space has to be mapped to a FID space. However, several features in FID are not defined in FComb, such as source to target (S2T) phrase probability, target to source (T2S) phrase probability, S2T lexical probability, T2S lexical probability and other model specific features. A mapping function H needs to be defined as follows:

$$F_{fid} = H(F_{fcomb}) \tag{3}$$

where F_{fcomb} denotes the feature vector from FComb space, while F_{fid} is the feature vector from FID space.

An easy mapping function is implemented with an intuitive motivation: PHS combination results are better than the ones in individual decoder and we prefer not to disorder the original search space. Thus, the undefined feature values of PHS from FComb space are assigned by corresponding feature values of the top-1 PH in original decoder. Experiments show that our method is not only practical but also quite effective.

2.7 Parameter Estimation

Minimum Error Rate Training (MERT) (Och, 2003) algorithm is adopted to estimate feature weights for hybrid decoding. As hybrid decoder makes use of PHS from both individual decoders and combination results as a whole, we devise a new feature vector representation. The feature vectors from FID space and FComb space are simply concatenated to form a longer vector without overlapping. The weights are tuned simultaneously in order to reach a relatively global optima.

3 Experiment

3.1 Data and Metric

We conducted our experiments on the test data of NIST 2005 and NIST 2006 Chinese-to-English machine translation tasks. The NIST 2003 test data is used as the development data to tune the parameters. Statistics of the data sets are shown in Table 2. Translation performances are measured with case-insensitive BLEU4 score (Papineni et al., 2002). Statistical significance test is performed using the bootstrap re-sampling method proposed by Koehn (2004).

The bilingual training corpora we used are listed in Table 3, which contains 498K sentence pairs, 12.1M Chinese words and 13.8M English words after pre-processing. Word alignment is performed by GIZA++ (Och and Ney, 2000) in both directions with the default setting, and the intersect-diag-grow method is used to refine the symmetric word alignment.

Data Set	# Sentences

Table 3: Training corpora for Chinese-English translation

The language model used for hybrid decoding and all the baseline systems is a 5-gram model trained with the Xinhua portion of LDC English Gigaword Version 3.0 plus the English part of bilingual training data.

3.2 Implementation

We use two baseline systems. The first one (SYS1) is re-implementation of Hiero, a hierarchical phrase-based system (Chiang, 2007) based on Synchronous Context Free Grammar (SCFG). Phrasal translation rules and hierarchical translation rules with nonterminals are extracted from all the bilingual sentence pairs. The second one (SYS2) is a phrase-based system (Xiong et al., 2006) based on Bracketing Transduction Grammar (Wu, 1997) with a lexicalized reordering model (Zhang et al., 2007) under maximum entropy framework, where the phrasal translation rules are exactly the same with that of SYS1. The lexicalized reordering model is trained using the MaxEnt toolkit (Zhang, 2006) where the training instances are extracted from subset of the training corpora, which contains LDC2003E07, LDC2003E14, LDC2005T06, LDC2005T10. Both systems use the bottom-up CKY-based decoding with cube-pruning (Chiang, 2007) and the beam size is set to 10 for decoding efficiency.

For hybrid decoder, we set δ to be $sentence.length - 3$, meaning that the PHS of individual decoders only perform local combination in the last three layers. The reason why we adopt this setting is because we find that starting local combination on short spans hurts the performance badly on test data. Experimental results are shown in the next section.

3.3 Translation Results

We present the overall results of hybrid decoding over two baseline systems on both test sets. We also implement an IHMM-based word-level system combination method (He et al., 2008) to make comparison with hybrid decoding system, and the n-best candidates used for IHMM-based word-level system combination is set to 10. Parameters for all the systems are tuned on NIST 2003 test set. The results are shown in Table 4.

In Table 4, we find that the hybrid decoding performs significantly better than SYS1 and SY2 on both test sets. Besides, compared to IHMM word-level system combination method, hybrid decoding also brings substantial gains with 0.63% and 0.92% points respectively.

	NIST 2005	NIST 2006
SYS1	0.3745	0.3346
SYS2	0.3699	0.3296
IHMM Word-Comb	0.3821^{*}	0.3421^{*}
Hybrid	0.3884^{*+}	0.3513^{*+}

Table 4: Hybrid decoding results on test sets, *:significantly better than SYS1 and SYS2 with $\boldsymbol{p}<0.01$, +:significantly better than IHMM Word-Comb with $\boldsymbol{p}<0.01$

We also try different layers for determining the start-up of local word-level PHS combination. Figure 5 gives the intuitive BLEU results.

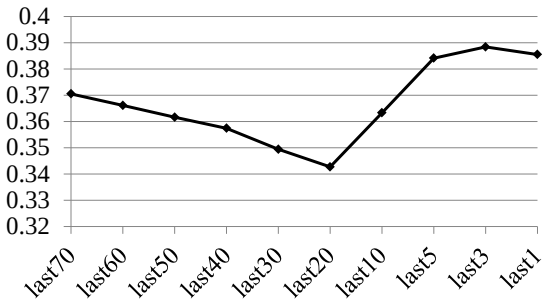

Figure 5: Performance of hybrid decoding with different start-up settings on NIST 2005 test set, where the "lastM" means to conduct local word-level PHS combination in the last M layers from the perspective of CKY-based decoding.

As shown in Figure 5, the performance drops drastically if we start to conduct word-level PHS combination too early. After considering about efficiency and performance, we determine to do that in the last three layers.

We then investigate the effects on hybrid decoding with different beam sizes, and compare the trend with two baseline systems and IHMM-based word-level system combination method as well. The results are illustrated in Figure 6.

From what we see in Figure 6, the performance of each system is monotonically increasing as the beam size becomes larger. Hybrid decoding performs consistently better than IHMM Word-Comb when the beam size is small, and the largest improvement (+0.63% points) is obtained when the beam size is set to 10. However, as the beam size

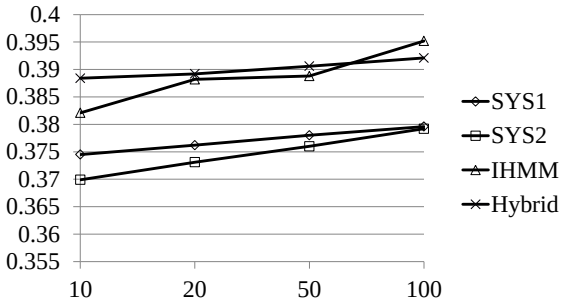

Figure 6: Performance of hybrid decoding with different beam sizes on NIST 2005 test set

increases, the performance gap is getting narrow. One intuitive observation is that hybrid decoding performs slightly worse than IHMM Word-Comb when the beam size is set to 100. One possible reason for this phenomenon is that, the alignment noise may be introduced to hybrid decoding since we have to generate monolingual alignments with many poor translation derivations.

The confusion network for PHS of each system can be built independently. We would like to evaluate the performance of single system hybrid decoding. Table 5 gives the results on both Hiero and BTG decoders.

	NIST 2005		NIST 2006	
	SYS1	SYS2	SYS1	SYS2
baseline	0.3745	0.3699	0.3346	0.3296
self-comb	0.3770	0.3758^{*}	0.3358	0.3355^{*}

Table 5: Hybrid decoding for single system, *:significantly better than baseline with $\boldsymbol{p}<0.05$

Table 5 shows that BTG decoder (SYS2) has more potential for so-called "self-boosting". The self-combination of BTG decoder improves the performance substantially over the baseline. However, we did not observe any significant improvement for Hiero decoder (SYS1).

Finally, we examine the impacts of skeleton selection for PHS in hybrid decoding. The results in Table 6 demonstrate that, compared to the top-1 selection method, translation performance can be improved significantly with MBR-based skeleton selection method. It strongly suggests that choosing the skeleton with more consistent word order

will lead to better translation results.

	NIST 2005	NIST 2006
Top-1	0.3817	0.3415
MBR	0.3884*	0.3513*

Table 6: Skeleton selection in hybrid decoding, *:significantly better than top-1 skeleton selection method with $p<0.01$

4 Discussion

System combination methods have been widely used in SMT to improve the performance. For example, in (Rosti et al., 2007a), several combination methods have been proposed to make use of different kinds of consensus information. In (He et al., 2008), better word alignment method is adopted to advance the word-level system combination. Our method is different from these methods in the sense that we do not exclusively rely on the n-best full hypotheses from each individual decoder, but emphasize the importance of word-level combination for PHS. Thus, it enlarges the search space and is more prone to find better translations. Experimental results have shown the effectiveness of our method.

The idea of multiple systems collaborative decoding (Li et al., 2009) works well on re-ranking the outputs of each system using n-gram agreement statistics. However, no new translation results are generated compared to individual decoding. Our method takes advantage of confusion network to give PHS which cannot be seen before.

Although (Liu et al., 2009) also work on PHS, we explore the cooperation of multiple systems from a new perspective. They use translation derivations from different decoders jointly as a bridge to connect different models. Different from their work, we devise a heuristic method to obtain word alignment information from the derivation of each decoder, which can be embedded for word-level PHS combination easily and efficiently.

5 Conclusion and Future Work

In this paper, we propose a new SMT decoding framework named hybrid decoding, in which multiple decoders work synchronously to conduct local decoding and local word-level PHS combination in turn. We also devise a heuristic method to obtain word alignment information directly from the translation derivations, which is both intuitive and efficient. Experimental results show that with hybrid decoding the overall performance can be improved significantly over both the individual baseline decoder and the state-of-the-art system combination method.

In the future, we will involve more individual SMT decoders into hybrid decoding. In addition, we would like to keep on this work in two directions. On the one hand, start-up threshold of PHS combination will be explored in detail to find its underlying impact on hybrid decoding. On the other hand, we will try to employ a more theoretically sound approach to conduct the feature space mapping from the feature space of confusion network to that of individual decoders.

Abstract

Global ranking, a new information retrieval (IR) technology, uses a ranking model for cases in which there exist relationships between the objects to be ranked. In the ranking task, the ranking model is defined as a function of the properties of the objects as well as the relations between the objects. Existing global ranking approaches address the problem by "learning to rank". In this paper, we propose a global ranking framework that solves the problem via data fusion. The idea is to take each retrieved document as a pseudo-IR system. Each document generates a pseudo-ranked list by a global function. The data fusion algorithm is then adapted to generate the final ranked list. Taking a biomedical information extraction task, namely, interactor normalization task (INT), as an example, we explain how the problem can be formulated as a global ranking problem, and demonstrate how the proposed fusion-based framework outperforms baseline methods. By using the proposed framework, we improve the performance of the top 1 INT system by 3.2% using the official evaluation metric of the BioCreAtIvE challenge. In addition, by employing the standard ranking quality measure, NDCG, we demonstrate that the proposed framework can be cascaded with different local ranking models and improve their ranking results.

1 Introduction

Information Retrieval (IR) involves finding documents that are relevant to a given query in a large corpus. The task is usually formulated as a ranking problem. When a user submits a query, the IR system retrieves all documents that contain at least one query term, calculates a ranking score for each of the documents using a ranking model, and sorts the documents according to the ranking scores. The scores represent the relevance, importance, and/or diversity of the retrieved documents. Thus, the quality of a search engine can be determined by the accuracy of the ranking results.

Recently, a machine learning technology called *learning to rank* has been applied extensively to the task. Several state-of-the-art machine learning-based ranking algorithms have been proposed, e.g., RankSVM and RankNet. These algorithms differ substantially in terms of the ranking models and optimization techniques employed, but most of them can be regarded as "local ranking" approaches in the sense that each model is defined on a single document without considering the possible relations to other documents to be ranked. In many applications, this is only a loose approximation as there is always relational information among documents. For example, in some cases, users may prefer that two similar documents have similar relevance scores; even

* Corresponding author

Beijing, August 2010

though one of the documents is not as relevant to the given query as the other; this problem is similar to Pseudo Relevance Feedback (Kwok, 1984). In other cases, web pages from the same site form a sitemap hierarchy in which a parent document should be ranked higher than its child documents (referred to as Topic Distillation at TREC (Chowdhury, 2007)). To utilize all available information, more advanced ranking algorithms define a ranking model as a function of all the documents to be ranked, i.e., a global ranking model (Qin et al., 2008a; Qin et al., 2008b).

Unlike conventional ranking and learning to rank models, such as BM25 and RankSVM, whose ranking functions are defined on a query and document pair, global ranking models utilize both content information and relation information. Qin et al. (2008) proposed the first supervised learning framework for the global ranking problem. They formulated the problem as an optimization problem that involves finding an objective function to minimize the trade-off between local consistence and global consistence and implemented it on SVM. Subsequently, they defined the global ranking problem formally in (Qin et al., 2008) and solved it by employing continuous conditional random fields (CRF).

In this paper, we propose a new framework for the global ranking problem. The major difference between our work and that of Qin et al. (2008a; 2008b) is that we do not compile a feature vector of relational information directly to construct a new machine-learned ranking model for global ranking. Instead, we use the ranking results generated by the original ranking model and then employ an algorithm with the relational information to transform the global ranking problem into a data fusion problem; that is also known as a rank aggregate problem. The proposed framework is flexible and can be cascaded with conventional ranking models or learning to rank models.

The remainder of this paper is organized as follows. In Section 2, we present a formal definition of global ranking. In Section 3, we describe the proposed framework and consider three fusion algorithms that can be used with our framework. We also explain how the algorithms can be adapted to solve the global ranking problem. In Section 4, we introduce a biomedical text mining task called the interactor normalization task (INT) (Krallinger et al., 2009) and show why it should be formulated as a global ranking problem. In Section 5, we report extensive experiments conducted on the INT dataset released by BioCreAtIvE (Krallinger et al., 2009). Section 6 contains some concluding remarks.

2 Global Ranking Problem

The global ranking problem was first defined formally by Qin et al. (2008). In this paper, we propose a new global ranking framework based on their definition. Although we developed the framework independently, we adopt Qin et al.'s terminology.

Let q denote a query. In addition, let $x^{(q)} = \left\{x_1^{(q)}, x_2^{(q)}, \dots, x_{n^{(q)}}^{(q)}\right\}$ denote the documents retrieved by q, and let $y^{(q)} = \left\{y_1^{(q)}, y_2^{(q)}, \dots, y_{n^{(q)}}^{(q)}\right\}$ denote the ranking scores assigned to the documents. Here, $n^{(q)}$ represents the number of documents retrieved by q. Note that the numbers of documents varies according to different queries. We assume that $y^{(q)}$ is determined by a ranking model.

If a ranking model is defined on a single document, i.e., in the form of

$$y_i^{(q)} = f\left(x_i^{(q)}\right), \mathrm{i} = 1, \dots, n^{(q)}, \quad (1)$$

it is called a "local ranking" model.

Let $\left\{g_k\left(y_i^{(q)}, y_j^{(q)}, x^{(q)}\right)\right\}_{k=1}^{K}$ be a set of real-value functions defined on $y_i^{(q)}$, $y_j^{(q)}$, and $x^{(q)}$ $(i, j = 1, \dots, n^{(q)}, i \neq j)$. The functions

$$g\left(y_i, y_j, x\right) \quad (2)$$

represents the relations between documents. Equation 2 is defined according to the requirements of different tasks. For example, for the Pseudo Relevance Feedback problem, Qin et al. (2008) defined Equation 2 as the similarities between any two documents in their CRF-based model.

If a ranking model takes all the documents as its input and exploits both local and global information (Equation 2) in the documents, i.e., in the form of

$$y^{(q)} = F\left(x^{(q)}\right),$$

it is called a "global ranking" approach.

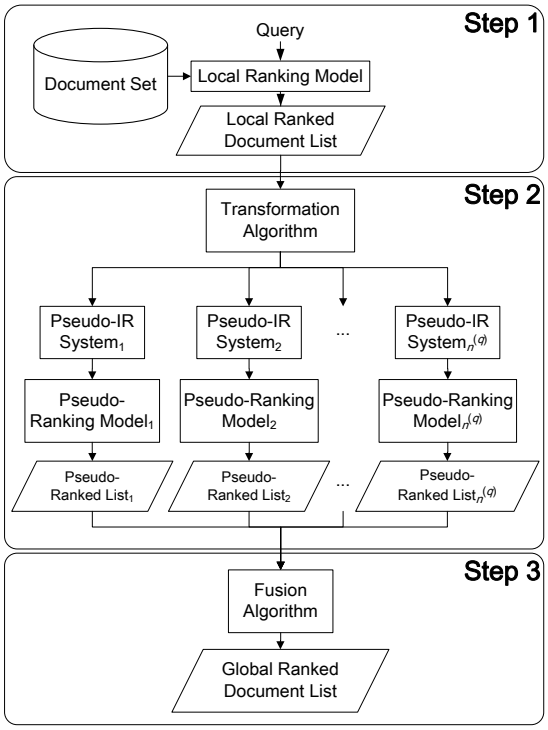

Figure 1. The Proposed Framework for Global Ranking.

3 Fusion-based Global Ranking Framework

It is usually difficult to develop a global ranking algorithm that can fully utilize all the local and global information in documents to produce a document rank and also consider the score ranks. One example of a global ranking algorithm that satisfied these criteria is the one proposed in (Qin et al., 2008) in which the modified CRF algorithm handles context (local) features and relational (global) features in the documents. Without solving a ranking problem directly, however, the modified CRF algorithm is more like a regression algorithm since it optimizes the CRF parameters in a maximum likelihood estimate without considering the score ranks. With respect to the ranking feature, in this section, we describe our framework based on the idea of data fusion for solving the global ranking problem.

3.1 Framework Description

The flow chart of the proposed framework is illustrated in Figure 1. The first step is the same as that of the traditional local ranking model. Given a query, the local ranking model $y_i^{(q)}$ defined in Equation 1 is used to calculate the ranking score for each document, and return a document list sorted according to the local scores.

The second step transforms the global ranking problem into a data fusion problem. Our idea is to take each retrieved document as a pseudo-IR system, and the pseudo-ranking model, $y'^{(q)}_i$, used by each system is the function defined in Equation 2. For each pseudo-IR system, $x_j^{(q)}$, the pseudo-ranking model for a document $x_i^{(q)}$ is defined as follows:

$$y'^{(q)}_i = f\left(x_i^{(q)}\right) = g\left(y_i^{(q)}, y_j^{(q)}, x^{(q)}\right), \quad i = 1, \ldots, n^{(q)}. \tag{3}$$

There are totally $n^{(q)}$ pseudo-IR systems, which generate $n^{(q)}$ pseudo-ranked lists. As a result, the global ranking problem is transformed into a data fusion problem, that is to aggregate the pseudo-ranked lists. Figure 2 shows the steps of the transformation algorithm.

The final step is to adapt fusion algorithms to aggregate the pseudo-ranked lists. A canonical data fusion task is called *meta-search* (Aslam and Montague, 2001; Fox and Shaw, 1994; Lee, 1997; Nuray and Can, 2006), which aggregates Web search query results from several engines into a more accurate ranking. The origin of research on data fusion can be traced back to (Borda, 1781). In recent years, the process has been used in many new applications, including aggregating data from microarray experiments to discover cancer-related genes (Pihura et al., 2008), integration of results from multiple mRNA studies (Lin and Ding, 2008), and similarity searches across datasets and information merging (Adler et al., 2009; Zhao et al., 2010).

Liu et al. (2007) classified data fusion technologies into two categories: order-based fusion and score-based fusion. In the first category, the orders of the entities in individual ranking lists are used by the fusion algorithm. In the second category, the entities in individual ranking lists are assigned scores and the fusion algorithm uses the scores. In the following sub-sections, we adapt three fusion algorithms

```
function transform (x^(q): the documents retrieved
with query q)
{generate pseudo-ranked lists for x^(q)}
# a dictionary that maps the pseudo-IR systems to
# their corresponding pseudo-ranked lists
1. pseudoRankedLists = {}
2. for x_i^(q) in x^(q):
     # a dictionary that maps the relation score (real
     # value) to a list of documents.
3.   relation = {}
     for x_j^(q) in x^(q):
4.     relation[g(y_i^(q), y_j^(q), x^(q))].append(x_j^(q))
     # relation.keys() returns all keys stored in the
     # dictionary relation. The key of relation is the
     # relation score.
5.   Sort relation.keys() in decreasing order
     # a dictionary that maps a new rank to a list of
     # documents.
6.   pseudoRankedList = {}
7.   newRank = 0
     for score in sorted relation.keys():
       # relation[score] returns the document list
       # corresponding to the given score
       for doc in relation[score]:
8.       pseudoRankedList[1+newRank]
                          .append(doc)
9.     newRank = newRank + 1
10.  pseudoRankedLists [x_i^(q)] = pseudoRankedList
   return pseudoRankedLists
```

Figure 2. The Dependent Ranked List Generation Algorithm (represented using python syntax).

for the proposed framework. The first is the Borda-fuse model (Aslam and Montague, 2001), an order-based fusion approach based on an optimal voting procedure. The second is a linear combination (LC) model (Vogt and Cottrell, 1999), which is a score-based fusion approach.

3.2 Borda-fuse

The Borda-fuse model (Aslam and Montague, 2001) is based on a political election strategy called the Borda Count. For our framework, the rationale behind the strategy is as follows. Each pseudo-IR system $x_j^{(q)}$ is an analogy for a voter; and each voter ranks a fixed set of $n^{(q)}$ documents in order of preference (Equation 3). For each voter, the top ranked document is given $n^{(q)}$ points, the second ranked document is given $n^{(q)}$-1 points, and so on. If some documents left unranked by the voter, the remaining points are divided equally among the unranked documents. The documents are ranked in descending order of the total points.

In our framework, we implement two Borda-fuse-based models. The first is the modified Borda-fuse (MBF) model. In MBF, the number of points given for a voter's first and subsequent preferences is determined by the number of documents they have actually ranked, rather than the total number of ranked. Because the ranking model, $y'^{(q)}_i$, used by the pseudo-IR system may only retrieve m documents where m is smaller than $n^{(q)}$, we penalize systems that do not rank a full document set by reducing the number of points their vote distributes among the documents. In other words, if there are ten documents, but the pseudo-IR system only retrieves five, then the first document will only receive 5 points; the second will receive 4 points, and so on.

The second is the weighted Borda-fuse (WBF) model. The original Borda-fuse model reflects a democratic election in which each voter has equal weight. However, in many cases, we prefer some voters because they are more reliable. We employ a simple weighting scheme that multiplies the points assigned to a document determined by system $x_j^{(q)}$ by a weight $w_{x_j^{(q)}}$.

3.3 LC Model

The LC model has been used by many IR researchers with varying degrees of success (Bartell et al., 1994; Knaus et al., 1995; Vogt and Cottrell, 1999; Vogt and Cottrell, 1998). In our framework, it is defined as follows. Given a query q, a document $x_i^{(q)}$, the weights $\mathbf{w} = (w_1, w_2, w_3, \ldots, w_{n^{(q)}})$ for $n^{(q)}$ individual pseudo-IR systems, and jth pseudo-IR system's ranking score $y_j{}'^{(q)}_i$, the LC model calculates the ranking score ρ of $x_i^{(q)}$ against all pseudo-IR systems as follows:

$$\rho\left(\mathbf{w}, x_i^{(q)}\right) = \sum_{j=1}^{n^{(q)}} w_i y_j{}'^{(q)}_i \qquad (4)$$

This score is then used to rank the documents. For example, for two pseudo-IR systems, this reduces to:

$$\rho\left(w_1, w_2, x_i^{(q)}\right) = w_1 y_1{}'^{(q)}_i + w_2 y_2{}'^{(q)}_i$$

Compared with MBF, Equation 4 requires both relevance scores and training data to de-

termine the weight w_i given to each pseudo-IR system.

4 Case Study

In this section, we describe the task examined in our study. We also explain how we formulate the task as a global ranking problem. The experiments results are detailed in Section 5.

4.1 Interactor Normalization Task

The interactor normalization task (INT) is a complicated text mining task that involves the following steps: (1) It recognizes gene mentions in a full text article. (2) It maps the recognized gene mentions to corresponding unique database identifiers which is similar to the word sense disambiguation task in computational linguistics. (3) It generates a ranked list of the identifiers according to their importance in the article and their probability of playing the interactor role in protein-protein interactions (PPIs). Such ranked lists are useful for human curators and can speed up PPI database curation.

Dai et al. (2010) won first place in the BioCreAtIvE II.5 INT challenge (Mardis et al., 2009) by using a SVM-based local ranking model in which they treat gene mentions' identifiers in an article as the document set, and the query is a constant string "interactor". Based on their feature sets and evaluation results, we can find that their local ranking model tends to rank focus genes higher (Dai et al., 2010). However, the primary objective of INT is to generate a ranked list of interaction gene identifiers. According to (Jenssen et al., 2001), co-mentioned genes are usually related in some way. For example, if two gene mentions frequently occur alongside each other in the same sentence in an article, they probably have an association and influence each other's rank. Take a low-ranked interactor that is only mentioned twice in an article as an example. If both mentions are next to the highest-ranked interactor in the article, then the low-ranked interactor's rank should be boosted significantly. Therefore, the ranking task for each article can be formulated as a global ranking problem; the global ranking algorithm should consider both the local information from Dai et al.'s model and the global information from the associations among identifiers.

4.2 Global Ranking in INT

Let q be a constant "interactor." The identifier set generated by an INT system for a full-text article is analogous to the document set $x^{(q)} = \left\{x_1^{(q)}, x_2^{(q)}, \ldots, x_{n^{(q)}}^{(q)}\right\}$. Here $n^{(q)}$ denotes the number of identifiers. Note that the number of identifiers varies for different articles. Let $y^{(q)} = \left\{y_1^{(q)}, y_2^{(q)}, \ldots, y_{n^{(q)}}^{(q)}\right\}$ denote the ranking scores assigned to the identifiers given by a local ranking model. In this study, we used the INT system and SVM-based local ranking model released by (Dai et al., 2010) to generate the identifier set and ranking scores.

To obtain the global information, we consider the co-occurrence of identifiers and employ mutual information (MI) to measure the association between two identifiers as follows:

$$g(y_i, y_j, x) = \mathrm{MI}(x_i, x_j) = P(x_i, x_j) / \left(P(x_i) \times P(x_j)\right).$$

In the above formula, the identifier probabilities $P(x_i)$ and $P(x_j)$ are estimated by counting the number of occurrences in an article normalized by N, i.e., the number of sentences containing identifiers. The joint probability, $P(x_i, x_j)$, is estimated by the number of times x_i co-occurs with x_j in a window of k words normalized by N. Note that, in practice, other advanced approaches can be used to calculate the association score.

For the proposed framework, each identifier $x_i^{(q)}$ is a pseudo-IR system with MI as its pseudo-ranking model $y'^{(q)}_i$. The identifiers that co-occur with $x_i^{(q)}$ become candidates on $x_i^{(q)}$'s pseudo-ranked list.

5 Experiments

In the following sub-sections, we introduce the dataset used in the experiments, describe the evaluation methods, report the results of the experiments conducted to compare the performance of different methods, and discuss the efficiency of the proposed global ranking framework.

5.1 Dataset

We used the BioCreAtIvE II.5 Elsevier corpus released by BioCreAtIvE II.5 challenge in the experiments. The corpus contains 1,190 full-text journal articles selected mainly from FEBS Letters. Following the same format as the BioCreAtIvE II.5 INT challenge, we used articles published in 2008 (61 articles) as our training set and articles published in 2007 or earlier (61 articles) as our test set.

5.2 A Fusion-based Global Ranking Framework for INT

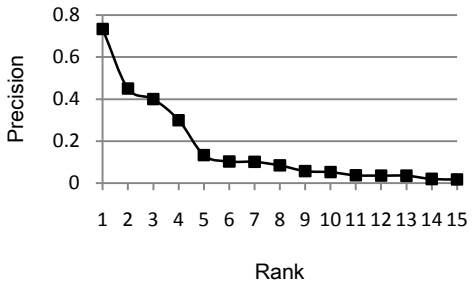

Figure 3. Precision of Different Ranks.

Before applying the proposed framework, we preprocess the articles in the dataset to identify all gene mentions, and map them to their corresponding identifiers. After preprocessing, each full-text article is associated with a list of identifiers (Step 1 in Figure 1). The transform and fusion algorithm is then applied on each article (Steps 2 and 3 in Figure 1).

To apply the WBF and LC models, we need to determine the weight assigned to each pseudo-IR system. To obtain the weight, we calculate the precision of each rank of the ranked lists generated by Dai et al.'s INT system. Figure 3 shows the precision of ranks 1 to 15 calculated by applying three-fold cross validation on the INT training set. We observe that the precision declines as the rank increases, which implies that the higher ranks predicted by their SVM-based local ranking model are more reliable than the lower ranks.

5.3 Evaluation Metrics

Our evaluations focus on two comparisons: the first compares the ranking of the proposed framework with the original local ranking model by using the area under the curve of the interpolated precision/recall (iP/R) curve. This is the evaluation metric used in the BioCreAtIvE II.5 challenge and is a common way to depict the degradation of precision as one traverses the retrieved results by plotting interpolated precision numbers against percentage recall. The area under the iP/R function f_{pr} is defined as follows:

$$Area\_iPR(f_{pr}) = \sum_{j=1}^{n}\left(p_{i_j} \times (r_j - r_{j-1})\right),$$

$$p_i(r) = \max_{r' \geq r} p(r')$$

where n is the total number of correct identifiers and p_i is the highest interpolated precision for the correct identifier j at r_j, the recall for that hit. The interpolated precision p_i is calculated for each recall r by taking the highest precision at r or any $r' \geq r$.

In the second comparison, we use a standard quality measure in IR to estimate the ranking performance of local ranking models and the proposed framework. We adopt Normalized Discounted Cumulative Gain (NDCG) to measure the performance. The NDCG score of a ranking is computed based on DCG (Discounted Cumulative Gain) as follows:

$$\mathrm{DCG}(r) = g(1) + \sum_{i=2}^{r} \frac{g(i)}{\log_2(i)},$$

where r is the rank position, and $g(i) \in \{0,1\}$ is the relevance grade of the ith identifier in the ranked result set. In our experiment, $g(i) = 1$ corresponds to an interaction identifier, and $g(i) = 0$ corresponds to other identifiers. NDCG is then computed as follows:

$$\mathrm{NDCG}(r) = \frac{\mathrm{DCG}(r)}{\mathrm{IDCG}(r)},$$

where IDCG denotes the results of a perfect ranking. The NDCG values for all articles are averaged to obtain the average performance of the proposed framework.

5.4 INT Test Set Performance

Figure 4 shows the *Area_iPR* scores of four configurations. In the baseline configuration (Local/Rank1), the SVM-based local ranking model released by Dai et al. is employed. In the configuration Global+LC, Global+MBF, and Global+WBF, the proposed global ranking framework is cascaded with the local ranking model and with three data fusion models: the LC model, the modified Borda-fuse (MBF) model, and the weighted Borda-fuse model. The figure also shows the *Area_iPR* scores of

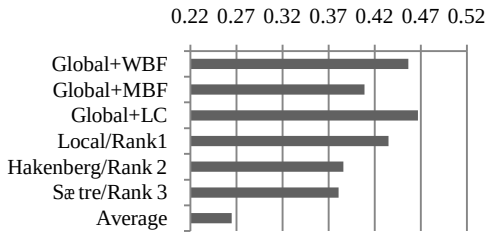

Figure 4. The *Area_iPR* Results of Different Ranking Models

the top three teams and the average *Area_iPR* score of all BioCreAtIvE II.5 INT participants (Average).

The results show that under the global ranking framework, *Area_iPR* performance is improved in addition to Global+MBF. The highest *Area_iPR* (Global+LC: 46.7%) is 3.2% higher than the Rank 1 score in the BioCreAtIvE II.5 INT challenge. According to our analysis, before global ranking, identifiers whose feature values rarely appear in the training set are often ranked incorrectly because their feature values are under-estimated by the ranking model. However, if the identifiers co-occur with higher-ranked identifiers whose feature values appear frequently, the proposed framework is very likely to increase their ranks. This results in an improved *Area_iPR* score.

5.5 Global Ranking Performance

Based on	Global Ranking	NDCG1	NDCG3	NDCG5
Local Ranking /Rank1	Global+LC	+0.908	+1.323	-0.003
	Global+MBF	-3.279	-1.034	-0.020
	Global+WBF	-0.016	+3.630	+2.071
Freq	Global+LC_f	+1.639	+3.152	+2.817
	Global+MBF_f	-6.860	-4.275	-4.839
	Global+WBF_f	+2.549	+2.390	+3.043

Table 1. The NDCG Gain (%) of Different Ranking Models.

To illustrate the effectiveness of the proposed global ranking framework and assess its performance when it is cascaded with other conventional ranking models, we implement a simple term frequency-based ranking function, which is based on the identifier frequency in an article as another local ranking model. If two or more identifiers have the same frequency, two heuristic rules are employed sequentially to rank them: (1) the identifier with the highest frequency in the Results section of the article, and (2) the identifier mentioned first in the article.

Table 1 shows the NDCG percentage gain of different ranking models. It compares the ranked list generated by our global ranking framework and by the local ranking models. We observe that (1) irrespective of whether the local ranking model is a conventional model or a learning to rank model, Global+LC and Global+WBF models achieve NDCG gains over the original rankings of the local ranking models; (2) the results show that our global ranking framework can improve the performance by only exploiting MI analysis. However, it is expected that employing more advanced relation extraction methods to determine the global information (Equation 3) would yield more reliable pseudo-ranked lists and lead to a further improvement in the final ranking; and (3) similar to the results in Section 5.4, the performance of Global+MBF does not improve. Global+MBF has a negative NDCG gain and the *Area_iPR* decreases by 2.61%. We believe this is due to MBF gives equal weight to each pseudo-IR system. As mentioned in Section 4.1, the document set in INT is comprised of the identifiers of the gene mentions derived by Dai et al.'s system. Unfortunately, there must be incorrect identifiers (the errors may be due to their gene mention recognition or identifier mapping processes). As in the meta-search, the best performance is often achieved by weighting the input systems unequally. Reasonable weights allow the algorithm to concentrate on good feedback from pseudo-IR systems and ignore poor feedback. As shown by the average precision results in Figure 3, the identifiers (corresponding to the pseudo-IR systems in our framework) in the higher ranks are more reliable; however, MBF cannot use this information, which leads to a negative NDCG gain and a lower *Area_iPR* score.

6 Conclusion

We have presented a new global ranking framework based on data fusion technology. Our approach solves the global ranking problem in three stages: the first stage ranks the document set by the original local ranking model; the second stage transforms the prob-

lem into a data fusion task by using global information, and the final stage adapts fusion algorithms to solve the ranking problem. The framework is flexible and it can be combined with other mature ranking models and fusion algorithms. We also show how the BioCreAtIvE INT can be formulated as a global ranking problem and solved by the proposed framework. Experiments on the INT dataset demonstrate the effectiveness of the proposed framework and its superior performance over other ranking models.

In our future work, we will address the following issues: (1) the use of advanced data fusion algorithms in the proposed framework; (2) assessing the performance of the proposed framework on other tasks, such as Pseudo Relevance Feedback and Topic Distillation; and (3) design an advanced supervised learning relation extraction algorithm to replace MI in INT to evaluate the system performance.

Abstract

In this paper the development of an opinion summarization system that works on Bengali News corpus has been described. The system identifies the sentiment information in each document, aggregates them and represents the summary information in text. The present sys-tem follows a topic-sentiment model for sentiment identification and aggregation. Topic-sentiment model is designed as discourse level theme identification and the topic-sentiment aggregation is achieved by theme clustering (k-means) and Document level Theme Relational Graph representation. The Document Level Theme Relational Graph is finally used for candidate summary sentence selection by standard page rank algorithms used in Information Retrieval (IR). As Bengali is a resource constrained language, the building of annotated gold standard corpus and acquisition of linguistics tools for lexico-syntactic, syntactic and discourse level features extraction are described in this paper. The reported accuracy of the Theme detection technique is 83.60% (precision), 76.44% (recall) and 79.85% (F-measure). The summarization system has been evaluated with Precision of 72.15%, Recall of 67.32% and F-measure of 69.65%.

1 Introduction

The Web has become a rich source of various opinions in the form of product reviews, travel advice, social issue discussions, consumer complaints, movie review, stock market predictions, real estate market predictions, etc. Present computational systems need to extend the power of understanding the sentiment/opinion expressed in an electronic text to act properly in the society rather than dealing with the topic of a document. The topic-document model of information retrieval has been studied for a long time and systems are available publicly since last decade. On the contrary Opinion Mining/Sentiment Analysis is still an unsolved research problem. Although a few systems like Twitter Sentiment Analysis Tool[1], TweetFeel[2] are available in World Wide Web since last few years still more research efforts are necessary to match the user satisfaction level and social need.

Researchers have taken multiple approaches towards the problem of Opinion Summarization like Topic-sentiment model, Textual summaries at single document or multiple document perspective and graphical summaries or visualization. The works on opinion tracking systems have explicitly incorporated temporal dimension. The topic-sentiment model is well established for opinion retrieval.

The concept of reputation system was first introduced in (Resnick et al., 2000). Reputation systems for both buyers and sellers are needed to earn each other's trust in online interactions.

Ku et al., (2005) selects representative words from a document set to identify the main concepts in the document set. A term is considered to represent a topic if it appears frequently across documents or in each document. Different methodologies have been used to assign weights to each word both at document level and paragraph level. The precision and recall values of the system have been reported as 0.56 and 0.85.

Beijing, August 2010

Zhou et al. (2006) have proposed the architecture for generative summary from blogosphere. Typical multi-document summarization (MDS) systems focus on content selection followed by synthesis by removing redundancy across multiple input documents. The online discussion summarization system (Zhou et al., 2006) work on an online discussion corpus involving multiple participants and discussion topics are passed back and forth by various participants. MDS systems are insufficient in representing this aspect of the interactions. Due to the complex structure of the dialogue, similar subtopic structure identification in the participant-written dialogues is essential. Maximum Entropy Model (MEMM) and Support Vector Machine (SVM) have been used with a number of relevant features.

Carenini et al. (2006) present and compare two approaches to the task of multi document opinion summarization on evaluative texts. The first is a sentence extraction based approach while the second one is a natural language generation-based approach. Relevant extracted features are categorized in two types: User Defined Features (UDF) and Crude Features (CF) as described in (Hu and Liu, 2004).

The summary generation technique uses the aggregation of the extracted features, CF and UDF. Opinion aggregation has been done by the two relevant features: opinion strength and polarity. A new opinion distribution function feature has been introduced to capture the overall opinion distributed in corpus.

Kawai et al. (2007) developed a news portal site called Fair News Reader (FNR) that recommends news articles with different sentiments for a user in each of the topics in which the user is interested. FNR can detect various sentiments of news articles and determine the sentimental preferences of a user based on the sentiments of previously read articles by the user. News articles crawled from various news sites are stored in a database. The contents are integrated as needed and the summary is presented on one page. A sentiment vector on the basis of word lattice model has been generated for every document. A user sentiment model has been proposed based on user sentiment state. The user sentiment state model works on the browsing history of the user. The intersection of the documents under User Vector and Sentiment Vector are the results.

2 Resource Organization

Resource acquisition is one of the most challenging obstacles to work with resource constrained languages like Bengali. Bengali is the fifth popular language in the World, second in India and the national language in Bangladesh. Extensive NLP research activities in Bengali have started recently but resources like annotated corpus, various linguistic tools are still unavailable for Bengali in the required measure. The manual annotation of gold standard corpus and acquisition of various tools used in the feature extraction for Bengali are described in this section.

2.1 Gold Standard Data Acquisition

2.1.1 Corpus

For the present task a Bengali news corpus has been developed from the archive of a leading Bengali news paper available on the Web (http://www.anandabazar.com/). A portion of the corpus from the editorial pages, i.e., Reader's opinion section or Letters to the Editor Section containing 28K word forms has been manually annotated with sentence level subjectivity and discourse level theme words. Detailed reports about this news corpus development in Bengali can be found in (Das and Bandyopadhyay, 2009b).

2.1.2 Annotation

From the collected document set (Letters to the Editor Section), some documents have been chosen for the annotation task. Some statistics about the Bengali news corpus is represented in the Table 1. Documents that have appeared within an interval of four months are chosen on the hypothesis that these letters to the editors will be on related events. A simple annotation tool has been designed for annotating the sentences considered to be important for opinion summarization. Three annotators (Mr. X, Mr. Y and Mr. Z) participated in the present task.

```
<Story>
……..
……..
<SS><TW>Sargeant O'Leary</TW> said "the
<TW>incident</TW> took place at 2:00pm."</SS>
……..
</Story>
```

Figure 1: XML Annotation Format

Annotators were asked to annotate sentences for summary and to mark the theme words (topical expressions) in those sentences. The documents with such annotated sentences are saved in

XML format. Figure 1 shows the XML annotation format. "<SS>" marker denotes subjective sentences and "<TW>" denotes the theme words.

Bengali NEWS Corpus Statistics	
Total number of documents in the corpus	100
Total number of sentences in the corpus	2234
Average number of sentences in a document	22
Total number of wordforms in the corpus	28807
Average number of wordforms in a document	288
Total number of distinct wordforms in the corpus	17176

Table 1: Bengali News Corpus Statistics

The annotation tool highlights the sentiment words (Das and Bandyopadhyay, 2010a)[3] by four different colors within a document according to their POS categories (Noun, Adjective, Adverb and Verb). This technique helps to increase the speed of annotation process. Finally 100 annotated documents have been developed.

2.1.3 Inter-annotator Agreement

The agreement of annotations among three annotators has been evaluated. The agreements of tag values at theme words level and sentence levels are listed in Tables 2 and 3 respectively.

Annotators	X vs. Y	X Vs. Z	Y Vs. Z	Avg
Percentage	82.64%	71.78%	80.47%	78.30%
All Agree	69.06%			

Table 2: Agreement of annotators at theme words level

Annotators	X vs. Y	X Vs. Z	Y Vs. Z	Avg
Percentage	73.87%	69.06%	60.44%	67.8%
All Agree	58.66%			

Table 3: Agreement of annotators at sentence level

From the analysis of inter-annotator agreement, it is observed that the agreement drops fast as the number of annotator's increases. It is less possible to have consistent annotations when more annotators are involved. In the present task the inter-annotator agreement is better for theme words annotation rather than candidate sentence identification for summary though a small number of documents have been considered.

Further discussion with annotators reveals that the psychology of annotators is to grasp as many as possible theme words identification during annotation but the same groups of annotators are more cautious during sentence identification for summary as they are very conscious to find out the most concise set of sentences that best describe the opinionated snapshot of any document. The annotators were working independent of each other and they were not trained linguists.

2.2 Subjectivity Classifier

Work in opinion mining and classification often assumes the incoming documents to be opinionated. Opinion mining system makes false hits while attempting to summarize non-subjective or factual sentences or documents. It becomes imperative to decide whether a given document contains subjective information or not as well as to identify which portions of the document are subjective or factual. This task is termed as subjectivity detection in sentiment literature. The subjectivity classifier that uses SVM machine learning technique and described in (Das and Bandyopadhyay, 2009a) has been used here. The recall measure of the present classifier is greater than its precision value. The evaluation results of the classifier are 72.16% (Precision) and 76.00 (recall) on the News Corpus.

2.3 Feature Organization

The set of features used in the present task have been categorized as Lexico-Syntactic, Syntactic and Discourse level features. These are listed in the Table 4 below and have been described in the subsequent subsections.

Types	Features
Lexico-Syntactic	POS
	SentiWordNet
	Frequency
	Stemming
Syntactic	Chunk Label
	Dependency Parsing Depth
Discourse Level	Title of the Document
	First Paragraph
	Term Distribution
	Collocation

Table 4: Features

2.3.1 Lexico-Syntactic Features

2.3.1.1 Part of Speech (POS)

It has been shown in (Hatzivassiloglou et. al., 2000), (Chesley et. al., 2006) etc. that opinion bearing words in sentences are mainly adjective, adverb, noun and verbs. Many opinion mining tasks, like (Nasukawa et. al., 2003) are mostly based on adjective words. Details of the Bengali POS tagger used can be found in (Das and Bandyopadhyay 2009b).

[3] http://www.amitavadas.com/sentiwordnet.php

2.3.1.2 SentiWordNet (Bengali)

Words that are present in the SentiWordNet carry opinion information. The developed SentiWordNet (Bengali) (Das and Bandyopadhyay, 2010a) is used as an important feature during the learning process. These features are individual sentiment words or word n-grams (multiword entities) with strength measure as strong subjective or weak subjective. Strong and weak subjective measures are treated as a binary feature in the supervised classifier. Words which are collected directly from SentiWordNet (Bengali) are tagged with positivity or negativity score. The subjectivity score of these words are calculated as:

$$E_s = | S_p | + | S_n |$$

where E_s is the resultant subjective measure and S_p , S_n are the positivity and negativity scores respectively.

2.3.1.3 Frequency

Frequency always plays a crucial role in identifying the importance of a word in the document. The system generates four separate high frequent word lists for four POS categories: Adjective, Adverb, Verb and Noun after function words are removed. Word frequency values are then effectively used as a crucial feature in the Theme Detection technique.

2.3.1.4 Stemming

Several words in a sentence that carry opinion information may be present in inflected forms and stemming is necessary for them before they can be searched in appropriate lists. Due to non availability of good stemmers in Indian languages especially in Bengali, a stemmer (Das and Bandyopadhyay, 2010b) based on stemming cluster technique has been used. This stemmer analyzes prefixes and suffixes of all the word forms present in a particular document. Words that are identified to have the same root form are grouped in a finite number of clusters with the identified root word as cluster center.

2.3.2 Syntactic Features

2.3.2.1 Chunk Label

Chunk level information is effectively used as a feature in supervised classifier. Chunk labels are defined as B-X (Beginning), I-X (Intermediate) and E-X (End), where X is the chunk label. In the task of identification of Theme expressions, chunk label markers play a crucial role. Further details of development of chunking system could be found in (Das and Bandyopadhyay 2009b).

2.3.2.2 Dependency Parser

Dependency depth feature is very useful to identify Theme expressions. A particular Theme word generally occurs within a particular range of depths in a dependency tree. Theme expressions may be a Named Entity (NE: person, organization or location names), a common noun (Ex: accident, bomb blast, strike etc) or words of other POS categories. It has been observed that depending upon the nature of Theme expressions it can occur within a certain depth in the dependency tree for the sentence. A statistical dependency parser has been used for Bengali as described in (Ghosh et al., 2009).

2.3.3 Discourse Level Features

2.3.3.1 Positional Aspect

Depending upon the position of the thematic clue, every document is divided into a number of zones. The features considered for each document are Title words of the document, the first paragraph words and the words from the last two sentences. A detailed study was done on the Bengali news corpus to identify the roles of the positional aspect features of a document (first paragraph, last two sentences) in the detection of theme words and subjective sentences for generating the summary of the document. The importance of these positional features is shown in Tables 5 on the Bengali gold standard set.

2.3.3.2 Title Words

Title words of a document always carry some meaningful thematic information. The title word feature has been used as a binary feature during CRF based machine learning.

2.3.3.3 First Paragraph Words

People usually give a brief idea of their beliefs and speculations in the first paragraph of the document and subsequently elaborate or support them with relevant reasoning or factual information. Hence first paragraph words are informative in the detection of Thematic Expressions.

2.3.3.4 Words From Last Two Sentences

Generally every document concludes with a summary of the opinions expressed in the document.

Positional Factors	Bengali
First Paragraph	56.80%
Last Two Sentences	78.00%

Table 5: Statistics on Positional Aspect.

2.3.3.5 Term Distribution Model

An alternative to the classical TF-IDF weighting mechanism of standard IR has been proposed as a model for the distribution of a word. The model characterizes and captures the informativeness of a word by measuring how regularly the word is distributed in a document. As discussed in Section 1, Carenini et al. (2006) have introduced the opinion distribution function feature to capture the overall opinion distributed in the corpus. Thus the objective is to estimate $f_d(w_i)$ that measures the distribution pattern of the k occurrences of the word w_i in a document d. Zipf's law describes distribution patterns of words in an entire corpus. In contrast, term distribution models capture regularities of word occurrence in subunits of a corpus (e.g., documents, paragraphs or chapters of a book). A good understanding of the distribution patterns is useful to assess the likelihood of occurrences of a word in some specific positions (e.g., first paragraph or last two sentences) of a unit of text. Most term distribution models try to characterize the informativeness of a word identified by inverse document frequency (IDF). In the present work, the distribution pattern of a word within a document formalizes the notion of topic-sentiment informativeness. This is based on the Poisson distribution. Significant Theme words are identified using TF, Positional and Distribution factor. The distribution function for each theme word in a document is evaluated as follows:

$$f_d(w_i) = \sum_{i=1}^{n} (S_i - S_{i-1}) / n + \sum_{i=1}^{n} (TW_i - TW_{i-1}) / n$$

where n=number of sentences in a document with a particular theme word, S_i=sentence id of the current sentence containing the theme word and S_{i-1}=sentence id of the previous sentence containing the query term, TW_i is the positional id of current Theme word and TW_{i-1} is the positional id of the previous Theme word.

2.3.3.6 Collocation

Collocation with other thematic word/expression is undoubtedly an important clue for identification of theme sequence patterns in a document. A window size of 5 including the present word is considered during training to capture the collocation with other thematic words/expressions.

3 Theme Detection

Term Frequency (TF) plays a crucial role to identify document relevance in Topic-Based Information Retrieval. The motivation behind developing Theme detection technique is that in many documents relevant words may not occur frequently or irrelevant words may occur frequently. Moreover for sentiment analysis topic words should have sentiment conceptuality. The Theme detection technique has been proposed to resolve these issues to identify discourse level relevant topic-semantic nodes in terms of word or expressions using a standard machine learning technique. The machine learning technique used here is Conditional Random Field (CRF)[4]. The theme word detection is defined as a sequence labeling problem. Depending upon the series of input feature, each word is tagged as either Theme Word (TW) or Other (O).

4 Theme Clustering

Theme clustering algorithms partition a set of documents into finite number of topic based groups or clusters in terms of theme words/expressions. The task of document clustering is to create a reasonable set of clusters for a given set of documents. A reasonable cluster is defined as the one that maximizes the within-cluster document similarity and minimizes between-cluster similarities. There are two principal motivations for the use of this technique in theme clustering setting: efficiency, and the **cluster hypothesis**.

The **cluster hypothesis** (Jardine and van Rijsbergen, 1971) takes this argument a step further by asserting that retrieval from a clustered collection will not only be more efficient, but will in fact improve retrieval performance in terms of recall and precision. The basic notion behind this hypothesis is that by separating documents according to topic, relevant documents will be found together in the same cluster, and non-relevant documents will be avoided since they will reside in clusters that are not used for retrieval. Despite the plausibility of this hypothesis, there is only mixed experimental support for it. Results vary considerably based on the clus-

[4] http://crfpp.sourceforge.net

tering algorithm and document collection in use (Willett, 1988; Shaw et al., 1996).

Application of the clustering technique to the three sample documents results in the following theme-by-document matrix, A, where the rows represent Docl, Doc7 and Doc13 and the columns represent the themes politics, sport, and travel.

$$A = \begin{bmatrix} election & cricket & hotel \\ parliament & sachin & vacation \\ governor & soccer & tourist \end{bmatrix}$$

The similarity between vectors is calculated by assigning numerical weights to these words and then using the cosine similarity measure as specified in the following equation.

$$s\left(\vec{q}_k, \vec{d}_j\right) = \vec{q}_k . \vec{d}_j = \sum_{i=1}^{N} w_{i,k} \times w_{i,j} \text{ ---- (1)}$$

This equation specifies what is known as the dot product between vectors. Now, in general, the dot product between two vectors is not particularly useful as a similarity metric, since it is too sensitive to the absolute magnitudes of the various dimensions. However, the dot product between vectors that have been length normalized has a useful and intuitive interpretation: it computes the **cosine** of the angle between the two vectors. When two documents are identical they will receive a cosine of one; when they are orthogonal (share no common terms) they will receive a cosine of zero. Note that if for some reason the vectors are not stored in a normalized form, then the normalization can be incorporated directly into the similarity measure as follows.

$$s\left(\vec{q}_k, \vec{d}_j\right) = \frac{\sum_{i=1}^{N} w_{i,k} \times w_{i,j}}{\sqrt{\sum_{i=1}^{N} w_{i,k}^2} \times \sqrt{\sum_{i=1}^{N} w_{i,k}^2}} \text{ ----(2)}$$

Of course, in situations where the document collection is relatively static, it makes sense to normalize the document vectors once and store them, rather than include the normalization in the similarity metric.

Calculating the similarity measure and using a predefined threshold value, documents are classified using standard bottom-up soft clustering k-means technique. The predefined threshold value is experimentally set to 0.5 as shown in Table 6.

A set of initial cluster centers is necessary in the beginning. Each document is assigned to the cluster whose center is closest to the document. After all documents have been assigned, the center of each cluster is recomputed as the centroid or mean $\vec{\mu}$ (where $\vec{\mu}$ is the clustering coefficient) of its members, that is $\vec{\mu} = \left(1/\left|c_j\right|\right)\sum_{x \in c_j} \vec{x}$. The distance function is the **cosine vector** similarity function.

ID	Themes	1	2	3
1	**প্রশাসন** (administration)	**0.63**	0.12	0.04
1	সুশাসন (good-government)	**0.58**	0.11	0.06
1	সমাজ (Society)	**0.58**	0.12	0.03
1	আইন (Law)	**0.55**	0.14	0.08
2	গবেষণা (Research)	0.11	**0.59**	0.02
2	কলেজ (College)	0.15	**0.55**	0.01
2	**উচ্চশিক্ষা (Higher Study)**	0.12	**0.66**	0.01
3	জেহাদি (Jehadi)	0.13	0.05	**0.58**
3	মসজিদ (Mosque)	0.05	0.01	**0.86**
3	মুশারফ (Musharaf)	0.05	0.01	**0.86**
3	**কাশ্মীর (Kashmir)**	0.03	0.01	**0.93**
3	পাকিস্তান (Pakistan)	0.06	0.02	**0.82**
3	নয়াদিল্লী (New Delhi)	0.12	0.04	**0.65**
3	বর্ডার (Border)	0.08	0.03	**0.79**

Table 6: Five cluster centroids (mean $\vec{\mu}_j$)

Table 6 gives an example of theme centroids from the K-means clustering. Bold words in Theme column are cluster centers. Cluster centers are assigned by maximum clustering coefficient. For each theme word, the cluster from table 6 is still the dominating cluster. For example, "প্রশাসন" has a higher membership probability in cluster 1. But each theme word also has some non-zero membership in all other clusters. This is useful for assessing the strength of association between a theme word and a topic. Comparing two members of the cluster2, "কাশ্মীর" and "নয়াদিল্লী", it is seen that "নয়াদিল্লী" is strongly associated with cluster2 (p=0.65) but has some affinity with other clusters as well (e.g., p =0.12 with the cluster1). This is a good example of the utility of soft clustering. These non-zero values are still useful for calculating vertex weights during Theme Relational Graph generation.

5 Construction of Document Level Theme Relational Graph

Representation of input text document(s) in the form of graph is the key to our design principle. The idea is to build a document graph G=<V,E> from a given source document $d \in D$. First, the input document *d* is parsed and split into a number of text fragments (sentence) using sentence delimiters (Bengali sentence marker "।", "?" or "!"). At this preprocessing stage, text is tokenized, stop words are eliminated, and words are

stemmed (Das and Bandyopadhyay, 2010b). Thus, the text in each document is split into fragments and each fragment is represented with a vector of constituent theme words. These text fragments become the nodes V in the document graph.

The similarity between two nodes is expressed as the weight of each edge E of the document graph. A weighted edge is added to the document graph between two nodes if they either correspond to adjacent text fragments in the text or are semantically related by theme words. The weight of an edge denotes the degree of the relationship. The weighted edges not only denote document level similarity between nodes but also inter document level similarity between nodes. Thus to build a document graph G, only the edges with edge weight greater than some predefined threshold value are added to G, which basically constitute the edges E of the graph G.

The Cosine similarity measure has been used here. In cosine similarity, each document d is denoted by the vector $\vec{V}(d)$ derived from d, with each component in the vector for each Theme words. The cosine similarity between two documents (nodes) d1 and d2 is computed using their vector representations $\vec{V}(d1)$ and $\vec{V}(d2)$ as equation (1) and (2) (Described in Section 4). Only a slight change has been done i.e. the dot product of two vectors $\vec{V}(d1) \bullet \vec{V}(d2)$ is defined as $\sum_{i=1}^{M} V(d1)V(d2)$. The Euclidean length of d is defined to be $\sqrt{\sum_{i=1}^{M} \vec{V}_i^{\,2}(d)}$ where M is the total number of documents in the corpus. Theme nodes within a cluster are connected by vertex, weight is calculated by the clustering co-efficient of those theme nodes. No inter cluster vertex are there. Cluster centers are interconnected with weighted vertex. The weight is calculated by cluster distance as measured by cosine similarity measure as discussed earlier.

To better aid our understanding of the automatically determined category relationships we visualized this network using the Fruchterman-Reingold force directed graph layout algorithm (Fruchterman and Reingold, 1991) and the NodeXL network analysis tool (Smith et al., 2009)[5]. A theme relational model graph drawn by NodeXL is shown in Figure 2.

[5] Available from http://www.codeplex.com/NodeXL

6 Summarization System

Present system is an extractive opinion summarization system for Bengali. In the previous sections, we described how to identify theme clusters that relates to different shared topics and subtopics, from a given input document set. But identifying those clusters is not only a step toward generating document level opinionated news summary rather another major step is to extract thematic sentences from each theme cluster that reflects the contextual concise content of the current theme cluster. Extraction of sentences based on their importance in representing the shared subtopic (cluster) is an important issue and it regulates the quality of the output summary. We have used Information Retrieval (IR) based technique to identify the most "informed" sentences from any cluster and it can be termed as IR based cluster center for that particular cluster. With the adaptation of ideas from page rank algorithms (Page et al., 1998), it can be easily observed that a text fragment (sentence) in a document is relevant if it is highly related to many relevant text fragments of other documents in the same cluster. Since, in our document graph structure, the edge score reflects the correlation measure between two nodes, it can be used to identify the most salient/informed sentence from a sentence cluster. We computed the relevance of a node/sentence by summing up the edge scores of those edges connecting the node with other nodes in the same cluster. Then the nodes are given rank according to their calculated relevance scores and the top ranking sentences is selected as the candidate sentence representing the opinion summary. For example four such candidate sentences are shown in Table 7. The words in bold are the theme words based on those theme words the sentences are extracted.

Candidate Sentence	IR Score
মহম্মদ আমিনের মতো **পলিটব্যুরোর** 'নবীনতম' সদস্যকেও কিন্তু বয়সের দিক হইতে নবীন ভাবা কঠিন।	151
এবার চিন্তা আরওএকটু বেশি, কারণ এই **মূল্যবৃদ্ধির** পিছনে যেমন দেশের ভিতরে জিনিসপত্রের জোগান কমে যাওয়া আছে, তেমনই আছে **আন্তর্জাতিক বাজারে মূল্যবৃদ্ধির** প্রবণতা।	167
স্বাধীনতার পর ষাট বছর গত হইল, এখনও প্রায় সকল **সরকারি পরিকল্পনার** পিছনে এই একটিই ভাবাদর্শ কাজ করে: বিভিন্ন **ভোটব্যাঙ্ককে** তুষ্ট করিয়া যেন তেন প্রকারেণ নিজেদের দলীয় স্থিতি নিশ্চিত করা।	130

Table 7: Candidate sentences

Another issue that is very important in summarization is sentence ordering so that the Output summary looks coherent. Once all the relevant sentences are extracted across the input documents, the summarizer has to decide in which order to present them so that the whole text makes sense for the user. We prefer the original order of sentences as they occurred in original document.

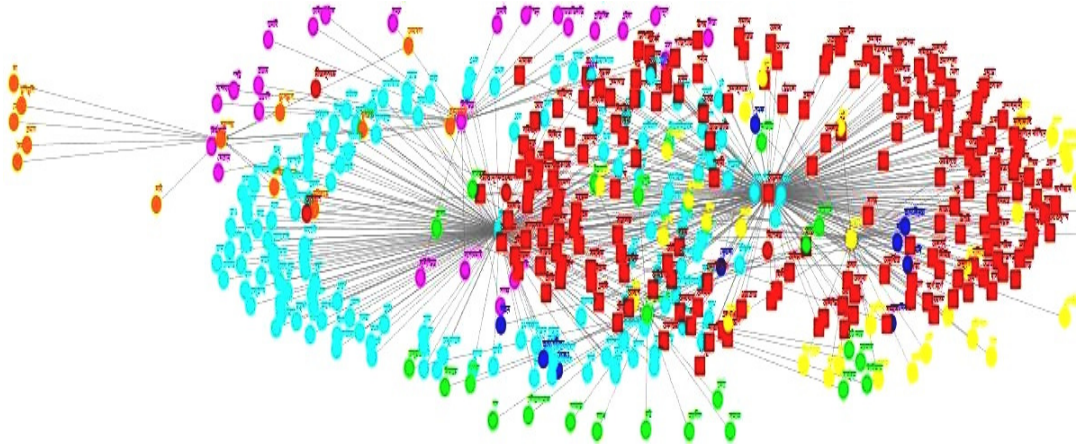

Figure 2: Document Level Theme Relational Graph by NodeXL

7 Experimental Result

The evaluation result of the CRF-based Theme Detection task for Bengali is presented in Table 8. The result is presented individually for every annotators and the overall result of the system.

	Metrics	X	Y	Z	Avg
Theme Detection	**Precision**	87.65%	85.06%	78.06%	83.60%
	Recall	80.78%	76.06%	72.46%	76.44%
	F-Score	84.07%	80.30%	75.16%	79.85%

Table 8: Results of CRF-based Theme Identifier

The evaluation result of subjective sentence identification of the system for opinion summary is in the Table 9.

	Metrics	X	Y	Z	Avg
Summarization	**Precision**	77.65%	67.22%	71.57%	72.15%
	Recall	68.76%	64.53%	68.68%	67.32%
	F-Score	72.94%	65.85%	70.10%	69.65%

Table 9: Final Results subjective sentence identification for summary

8 Error Analysis

The evaluation result of the present summarization system is reasonably good but still not outstanding. During the error analysis we found that the main false hits occurring for subjectivity identifier. It has been reported (Section 2.2) that the recall value of the classifier is higher than its precision. Hence some objective sentences are identified during subjectivity analysis. Some of the sentences get high score during Theme detection or Theme clustering and being included in final summary. Our observation is at least 2-3% sentences are included due to the wrong identification by Subjectivity identifier.

Another vital source of errors occurring in the accuracy level of linguistics resources and tools are the POS tagger, Chunker and Dependency Parser. These linguistics tools are not well performing hence the resultant Theme identification system is missing some of the important theme words. Successive Theme clustering, Document level weighted theme relational model fails to accumulate those important theme expressions. Our observation is at most 3-5% improvement could be possible on final system by granular improvement of every linguistic tool.

9 Conclusion

In this work we have reported our work on single-document opinion summarization for Bengali. The novelty of the proposed technique is the topic based document-level theme relational graphical representation. According to best of our knowledge this is the first attempt on opinion summarization for Bengali. The approach presented here is unique in every aspect as in literature and for a new language like Bengali.

Our next research target is to generate a hierarchical cluster of theme words with time-frame relations. Time-frame relations could be useful for time wise opinion tracking.

Abstract

Automated identification of diverse sentiment types can be beneficial for many NLP systems such as review summarization and public media analysis. In some of these systems there is an option of assigning a sentiment value to a single sentence or a very short text.

In this paper we propose a supervised sentiment classification framework which is based on data from Twitter, a popular microblogging service. By utilizing 50 Twitter tags and 15 smileys as sentiment labels, this framework avoids the need for labor intensive manual annotation, allowing identification and classification of diverse sentiment types of short texts. We evaluate the contribution of different feature types for sentiment classification and show that our framework successfully identifies sentiment types of untagged sentences. The quality of the sentiment identification was also confirmed by human judges. We also explore dependencies and overlap between different sentiment types represented by smileys and Twitter hashtags.

1 Introduction

A huge amount of social media including news, forums, product reviews and blogs contain numerous sentiment-based sentences. Sentiment is defined as "a personal belief or judgment that is not founded on proof or certainty"[1]. Sentiment expressions may describe the mood of the writer (happy/sad/bored/grateful/...) or the opinion of the writer towards some specific entity (X is great/I hate X, etc.).

Automated identification of diverse sentiment types can be beneficial for many NLP systems such as review summarization systems, dialogue systems and public media analysis systems. Sometimes it is directly requested by the user to obtain articles or sentences with a certain sentiment value (e.g Give me all positive reviews of product X/ Show me articles which explain why movie X is boring). In some other cases obtaining sentiment value can greatly enhance information extraction tasks like review summarization. While the majority of existing sentiment extraction systems focus on polarity identification (e.g., positive vs. negative reviews) or extraction of a handful of pre-specified mood labels, there are many useful and relatively unexplored sentiment types.

Sentiment extraction systems usually require an extensive set of manually supplied sentiment words or a handcrafted sentiment-specific dataset. With the recent popularity of article tagging, some social media types like blogs allow users to add sentiment tags to articles. This allows to use blogs as a large user-labeled dataset for sentiment learning and identification. However, the set of sentiment tags in most blog platforms is somewhat restricted. Moreover, the assigned tag applies to the whole blog post while a finer grained sentiment extraction is needed (McDonald et al., 2007).

With the recent popularity of the Twitter microblogging service, a huge amount of frequently

self-standing short textual sentences (*tweets*) became openly available for the research community. Many of these tweets contain a wide variety of user-defined hashtags. Some of these tags are sentiment tags which assign one or more sentiment values to a tweet. In this paper we propose a way to utilize such tagged Twitter data for classification of a wide variety of sentiment types from text.

We utilize 50 Twitter tags and 15 smileys as sentiment labels which allow us to build a classifier for dozens of sentiment types for short textual sentences. In our study we use four different feature types (punctuation, words, n-grams and patterns) for sentiment classification and evaluate the contribution of each feature type for this task. We show that our framework successfully identifies sentiment types of the untagged tweets. We confirm the quality of our algorithm using human judges.

We also explore the dependencies and overlap between different sentiment types represented by smileys and Twitter tags.

Section 2 describes related work. Section 3 details classification features and the algorithm, while Section 4 describes the dataset and labels. Automated and manual evaluation protocols and results are presented in Section 5, followed by a short discussion.

2 Related work

Sentiment analysis tasks typically combine two different tasks: (1) Identifying sentiment expressions, and (2) determining the polarity (sometimes called *valence*) of the expressed sentiment. These tasks are closely related as the purpose of most works is to determine whether a sentence bears a positive or a negative (implicit or explicit) opinion about the target of the sentiment.

Several works (Wiebe, 2000; Turney, 2002; Riloff, 2003; Whitelaw et al., 2005) use lexical resources and decide whether a sentence expresses a sentiment by the presence of lexical items (sentiment words). Others combine additional feature types for this decision (Yu and Hatzivassiloglou, 2003; Kim and Hovy, 2004; Wilson et al., 2005; Bloom et al., 2007; McDonald et al., 2007; Titov and McDonald, 2008a; Melville et al., 2009).

It was suggested that sentiment words may have different senses (Esuli and Sebastiani, 2006; Andreevskaia and Bergler, 2006; Wiebe and Mihalcea, 2006), thus word sense disambiguation can improve sentiment analysis systems (Akkaya et al., 2009). All works mentioned above identify evaluative sentiment expressions and their polarity.

Another line of works aims at identifying a broader range of sentiment classes expressing various emotions such as happiness, sadness, boredom, fear, and gratitude, regardless (or in addition to) positive or negative evaluations. Mihalcea and Liu (2006) derive lists of words and phrases with happiness factor from a corpus of blog posts, where each post is annotated by the blogger with a mood label. Balog et al. (2006) use the mood annotation of blog posts coupled with news data in order to discover the events that drive the dominant moods expressed in blogs. Mishne (2005) used an ontology of over 100 moods assigned to blog posts to classify blog texts according to moods. While (Mishne, 2005) classifies a blog entry (post), (Mihalcea and Liu, 2006) assign a happiness factor to specific words and expressions. Mishne used a much broader range of moods. Strapparava and Mihalcea (2008) classify blog posts and news headlines to six sentiment categories.

While most of the works on sentiment analysis focus on full text, some works address sentiment analysis in the phrasal and sentence level, see (Yu and Hatzivassiloglou, 2003; Wilson et al., 2005; McDonald et al., 2007; Titov and McDonald, 2008a; Titov and McDonald, 2008b; Wilson et al., 2009; Tsur et al., 2010) among others.

Only a few studies analyze the sentiment and polarity of tweets targeted at major brands. Jansen et al. (2009) used a commercial sentiment analyzer as well as a manually labeled corpus. Davidov et al. (2010) analyze the use of the *#sarcasm* hashtag and its contribution to automatic recognition of sarcastic tweets. To the best of our knowledge, there are no works employing Twitter hashtags to learn a wide range of emotions and the relations between the different emotions.

3 Sentiment classification framework

Below we propose a set of classification features and present the algorithm for sentiment classification.

3.1 Classification features

We utilize four basic feature types for sentiment classification: single word features, n-gram features, pattern features and punctuation features. For the classification, all feature types are combined into a single feature vector.

3.1.1 Word-based and n-gram-based features

Each word appearing in a sentence serves as a binary feature with weight equal to the inverted count of this word in the Twitter corpus. We also took each consecutive word sequence containing 2–5 words as a binary n-gram feature using a similar weighting strategy. Thus n-gram features always have a higher weight than features of their component words, and rare words have a higher weight than common words. Words or n-grams appearing in less than 0.5% of the training set sentences do not constitute a feature. ASCII smileys and other punctuation sequences containing two or more consecutive punctuation symbols were used as single-word features. Word features also include the substituted meta-words for URLs, references and hashtags (see Subsection 4.1).

3.1.2 Pattern-based features

Our main feature type is based on surface patterns. For automated extraction of patterns, we followed the pattern definitions given in (Davidov and Rappoport, 2006). We classified words into high-frequency words (HFWs) and content words (CWs). A word whose corpus frequency is more (less) than F_H (F_C) is considered to be a HFW (CW). We estimate word frequency from the training set rather than from an external corpus. Unlike (Davidov and Rappoport, 2006), we consider all single punctuation characters or consecutive sequences of punctuation characters as HFWs. We also consider URL, REF, and HASHTAG tags as HFWs for pattern extraction. We define a pattern as an ordered sequence of high frequency words and slots for content words. Following (Davidov and Rappoport, 2008), the F_H and F_C thresholds were set to 1000 words per million (upper bound for F_C) and 100 words per million (lower bound for F_H)[2].

The patterns allow 2–6 HFWs and 1–5 slots for CWs. To avoid collection of patterns which capture only a part of a meaningful multiword expression, we require patterns to start and to end with a HFW. Thus a minimal pattern is of the form [HFW] [CW slot] [HFW]. For each sentence it is possible to generate dozens of different patterns that may overlap. As with words and n-gram features, we do not treat as features any patterns which appear in less than 0.5% of the training set sentences.

Since each feature vector is based on a single sentence (tweet), we would like to allow approximate pattern matching for enhancement of learning flexibility. The value of a pattern feature is estimated according the one of the following four scenarios[3]:

$$\begin{cases} \frac{1}{count(p)}: & \text{Exact match – all the pattern components appear in the sentence in correct order without any additional words.} \\ \frac{\alpha}{count(p)}: & \text{Sparse match – same as exact match but additional non-matching words can be inserted between pattern components.} \\ \frac{\gamma * n}{N * count(p)}: & \text{Incomplete match – only } n > 1 \text{ of } N \text{ pattern components appear in the sentence, while some non-matching words can be inserted in-between. At least one of the appearing components should be a HFW.} \\ 0: & \text{No match – nothing or only a single pattern component appears in the sentence.} \end{cases}$$

$0 \leq \alpha \leq 1$ and $0 \leq \gamma \leq 1$ are parameters we use to assign reduced scores for imperfect matches. Since the patterns we use are relatively long, exact matches are uncommon, and taking advantage of partial matches allows us to significantly reduce the sparsity of the feature vectors. We used $\alpha = \gamma = 0.1$ in all experiments.

This pattern based framework was proven efficient for sarcasm detection in (Tsur et al., 2010;

[2]Note that the F_H and F_C bounds allow overlap between some HFWs and CWs. See (Davidov and Rappoport, 2008) for a short discussion.

[3]As with word and n-gram features, the maximal feature weight of a pattern p is defined as the inverse count of a pattern in the complete Twitter corpus.

Davidov et al., 2010).

3.1.3 Efficiency of feature selection

Since we avoid selection of textual features which have a training set frequency below 0.5%, we perform feature selection incrementally, on each stage using the frequencies of the features obtained during the previous stages. Thus first we estimate the frequencies of single words in the training set, then we only consider creation of n-grams from single words with sufficient frequency, finally we only consider patterns composed from sufficiently frequent words and n-grams.

3.1.4 Punctuation-based features

In addition to pattern-based features we used the following generic features: (1) Sentence length in words, (2) Number of "!" characters in the sentence, (3) Number of "?" characters in the sentence, (4) Number of quotes in the sentence, and (5) Number of capitalized/all capitals words in the sentence. All these features were normalized by dividing them by the (maximal observed value *times* averaged maximal value of the other feature groups), thus the maximal weight of each of these features is equal to the averaged weight of a single pattern/word/n-gram feature.

3.2 Classification algorithm

In order to assign a sentiment label to new examples in the test set we use a k-nearest neighbors (kNN)-like strategy. We construct a feature vector for each example in the training and the test set. We would like to assign a sentiment class to each example in the test set. For each feature vector V in the test set, we compute the Euclidean distance to each of the matching vectors in the training set, where matching vectors are defined as ones which share at least one pattern/n-gram/word feature with v.

Let $t_i, i = 1 \ldots k$ be the k vectors with lowest Euclidean distance to v[4] with assigned labels $L_i, i = 1 \ldots k$. We calculate the mean distance $d(t_i, v)$ for this set of vectors and drop from the set up to five outliers for which the distance was more then twice the mean distance. The label assigned to v is the label of the majority of the remaining vectors.

If a similar number of remaining vectors have different labels, we assigned to the test vector the most frequent of these labels according to their frequency in the dataset. If there are no matching vectors found for v, we assigned the default "no sentiment" label since there is significantly more non-sentiment sentences than sentiment sentences in Twitter.

4 Twitter dataset and sentiment tags

In our experiments we used an extensive Twitter data collection as training and testing sets. In our training sets we utilize sentiment hashtags and smileys as classification labels. Below we describe this dataset in detail.

4.1 Twitter dataset

We have used a Twitter dataset generously provided to us by Brendan O'Connor. This dataset includes over 475 million tweets comprising roughly 15% of all public, non-"low quality" tweets created from May 2009 to Jan 2010. Tweets are short sentences limited to 140 UTF-8 characters. All non-English tweets and tweets which contain less than 5 proper English words[5] were removed from the dataset.

Apart of simple text, tweets may contain URL addresses, references to other Twitter users (appear as @<user>) or a content tags (also called *hashtags*) assigned by the tweeter (#<tag>) which we use as labels for our supervised classification framework.

Two examples of typical tweets are: *"#ipad #sucks and 6,510 people agree. See more on Ipad sucks page: http://j.mp/4OiYyg?"*, and *"Pay no mind to those who talk behind ur back, it simply means that u're 2 steps ahead. #ihatequotes"*. Note that in the first example the hashtagged words are a grammatical part of the sentence (it becomes meaningless without them) while *#ihatequotes* of the second example is a mere sentiment label and not part of the sentence. Also note that hashtags can be composed of multiple words (with no spaces).

[4] We used $k = 10$ for all experiments.

[5] Identification of proper English words was based on an available WN-based English dictionary

Category	# of tags	% agreement
Strong sentiment	52	87
Likely sentiment	70	66
Context-dependent	110	61
Focused	45	75
No sentiment	3564	99

Table 1: Annotation results (2 judges) for the 3852 most frequent tweeter tags. The second column displays the average number of tags, and the last column shows % of tags annotated similarly by two judges.

During preprocessing, we have replaced URL links, hashtags and references by URL/REF/TAG meta-words. This substitution obviously had some effect on the pattern recognition phase (see Section 3.1.2), however, our algorithm is robust enough to overcome this distortion.

4.2 Hashtag-based sentiment labels

The Twitter dataset contains above 2.5 million different user-defined hashtags. Many tweets include more than a single tag and 3852 "frequent" tags appear in more than 1000 different tweets. Two human judges manually annotated these frequent tags into five different categories: 1 – strong sentiment (e.g *#sucks* in the example above), 2 – most likely sentiment (e.g., *#notcute*), 3 – context-dependent sentiment (e.g., *#shoutsout*), 4 – focused sentiment (e.g., *#tmobilesucks* where the target of the sentiment is part of the hashtag), and 5 – no sentiment (e.g. *#obama*). Table 1 shows annotation results and the percentage of similarly assigned values for each category.

We selected 50 hashtags annotated "1" or "2" by both judges. For each of these tags we automatically sampled 1000 tweets resulting in 50000 labeled tweets. We avoided sampling tweets which include more than one of the sampled hashtags. As a no-sentiment dataset we randomly sampled 10000 tweets with no hashtags/smileys from the whole dataset assuming that such a random sample is unlikely to contain a significant amount of sentiment sentences.

4.3 Smiley-based sentiment labels

While there exist many "official" lists of possible ASCII smileys, most of these smileys are infrequent or not commonly accepted and used as sentiment indicators by online communities. We used the Amazon Mechanical Turk (AMT) service in order to obtain a list of the most commonly used and unambiguous ASCII smileys. We asked each of ten AMT human subjects to provide at least 6 commonly used ASCII mood-indicating smileys together with one or more single-word descriptions of the smiley-related mood state. From the obtained list of smileys we selected a subset of 15 smileys which were (1) provided by at least three human subjects, (2) described by at least two human subject using the same single-word description, and (3) appear at least 1000 times in our Twitter dataset. We then sampled 1000 tweets for each of these smileys, using these smileys as sentiment tags in the sentiment classification framework described in the previous section.

5 Evaluation and Results

The purpose of our evaluation was to learn how well our framework can identify and distinguish between sentiment types defined by tags or smileys and to test if our framework can be successfully used to identify sentiment types in new untagged sentences.

5.1 Evaluation using cross-validation

In the first experiment we evaluated the consistency and quality of sentiment classification using cross-validation over the training set. Fully automated evaluation allowed us to test the performance of our algorithm under several different feature settings: *Pn+W-M-Pt-*, *Pn+W+M-Pt-*, *Pn+W+M+Pt-*, *Pn-W-M-Pt+* and *FULL*, where $+/-$ stands for utilization/omission of the following feature types: *Pn*:punctuation, *W*:Word, *M*:n-grams (M stands for 'multi'), *Pt*:patterns. *FULL* stands for utilization of all feature types.

In this experimental setting, the training set was divided to 10 parts and a 10-fold cross validation test is executed. Each time, we use 9 parts as the labeled training data for feature selection and construction of labeled vectors and the remaining part is used as a test set. The process was repeated ten times. To avoid utilization of labels as strong features in the test set, we removed all instances of involved label hashtags/smileys from the tweets used as the test set.

Setup	Smileys	Hashtags
random	0.06	0.02
Pn+W-M-Pt-	0.16	0.06
Pn+W+M-Pt-	0.25	0.15
Pn+W+M+Pt-	0.29	0.18
Pn-W-M-Pt+	0.5	0.26
FULL	0.64	0.31

Table 2: Multi-class classification results for smileys and hashtags. The table shows averaged harmonic f-score for 10-fold cross validation. 51 (16) sentiment classes were used for hashtags (smileys).

Hashtags	Avg	#hate	#jealous	#cute	#outrageous
Pn+W-M-Pt-	0.57	0.6	0.55	0.63	0.53
Pn+W+M-Pt-	0.64	0.64	0.67	0.66	0.6
Pn+W+M+Pt-	0.69	0.66	0.67	0.69	0.64
Pn-W-M-Pt+	0.73	0.75	0.7	0.69	0.69
FULL	0.8	0.83	0.76	0.71	0.78
Smileys	Avg	:)	;)	$X($	$: d$
Pn+W-M-Pt-	0.64	0.66	0.67	0.56	0.65
Pn+W+M-Pt-	0.7	0.73	0.72	0.64	0.69
Pn+W+M+Pt-	0.7	0.74	0.75	0.66	0.69
Pn-W-M-Pt+	0.75	0.78	0.75	0.68	0.72
FULL	0.86	0.87	0.9	0.74	0.81

Table 3: Binary classification results for smileys and hashtags. *Avg* column shows averaged harmonic f-score for 10-fold cross validation over *all* 50(15) sentiment hashtags (smileys).

Multi-class classification. Under multi-class classification we attempt to assign a single label (51 labels in case of hashtags and 16 labels in case of smileys) to each of vectors in the test set. Note that the random baseline for this task is 0.02 (0.06) for hashtags (smileys). Table 2 shows the performance of our framework for these tasks.

Results are significantly above the random baseline and definitely nontrivial considering the equal class sizes in the test set. While still relatively low (0.31 for hashtags and 0.64 for smileys), we observe much better performance for smileys which is expected due to the lower number of sentiment types.

The relatively low performance of hashtags can be explained by ambiguity of the hashtags and some overlap of sentiments. Examination of classified sentences reveals that many of them can be reasonably assigned to more than one of the available hashtags or smileys. Thus a tweet *"I'm reading stuff that I DON'T understand again! hahaha...wth am I doing"* may reasonably match tags #sarcasm, #damn, #haha, #lol, #humor, #angry etc. Close examination of the incorrectly classified examples also reveals that substantial amount of tweets utilize hashtags to explicitly indicate the specific hashtagged sentiment, in these cases that no sentiment value could be perceived by readers unless indicated explicitly, e.g. *"De Blob game review posted on our blog. #fun"*. Obviously, our framework fails to process such cases and captures noise since no sentiment data is present in the processed text labeled with a specific sentiment label.

Binary classification. In the binary classification experiments, we classified a sentence as either appropriate for a particular tag or as not bearing any sentiment[6]. For each of the 50 (15) labels for hashtags (smileys) we have performed a binary classification when providing as training/test sets only positive examples of the specific sentiment label together with non-sentiment examples. Table 3 shows averaged results for this case and specific results for selected tags. We can see that our framework successfully identifies diverse sentiment types. Obviously the results are much better than those of multi-class classification, and the observed > 0.8 precision confirms the usefulness of the proposed framework for sentiment classification of a variety of different sentiment types.

We can see that even for binary classification settings, classification of smiley-labeled sentences is a substantially easier task compared to classification of hashtag-labeled tweets. Comparing the contributed performance of different feature types we can see that punctuation, word and pattern features, each provide a substantial boost for classification quality while we observe only a marginal boost when adding n-grams as classification features. We can also see that pattern features contribute the performance more than all other features together.

5.2 Evaluation with human judges

In the second set of experiments we evaluated our framework on a test set of unseen and untagged tweets (thus tweets that were not part of the train-

[6]Note that this is a useful application in itself, as a filter that extracts sentiment sentences from a corpus for further focused study/processing.

ing data), comparing its output to tags assigned by human judges. We applied our framework with its FULL setting, learning the sentiment tags from the training set for hashtags and smileys (separately) and executed the framework on the reduced Tweeter dataset (without untagged data) allowing it to identify at least five sentences for each sentiment class.

In order to make the evaluation harsher, we removed all tweets containing at least one of the relevant classification hashtags (or smileys). For each of the resulting 250 sentences for hashtags, and 75 sentences for smileys we generated an 'assignment task'. Each task presents a human judge with a sentence and a list of ten possible hashtags. One tag from this list was provided by our algorithm, 8 other tags were sampled from the remaining 49 (14) available sentiment tags, and the tenth tag is from the list of frequent non-sentiment tags (e.g. *travel* or *obama*). The human judge was requested to select the 0-2 most appropriate tags from the list. Allowing assignment of multiple tags conforms to the observation that even short sentences may express several different sentiment types and to the observation that some of the selected sentiment tags might express similar sentiment types.

We used the Amazon Mechanical Turk service to present the tasks to English-speaking subjects. Each subject was given 50 tasks for Twitter hashtags or 25 questions for smileys. To ensure the quality of assignments, we added to each test five manually selected, clearly sentiment bearing, assignment tasks from the tagged Twitter sentences used in the training set. Each set was presented to four subjects. If a human subject failed to provide the intended "correct" answer to at least two of the control set questions we reject him/her from the calculation. In our evaluation the algorithm is considered to be correct if one of the tags selected by a human judge was also selected by the algorithm. Table 4 shows results for human judgement classification. The agreement score for this task was $\kappa = 0.41$ (we consider agreement when at least one of two selected items are shared).

Table 4 shows that the majority of tags selected by humans matched those selected by the algorithm. Precision of smiley tags is substantially higher than of hashtag labels, due to the lesser number of possible smileys and the lesser ambiguity of smileys in comparison to hashtags.

Setup	% Correct	% No sentiment	Control
Smileys	84%	6%	92%
Hashtags	77%	10%	90%

Table 4: Results of human evaluation. The second column indicates percentage of sentences where judges find no appropriate tags from the list. The third column shows performance on the control set.

Hashtags	#happy	#sad	#crazy	# bored
#sad	0.67	-	-	-
#crazy	0.67	0.25	-	-

Table 5: Percentage of co-appearance of tags in tweeter corpus.

5.3 Exploration of feature dependencies

Our algorithm assigns a single sentiment type for each tweet. However, as discussed above, some sentiment types overlap (e.g., *#awesome* and *#amazing*). Many sentences may express several types of sentiment (e.g., *#fun* and *#scary* in *"Oh My God http://goo.gl/fb/K2N5z #entertainment #fun #pictures #photography #scary #teaparty"*). We would like to estimate such inter-sentiment dependencies and overlap automatically from the labeled data. We use two different methods for overlap estimation: tag co-occurrence and feature overlap.

5.3.1 Tag co-occurrence

Many tweets contain more than a single hashtag or a single smiley type. As mentioned, we exclude such tweets from the training set to reduce ambiguity. However such tag co-appearances can be used for sentiment overlap estimation. We calculated the relative co-occurrence frequencies of some hashtags and smileys. Table 5 shows some of the observed co-appearance ratios. As expected some of the observed tags frequently co-appear with other similar tags.

Hashtags	#happy	#sad	#crazy	# bored
#sad	12.8	-	-	-
#crazy	14.2	3.5	-	-
#bored	2.4	11.1	2.1	-
#fun	19.6	2.1	15	4.4
Smileys	:)	;)	:(	$X($
;)	35.9	-	-	-
:(	31.9	10.5	-	-
$X($	8.1	10.2	36	-
$:S$	10.5	12.6	21.6	6.1

Table 6: Percentage of shared features in feature vectors for different tags.

Interestingly, it appears that a relatively high ratio of co-appearance of tags is with opposite meanings (e.g., *"#ilove eating but #ihate feeling fat lol"* or *"happy days of training going to end in a few days #sad #happy"*). This is possibly due to frequently expressed contrast sentiment types in the same sentence – a fascinating phenomena reflecting the great complexity of the human emotional state (and expression).

5.3.2 Feature overlap

In our framework we have created a set of feature vectors for each of the Twitter sentiment tags. Comparison of shared features in feature vector sets allows us to estimate dependencies between different sentiment types even when direct tag co-occurrence data is very sparse. A feature is considered to be shared between two different sentiment labels if for both sentiment labels there is at least a single example in the training set which has a positive value of this feature. In order to automatically analyze such dependencies we calculate the percentage of shared Word/n-gram/Pattern features between different sentiment labels. Table 6 shows the observed feature overlap values for selected sentiment tags.

We observe the trend of results obtained by comparison of shared feature vectors is similar to those obtained by means of label co-occurrence, although the numbers of the shared features are higher. These results, demonstrating the pattern-based similarity of conflicting, sometimes contradicting, emotions are interesting from a psychological and cognitive perspective.

6 Conclusion

We presented a framework which allows an automatic identification and classification of various sentiment types in short text fragments which is based on Twitter data. Our framework is a supervised classification one which utilizes Twitter hashtags and smileys as training labels. The substantial coverage and size of the processed Twitter data allowed us to identify dozens of sentiment types without any labor-intensive manually labeled training sets or pre-provided sentiment-specific features or sentiment words.

We evaluated diverse feature types for sentiment extraction including punctuation, patterns, words and n-grams, confirming that each feature type contributes to the sentiment classification framework. We also proposed two different methods which allow an automatic identification of sentiment type overlap and inter-dependencies.

In the future these methods can be used for automated clustering of sentiment types and sentiment dependency rules. While hashtag labels are specific to Twitter data, the obtained feature vectors are not heavily Twitter-specific and in the future we would like to explore the applicability of Twitter data for sentiment multi-class identification and classification in other domains.

Abstract

Recent work on distributional methods for similarity focuses on using the context in which a target word occurs to derive context-sensitive similarity computations. In this paper we present a method for computing similarity which builds vector representations for words *in context* by modeling senses as latent variables in a large corpus. We apply this to the Lexical Substitution Task and we show that our model significantly outperforms typical distributional methods.

1 Introduction

Distributional methods for word similarity ((Landauer and Dumais, 1997), (Schuetze, 1998)) are based on co-occurrence statistics extracted from large amounts of text. Typically, each word is assigned a representation as a point in a high-dimensional space, where the dimensions represent contextual features such as co-occurring words. Following this, meaning relatedness scores are computed by using various similarity measures on the vector representations.

One of the major issues that all distributional methods have to face is sense ambiguity. Since vector representations reflect *mixtures of uses* additional methods have to be employed in order to capture specific meanings of a word in context. Consider the occurrence of verb *shed* in the following SemEval 2007 Lexical Substitution Task (McCarthy and Navigli, 2007) example:

Cats in the latent phase only have the virus internally , but feel normal and do not ***shed*** *the virus to other cats and the environment .*

Human participants in this task provided words such as *transmit* and *spread* as good substitutes for *shed* in this context, however a vector space representation of *shed* will not capture this infrequent sense.

For these reasons, recent work on distributional methods for similarity such as (Mitchell and Lapata, 2008) (Erk and Padó, 2008) (Thater et al., 2009) focuses on using the context in which a target word occurs to derive context-sensitive similarity computations.

In this paper we present a method for computing similarity which builds vector representations for words *in context*. Most distributional methods so far extract representations from large texts, and only as a follow-on step they either 1) alter these in order to reflect a *disambiguated* word (such as (Erk and Padó, 2008)) or 2) directly asses the appropriateness of a similarity judgment, given a specific context (such as (Pantel et al., 2007)). Our approach differs from this as we assume ambiguity of words at the, initial, acquisition step, by encoding senses of words as a hidden variable in the text we process.

In this paper we focus on a particular distributional representation inspired by (Lin and Pantel, 2001a) and induce context-sensitive similarity between phrases represented as paths in dependency graphs. It is inspired by recent work on topic models and it deals with sense-ambiguity in a natural manner by modeling senses as latent variables in a large corpus. We apply this to the Lexical Substitution Task and we show that our model outperforms the (Lin and Pantel, 2001a) method by inducing context-appropriate similarity judgments.

2 Related work

Discovery of Inference Rules from Text (DIRT) A popular distributional method for meaning relatedness is the DIRT algorithm for extracting inference rules (Lin and Pantel, 2001a). In this algorithm a $pattern$ is a noun-ending path in a dependency graph and the goal is to acquire pairs of patterns for which entailment holds (in at least one direction) such as *(X solve Y, X find solution to Y)*.

The method can be seen a particular instance of a vector space. Each pattern is represented by the sets of its left hand side (X) and right hand side (Y) noun fillers in a large corpus. Two patterns are compared in the X-filler space, and correspondingly in the Y-filler space by using the Lin similarity measure:

$$\mathrm{sim}_{\mathrm{Lin}}(v, w) = \frac{\sum_{i \in I(v) \cap I(w)} (v_i + w_i)}{\sum_{i \in I(v)} v_i + \sum_{l \in I(w)} w_i}$$

where values in v and w are point-wise mutual information, and $I(\cdot)$ gives the indices of positive values in a vector.

The final similarity score between two patterns is obtained by multiplying the X and Y similarity scores. Table 1 shows a fragment of a DIRT-like vector space.

	..	*case*	*problem*	..
(*X solve Y,* ***Y***)	..	6.1	4.4	..
(*X settle Y,* ***Y***)	..	5.2	5.9	..

Table 1: DIRT-like vector representation in the **Y**-filler space. The values represent mutual information.

Further on, this similarity method is used for the task of paraphrasing. A total set of patterns is extracted from a large corpus and each of them can be paraphrased by returning its most similar patterns, according to the similarity score. Although relatively accurate[1], it has been noted (Lin and Pantel, 2001b) that the paraphrases extracted this way reflect, as expected, various meanings, and that a context-sensitive representation would be appropriate.

[1]Precision is estimated to lie around 50% for the most confident paraphrases

Context-sensitive extensions of DIRT (Pantel et al., 2007) and (Basili et al., 2007) focus on making DIRT rules context-sensitive by attaching appropriate semantic classes to the X and Y slots of an inference rule. For this purpose, the initial step in their methods is to acquire an inference rule database, using the DIRT algorithm. Following this, given an inference rule, they identify semantic classes for the X and Y fillers which make the application of the rule appropriate. For this (Pantel et al., 2007) build a set of semantic classes using WordNet in one case and CBC clustering algorithm in the other; for each rule, they use the overlap of the fillers found in the input corpus as an indicator of the correct semantic classes. The same idea is used in (Basili et al., 2007) where, this time, the X and Y fillers are clustered for each rule individually; these nouns are clustered using an LSA-vector representation extracted from a large corpus.

(Connor and Roth, 2007) take a slightly different approach as they attempt to classify the context of a rule as appropriate or not, again using the overlap of fillers as an indicator. They all show improvement over DIRT by evaluating on occurrences of rules in context which are annotated as correct/incorrect by human participants. On a common data set (Pantel et al., 2007) and (Basili et al., 2007) achieve significant improvements over DIRT at 95% confidence level when employing the clustering methods. (Szpektor et al., 2008) propose a general framework for these methods and show that some of these settings obtain significant (level 0.01) improvements over the DIRT algorithm on data derived from the ACE 2005 event detection task.

Related work on topic models Topic models have been previously used for semantic tasks. Work such as (Cai et al., 2007) or (Boyd-Graber et al., 2007) use the document-level topics extracted with Latent Dirichlet Allocation (LDA) as indicators of meanings for word sense disambiguation. More related to our work are (Brody and Lapata, 2009) or (Toutanova and Johnson, 2008) who use LDA-based models which induce latent variables from task-specific data rather than from simple documents.

(Brody and Lapata, 2009) apply such a model for word sense induction on a set of 35 target nouns. They assume senses as latent variables and context features as observations; unlike our model they induce local senses specific to every target word by estimating separate models with the final goal of explicitly inducing word senses.

(Toutanova and Johnson, 2008) use an LDA-based model for semi-supervised part-of-speech tagging. They build a word context model in which each token involves: generating a distribution over tags, sampling a tag, and finally generating context words according to a tag-specific word distribution (context words are observations). Their model achieves highest performance when combined with a ambiguity class component which uses a dictionary for possible tags of target words.

Both these papers show improvements over state-of-the-art systems for their tasks.

3 Generative model for similarity in context

We develop a method for computing similarity of patterns in context, i.e. patterns with instantiated X and Y values. We do not enhance the representation of an inference rule with sense (context-appropriateness) information but rather focus on the task of assigning similarity scores to such pairs of *instantiated* patterns. Unlike previous work, we do not employ any other additional resources, investigating this way whether structurally richer information can be learned from the same input co-occurrence matrix as the original DIRT method.

Our model, as well as the DIRT algorithm, uses *context* information extracted from large corpora to learn similarities between *patterns*; however ideally we would like to learn contextual preferences (or, in general, some form of sense-disambiguation) for these patterns. This is achieved in our model by assuming an intermediate layer consisting of *meanings* (senses): the *context* surrounding a pattern is indicative of *meanings*, and preference for some *meanings* gives the characterization of a *pattern*.

For this we use a generative model inspired by Latent Dirichlet Allocation (Blei et al., 2003) (Griffiths and Steyvers, 2004) which is successfully employed for modeling collections of documents and the underlying topics which occur in them. The statistical model is characterized by the following distributions:

$w_i \vert z_i, \phi^{z_i}$	$Discrete(\phi^{z_i})$
ϕ^z	$Dirichlet(\beta)$
$z_i \vert \theta^p$	$Discrete(\theta^p)$
θ^p	$Dirichlet(\alpha)$

θ^p is the distribution over meanings associated to a pattern p and ϕ^z is the distribution over words associated to a meaning z. The occurrence of each filler word w_i with a pattern p, is then generated by sampling 1) a meaning conditioned on the meaning distribution associated to p: $z_i|\theta^p$ and 2) a word conditioned on the word distribution associated to the meaning z_i: $w_i|z_i, \phi^{z_i}$. θ^p and ϕ^z are assumed to be Dirichlet distributions with parameters α and β.

The set of context words (X and Y fillers) occurring with a pattern p form the *document* (in LDA terms) associated to a pattern p. Table 2 lists a fragment of the document associated to pattern *X solve Y*. These are built simply by listing for each pattern, occurrence counts with specific filler words. Since we want our model to differentiate between X and Y fillers, words occurring as fillers are made disjoint by adding a corresponding suffix.

X solve Y
we-X:122, country-X:89, government-X:82, it-X:69,..., problem-Y:1088, issue-Y:134, crisis-Y:99, dispute-Y:78,...

Table 2: Fragments of the *document* associated to *X solve Y*. *we-X: 122* indicates that *X solve Y* occurs 122 times with we as an X filler.

The total set of such *documents* extracted from a large corpus is then used for estimating the model. We use Gibbs sampling[2] and the result is a set of samples from $P(z|w)$ (i.e. meaning assignments for each occurring filler word) from which θ^p (pattern-meaning distributions) and ϕ^z(meaning-word distributions) can be estimated.

Our model has the advantage that, once these

[2] *http://gibbslda.sourceforge.net/*

distributions are estimated, given a pattern p and a context w_n, *in-context* vector representations can be built in a straightforward manner.

Meaning representation in-context Let K be the assumed number of meanings, $(z_1, ..., z_K)$. We associate to a pattern in context (p,w_n), the ***K***-dimensional vector containing for each meaning z_i ($i : 1..K$), the probability of z_i, conditioned on pattern p and context word w_n:

$$vec(p, w_n) = (P(z_1|w_n, p), ..., P(z_K|w_n, p)) \quad (1)$$

where,

$$P(z_i|w_n, p) = \frac{P(z_i, p)P(w_n|z_i)}{\Sigma_{i=1}^{K} P(z_i, p)P(w_n|z_i)} \quad (2)$$

This is the probability that w_n is generated by meaning z_i conditioned on p, therefore, the probability that pattern p has meaning z_i in context w_n, exactly the concept we want to model.

Meaning representation out-of-context We can also associate to pattern p an *out-of-context* vector representation: the ***K***-dimensional vector representing its distribution over meanings:

$$vec(p) = (P(z_1|p), ..., P(z_K|p)) \quad (3)$$

This can be seen as a dimensionality reduction method, since we bring vector representations to a lower dimensional space over (ideally) meaningful concepts.

From the generative model we obtain the desired distributions $P(z_i|p) = \theta_i^p$ and $P(w_n|z_i) = \phi_n^{z_i}$.[3]

Computing similarity between patterns The similarity between patterns occurring with X and Y filler-words is computed following (Lin and Pantel, 2001a) by multiplying the similarities obtained separately in the X and Y spaces.:

$$\begin{aligned} sim((w_{X1}, p_1, w_{Y1})(w_{X2}, p_2, w_{Y2})) = \\ sim(vec(p_1, w_{X1}), vec(p_2, w_{X2}))* \\ sim(vec(p_1, w_{Y1}), vec(p_2, w_{Y2})) \end{aligned} \quad (4)$$

[3]For similarity in context, we use the conditional $P(z_i|p)$ instead of the joint $P(z_i, p)$ which is computationally equivalent for the paraphrasing setting.

$we \xleftarrow{subj} make \xrightarrow{dobj} statement$	
$we \xleftarrow{subj} give \xrightarrow{dobj} statement$	*good*
$we \xleftarrow{subj} prepare \xrightarrow{dobj} statement$	*bad*

Table 3: Development set: good/bad substitutes for $we \xleftarrow{subj} make \xrightarrow{dobj} statement$

Out-of-context similarity is defined in a straightforward manner:

$$sim(p_1, p_2) = sim(vec(p_1,), vec(p_2)) \quad (5)$$

4 Evaluation setup

In this paper we evaluate our model on computing similarities between pairs of the type $(X, pattern, Y), (X, pattern', Y)$ where two different patterns are compared in identical contexts. For this we use the Semeval Lexical Substitution dataset, which requires human participants to provide substitutes for a set of target words occurring in different contexts. This section describes the evaluation methodology for this data as well as the automatically generated data set we use for development.

Development set For finding good model parameters, we use the SemCor corpus providing text in which all content words are tagged with WordNet 1.6 senses. We used this data in the following manner: We parse the text using Stanford parser and extract occurrences of triples *(X, pattern, Y)*. Given these triples we generate *good* and *bad* substitutes for them: the *good* substitutes are generated by replacing the words occurring in the patterns with sense-appropriate synonyms, while *bad* ones are obtained by substitution with synonyms corresponding to the rest of the senses (the wrong senses). The synonyms are extracted from WordNet 1.6 synsets using the sense annotation present in the text.

For evaluation we feed the models pairs of instantiated patterns. One of them is the original phrase encountered in the data, and the other one is a *good/bad* substitute for it. Table 3 shows an example of the data.

We evaluate the output of a system by requiring that, for each instance, every good substitute is scored more similar to the original phrase than

every bad substitute. This leads to an accuracy score which can be compared against a random baseline of 50%.

The data set obtained is far from being a very reliable resource for the task of lexical substitution, however this method of generating data has the advantage of producing a large number of instances which can be easily acquired from any sense-annotated data set. In our experiments we use the Brown2 fragment from which we extract over 3000 instances of patterns in context.

Lexical substitution task The Lexical Substitution Task (McCarthy and Navigli, 2007) presents 5 annotators with a set of target words, each in different context sentences. The task requires the participants to provide appropriate substitute words for each occurrence of the target words.

We use this data similarly to (Erk and Padó, 2008) and (Thater et al., 2009) and for each target word, we pool together all the substitutes given for *all* context sentences. Similarly to the SemCor data, we do not use the entire sentence as a context as we extract only *patterns* containing target words together with their X and Y fillers. The models assign similarity scores to each candidate by comparing them to the pattern occurring in the original sentence. A ranked list of candidates is obtained which in turn is compared with the substitutes provided by the participants. Table 4 gives an example of this data set (for each substitute we list the number of participants providing it).

To evaluate the performance of a model we employ two similarity measures, which capture different aspects of the task. Kendall τ rank coefficient measures the correlation between two ranks; since the gold ranking is usually only a partial order, we use τ_b which makes adjustments for ties. We employ a second evaluation measure: Generalized Average Precision (Kishida, 2005). This is a measure inspired from information retrieval and has been previously used for evaluating this task (Thater et al., 2009). It evaluates a system on its ability to retrieve correct substitutes using the gold ranking together with the associated confidence scores. The confidence scores are in turn determined by the number of people providing each substitute.

pattern	*human substitutes*
$study \xleftarrow{subj} shed \xrightarrow{dobj} light$	throw 3, reveal 2, shine 1
$cat \xleftarrow{subj} shed \xrightarrow{dobj} virus$	spread 2, pass 2, transmit 2, emit 1

Table 4: Lexical substitution data set: target verb *shed*

5 Experiments

5.1 Model selection

The data we use to estimate our models is extracted from a GigaWord fragment containing approximately 100 million tokens. We parse the text with Stanford dependency parser to obtain dependency graphs from which we extract paths together with counts of their left and right fillers. We extract paths containing at most four words, including the two noun anchors. Furthermore we impose a frequency threshold on patterns and words, leading us to a collection of ≈80 000 paths, with filler nouns over a vocabulary of ≈40 000 words.

We estimate a total number of 20 models. We set $\beta = 0.01$ as previous work (Wang et al., 2009) reports good results with this value. For parameter α we test 4 settings: $\alpha_1 = \frac{2}{K}$ and $\alpha_4 = \frac{50}{K}$ which are reported in the literature as good ((Porteous et al., 2008) and (Griffiths and Steyvers, 2004)), as well as 2 intermediate values: $\alpha_2 = \frac{5}{K}$ and $\alpha_3 = \frac{10}{K}$. We test a set of 5 K values: $\{800, 1000, 1200, 1400, 1600\}$. These are chosen to be large since they represent the global set of meanings shared by all the patterns in the collection.

As vector similarity measure we test scalar product (*sp*), which in our model is interpreted as the probability that two patterns share a common meaning. Additionally we test cosine (cos) similarity and inverse Jensen-Shannon (JS) divergence, which is a popular measure for comparing probability distributions:

$$JSD(v, w) = \frac{1}{2}KLD(v|m) + \frac{1}{2}KLD(w|m)$$

with $m = \frac{1}{2}(v + w)$ and KLD the standard Kullback-Leibler divergence: $KLD(v|w) = \Sigma_i v_i log(\frac{v_i}{w_i})$.

We perform both in-context (using eq. (4)) as well as out-of-context computations (eq. (5)). Similarly to previous work (Erk and Padó, 2008), we observe that comparing a contextualized representation against a non-contextualized one brings significant improvements over comparing two representations in context. We assume this is specific to the type of data we work with, in which two patterns are compared in an identical context, rather than across different contexts; we therefore compute context-sensitive similarities by contextualizing just the target word.

Number of topics Although the parameters cover relatively large ranges the models perform surprisingly similar across different α and K values, as well as across all three similarity measures. For sp similarity, the accuracy scores we obtain are in the range [56.5-59.5] with a average deviation from the mean of just 0.8%; similar figures are obtained using the other similarity measures. Figure 1 plots the average of the accuracy scores using sp as similarity measure, across different number of topics. A small preference for higher K values is observed, all models performing consistently good at 1200, 1400 and 1600 topics.

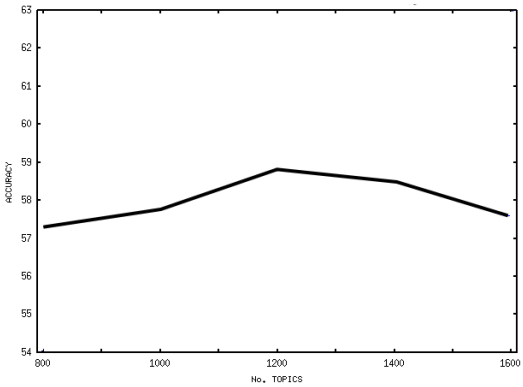

Figure 1: Average accuracy across the 5 K values.

Mixture models This leads us to attempting a very simple mixture model, which computes the similarity score between two patterns as the average similarity obtained across a number of models. For each α setting, we mix models across the three best topic numbers: $\{1200, 1400, 1600\}$. In Figure 2 we plot this mixture model together with the three single ones, at each α value. It can be

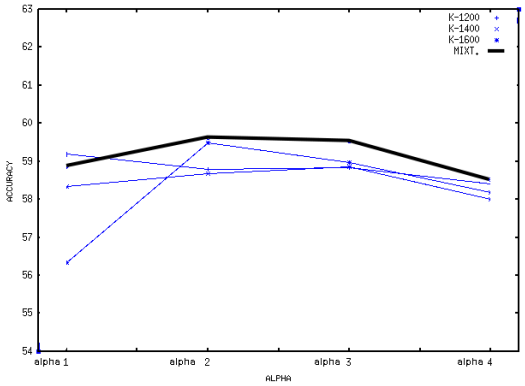

Figure 2: Mixture model $\{1200, 1400, 1600\}$ (bold) vs. the three individual models, across the 4 α values.

noticed that the mixture model improves over all three single models for three out of the four α values.

In-context vs. out-of-context computations Further on we compare *in-context* versus *out-of-context* computations. The similarity measures exhibit significant differences in regard to this aspect. In Figure 3 we plot *in-context* vs. *out-of-context* computations using scalar product (left) and JS (right) with the mixture model previously defined, plotted at different α values. For sp *in-context* computations significantly outperform *out-of-context* ones and the two intermediate alpha values seem to be the best. However for JS similarity the *out-of-context* computations are significantly better and a clear preference for smaller α values can be observed.

Finally, on the test data, we use the following models (where $GM_{mixt/sing,sim}$ stands for a *mixture* or *single* model with similarity measure *sim*):

- $GM_{mixt,sp/cos}$
  mixt($\{1200, 1400, 1600\}$x$\{\alpha_2, \alpha_3\}$)
- $GM_{mixt,js}$
  mixt($\{1200, 1400, 1600\}$x$\{\alpha_1, \alpha_2\}$)
- $GM_{sing,sp}$: (1600, $\alpha 2$)
- $GM_{sing,cos/js}$: (1200, $\alpha 1$)

The mixture models are build based on the observations previously made while the single mod-

Model	*In-context*	*Out-of-context*
$GM_{mixt,sp}$	59.89	58.68
$GM_{mixt,cos}$	59.50	58.67
$GM_{mixt,js}$	59.73	60.68
$GM_{sing,sp}$	59.48	58.86
$GM_{sing,cos}$	59.43	57.87
$GM_{sing,js}$	58.65	59.36

Table 5: Accuracy results on development set

els are the best performing ones, for each similarity measure. The accuracy scores obtained with these models are given in Table 5. Mixture models generally outperform single ones and *in-context* computations outperform *out-of-context* ones for sp and cos. The best results on the development set are however achieved by *out-of-context* models using JS as similarity measure.

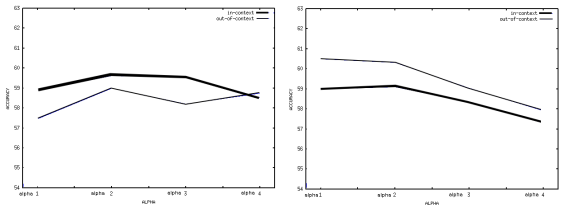

Figure 3: *In-context* (bold) vs. *out-of-context* computations across the 4 α values using scalar product (left) and JS (right)

5.2 Results

Table 6 shows the results for the Lexical Substitution data set. We use the subset of the data containing sentences in which the target word is part of a syntactic path which is present in the total collection of patterns. This leads to a set containing 165 instances of patterns in context, most of these containing target verbs.

Since sp and cos measures perform very similarly we only list results with cosine similarity measure. In addition to the models with settings determined on the development set, we also test a very simple mixture model: $GM_{mixt-all,sim}$. This simply averages over *all* 20 configurations and its purpose is to investigate the necessity of a carefully selected mixture model.

It can be noticed that all GM mixture models outperform DIRT, which is reflected in both

Model	τ_b	GAP
Random	0.0	34.91
DIRT	14.53	48.06
$\mathbf{GM_{mixt,cos}}$	**22.35**	**52.04**
$GM_{mixt,js}$	18.17	50.80
$\mathbf{GM_{mixt-all,cos}}$	**20.42**	**51.13**
$GM_{mixt-all,js}$	19.03	51.15
$GM_{sing,cos}$	15.10	48.20
$GM_{sing,js}$	14.17	47.97

Table 6: Results on Lexical Substitution data

similarity measures. Notably the very simple model which averages all the configurations implemented is surprisingly performant. Using randomized significance testing we obtained that $GM_{mixt,cos}$ is significantly better than DIRT at p level 1e-03 on both GAP and τ_b. $GM_{mixt-all,cos}$ outperforms DIRT at level 0.05.

In terms of similarity measures, the observations made on the development set hold, as for the *in-context* computations cos and sp outperform JS. However, unlike on the development data, the single models perform much worse than the mixture ones which can indicate that the development set is not perfectly suited for choosing model parameters.

Out-of-context computations for all models and all similarity measures are significantly outperformed, leading to scores in ranges [11-14] τ_b and [45-48] GAP.

In Table 7 we list the rankings produced by three models for the target word $shed$ in context $virus \xleftarrow{obj} shed \xrightarrow{prep} to \xrightarrow{pobj} cat$. As it can be observed, the model performing context-sensitive computations $GM_{mixt,cos}$-*in-context* returns a better ranking in comparison to the $DIRT$ and $GM_{mixt,cos}$-*out-of-context* models.

6 Conclusion

We have addressed the task of computing meaning similarity in context using distributional methods. The specific representation we use follows (Lin and Pantel, 2001a): we extract *patterns* (paths in dependency trees which connect two nouns) and we use the co-occurrence with these nouns to build high-dimensional vectors. Using this data

$virus \xleftarrow{obj} shed \xrightarrow{prep} to \xrightarrow{pobj} cat$

$GM_{mixt,cos}$ *in-context*	$GM_{mixt,cos}$ *out-of-context*	$DIRT$	GOLD	
lose	*lose*	*drop*	pass	2
drop	*drop*	*lose*	spread	2
transmit	*relinquish*	*give*	transmit	2
spread	*reveal*	**transmit**

relinquish	*throw*	*reveal*		
reveal	**spread**	*relinquish*		
throw	**transmit**	*throw*		
give	*give*	**pass**		

Table 7: Ranks returned for $virus \xleftarrow{obj} shed \xrightarrow{prep} to \xrightarrow{pobj} cat$

we develop a principled method to induce context-sensitive representations by modeling the *meaning* of a pattern as a latent variable in the input corpus. We apply this model to the task of Lexical Substitution and we show it allows the computation of context-sensitive similarities; it significantly outperforms the original method, while using the exact same input data.

In future work, we plan to use our model for generating paraphrases for patterns occurring in context, a scenario closer to real applications than *out-of-context* paraphrasing.

Finally, a formulation of our model in a typical bag-of-words semantic space for word similarity can be employed in a wider range of applications and will allow comparison with other methods for building context-sensitive vector representations.

Recognizing Medication related Entities in Hospital Discharge Summaries using Support Vector Machine

Son Doan and **Hua Xu**
Department of Biomedical Informatics
School of Medicine, Vanderbilt University

Abstract

Due to the lack of annotated data sets, there are few studies on machine learning based approaches to extract named entities (NEs) in clinical text. The 2009 i2b2 NLP challenge is a task to extract six types of medication related NEs, including medication names, dosage, mode, frequency, duration, and reason from hospital discharge summaries. Several machine learning based systems have been developed and showed good performance in the challenge. Those systems often involve two steps: 1) recognition of medication related entities; and 2) determination of the relation between a medication name and its modifiers (e.g., dosage). A few machine learning algorithms including Conditional Random Field (CRF) and Maximum Entropy have been applied to the Named Entity Recognition (NER) task at the first step. In this study, we developed a Support Vector Machine (SVM) based method to recognize medication related entities. In addition, we systematically investigated various types of features for NER in clinical text. Evaluation on 268 manually annotated discharge summaries from i2b2 challenge showed that the SVM-based NER system achieved the best F-score of 90.05% (93.20% Precision, 87.12% Recall), when semantic features generated from a rule-based system were included.

1 Introduction

Named Entity Recognition (NER) is an important step in natural language processing (NLP). It has many applications in general language domain such as identifying person names, locations, and organizations. NER is crucial for biomedical literature mining as well (Hirschman, Morgan, & Yeh, 2002; Krauthammer & Nenadic, 2004) and many studies have focused on biomedical entities, such as gene/protein names. There are mainly two types of approaches to identify biomedical entities: rule-based and machine learning based approaches. While rule-based approaches use existing biomedical knowledge/resources, machine learning (ML) based approaches rely much on annotated training data. The advantage of rule-based approaches is that they usually can achieve stable performance across different data sets due to the verified resources, while machine learning approaches often report better results when the training data are good enough. In order to harness the advantages of both approaches, the combination of them, called the hybrid approach, has often been used as well. CRF and SVM are two common machine learning algorithms that have been widely used in biomedical NER (Takeuchi & Collier, 2003; Kazama, Makino, Ohta, & Tsujii, 2002; Yamamoto, Kudo, Konagaya, & Matsumoto, 2003; Torii, Hu, Wu, & Liu, 2009; Li, Savova, & Kipper-Schuler, 2008). Some studies reported better results using CRF (Li, Savova, & Kipper-Schuler, 2008), while others showed that the SVM was better (Tsochantaridis, Joachims, & Hofmann, 2005) in NER. Keerthi & Sundararajan (Keerthi & Sundararajan, 2007) conducted some experiments and demonstrated that CRF and SVM were quite close in performance, when identical feature functions were used.

2 Background

There has been large ongoing effort on processing clinical text in Electronic Medical Records (EMRs). Many clinical NLP systems

Coling 2008: Poster Volume, pages 259–266,
Beijing, August 2010

have been developed, including MedLEE (Friedman, Alderson, Austin, Cimino, & Johnson, 1994), SymTex (Haug et al., 1997), MetaMap (Aronson, 2001). Most of those systems recognize clinical named entities such as diseases, medications, and labs, using rule-based methods such as lexicon lookup, mainly because of two reasons: 1) there are very rich knowledge bases and vocabularies of clinical entities, such as the Unified Medical Language System (UMLS) (Lindberg, Humphreys, & McCray, 1993), which includes over 100 controlled biomedical vocabularies, such as RxNorm, SNOMED, and ICD-9-CM; 2) very few annotated data sets of clinical text are available for machine learning based approaches.

Medication is one of the most important types of information in clinical text. Several studies have worked on extracting drug names from clinical notes. Evans et al. (Evans, Brownlow, Hersh, & Campbell, 1996) showed that drug and dosage phrases in discharge summaries could be identified by the CLARIT system with an accuracy of 80%. Chhieng et al. (Chhieng, Day, Gordon, & Hicks, 2007) reported a precision of 83% when using a string matching method to identify drug names in clinical records. Levin et al. (Levin, Krol, Doshi, & Reich, 2007) developed an effective rule-based system to extract drug names from anesthesia records and map to RxNorm concepts with 92.2% sensitivity and 95.7% specificity. Sirohi and Peissig (Sirohi & Peissig, 2005) studied the effect of lexicon sources on drug extraction. Recently, Xu et al. (Xu et al., 2010) developed a rule-based system for medication information extraction, called MedEx, and reported F-scores over 90% on extracting drug names, dose, route, and frequency from discharge summaries.

Starting 2007, Informatics for Integrating Biology and the Bedside (i2b2), an NIH-funded National Center for Biomedical Computing (NCBC) based at Partners Healthcare System in Boston, organized a series of shared tasks of NLP in clinical text. The 2009 i2b2 NLP challenge was to extract medication names, as well as their corresponding signature information including dosage, mode, frequency, duration, and reason from de-identified hospital discharge summaries (Uzüner, Solti, & Cadag, 2009). At the beginning of the challenge, a training set of 696 notes were provided by the organizers. Among them, 17 notes were annotated by the i2b2 organizers, based on an annotation guideline (see Table 1 for examples of medication information in the guideline), and the rest were un-annotated notes. Participating teams would develop their systems based on the training set, and they were

Class	#	Example	Description
Medication	12773	“Lasix”, “Caltrate plus D”, “fluocinonide 0.5% cream”, “TYLENOL (ACETAMINOPHEN)”	Prescription substances, biological substances, over-the-counter drugs, excluding diet, allergy, lab/test, alcohol.
Dosage	4791	“1 TAB”, “One tablet”, “0.4 mg” “0.5 m.g.”, “100 MG”, “100 mg x 2 tablets”	The amount of a single medication used in each administration.
Mode	3552	“Orally”, “Intravenous”, “Topical”, “Sublingual”	Describes the method for administering the medication.
Frequency	4342	“Prn”, “As needed”, “Three times a day as needed”, “As needed three times a day”, “x3 before meal”, “x3 a day after meal as needed”	Terms, phrases, or abbreviations that describe how often each dose of the medication should be taken.
Duration	597	“x10 days”, “10-day course”, “For ten days”, “For a month”, “During spring break”, “Until the symptom disappears”, “As long as needed”	Expressions that indicate for how long the medication is to be administered.
Reason	1534	“Dizziness”, “Dizzy”, “Fever”, “Diabetes”, “frequent PVCs”, “rare angina”	The medical reason for which the medication is stated to be given.

Table 1.Number of classes and descriptions with examples in i2b2 2009 dataset.

allowed to annotate additional notes in the training set. The test data set included 547clinical notes, from which 251 notes were randomly picked by the organizers. Those 251 notes were then annotated by participating teams, as well as the organizers, and they served as the gold standard for evaluating the performance of systems submitted by participating teams. An example of original text and annotated text were shown in Figure 1.

The results of systems submitted by the participating teams were presented at the i2b2 workshop and short papers describing each system were available at i2b2 web site with protected passwords. Among top 10 systems which achieved the best performance, there were 6 rule-based, 2 machine learning based, and 2 hybrid systems. The best system, which used a machine learning based approach, reached the highest F-score of 85.7% (Patrick & Li, 2009). The second best system, which was a rule-based system using the existing MedEx tool, reported an F-score of 82.1% (Doan, Bastarache L., Klimkowski S., Denny J.C., & Xu, 2009). The difference between those two systems was statistically significant. However, this finding was not very surprising, as the machine learning based system utilized additional 147 annotated notes by the participating team, while the rule-based system mainly used 17 annotated training data to customize the system.

Interestingly, two machine learning systems in the top ten systems achieved very different performance, one (Patrick et al., 2009) achieved an F-score of 85.7%, ranked the first; while another (Li et al., 2009) achieved an F-score of 76.4%, ranked the 10th on the final evaluation. Both systems used CRF for NER, on the equivalent number of training data (145 and 147 notes respectively). The large difference in F-score of those two systems could be due to: the quality of training set, and feature sets using for classification. More recently, i2b2 organizers also reported a Maximum Entropy (ME) based approach for the 2009 challenge (Halgrim, Xia, Solti, Cadag, & Uzuner, 2010). Using the same annotated data set as in (Patrick et al., 2009), they reported an F-score of 84.1%, when combined features such as unigram, word bigrams/trigrams, and label of previous words were used. These results indicated the importance of feature sets used in machine learning algorithms in this task.

For supervised machine learning based systems in the i2b2 challenge, the task was usually divided into two steps: 1) NER of six medication related findings; and 2) determination of the relation between detected medication names and other entities. It is obvious that NER is the first crucial step and it affects the performance of the whole system. However, short papers presented at the i2b2 workshop did not show much detailed evaluation on NER components in machine learning based systems. The variation in performance of different machine learning based systems also motivated us to further investigate the effect of different types of features on recogniz-

ing medication related entities.

In this study, we developed an SVM-based NER system for recognizing medication related entities, which is a sub-task of the i2b2 challenge. We systematically investigated the effects of typical local contextual features that have been reported in many biomedical NER studies. Our studies provided some valuable insights to NER tasks of medical entities in clinical text.

3 Methods

A total of 268 annotated discharge summaries (17 from training set and 251 from test set) from i2b2 challenge were used in this study. This annotated corpus contains 9,689 sentences, 326,474 words, and 27,589 entities. Annotated notes were converted into a BIO format and different types of feature sets were used in an SVM classifier for NER. Performance of the NER system was evaluated using precision, recall, and F-score, based on 10-fold cross validation.

3.1 Preprocessing

The annotated corpus was converted into a BIO format (see an example in Figure 2). Specifically, it assigned each word into a class as follows: **B** means beginning of an entity, **I** means inside an entity, and **O** means outside of an entity. As we have six types of entities, we have six different B classes and six different I classes. For example, for medication names, we define the B class as "B-m", and the I class as "I-m". Therefore, we had total 13 possible classes to each word (including O class).

DISCHARGE			MEDICATION:	
O			**O**	
Additionally,		Percocet	1-2	Tablets
O		**B-m**	**B-do**	**I-do**
p.o.	Q	4	prn,	
B-mo	**B-f**	**I-f**	**I-f**	

Figure 2. An example of the BIO representation of annotated clinical text (Where m as medication, do as dose, mo as mode, and f as frequency).

After preprocessing, the NER problem now can be considered as a classification problem, which is to assigns one of the 13 class labels to each word.

3.2 SVM

Support Vector Machine (SVM) is a machine learning method that is widely used in many NLP tasks such as chunking, POS, and NER. Essentially, it constructs a binary classifier using labeled training samples. Given a set of training samples, the SVM training phrase tries to find the optimal hyperplane, which maximizes the distance of training sample nearest to it (called support vectors). SVM takes an input as a vector and maps it into a feature space using a kernel function.

In this paper we used TinySVM[1] along with Yamcha[2] developed at NAIST (Kudo & Matsumoto, 2000; Kudo & Matsumoto, 2001). We used a polynomial kernel function with the degree of kernel as 2, context window as +/-2, and the strategy for multiple classification as pairwise (one-against-one). Pairwise strategy means it will build K(K-1)/2 binary classifiers in which K is the number of classes (in this case K=13). Each binary classifier will determine whether the sample should be classified as one of the two classes. Each binary classifier has one vote and the final output is the class with the maximum votes. These parameters were used in many biomedical NER tasks such as (Takeuchi & Collier, 2003; Kazama et al., 2002; Yamamoto et al., 2003).

3.3 Features sets

In this study, we investigated different types of features for the SVM-based NER system for medication related entities, including 1) words; 2) Part-of-Speech (POS) tags; 3) morphological clues; 4) orthographies of words; 5) previous history features; 6) semantic tags determined by MedEx, a rule based medication extraction system. Details of those features are described below:

- Words features: Words only. We referred it as a baseline method in this study.
- POS features: Part-of-Speech tags of words. To obtain POS information, we used a POS tagger in the NLTK package[3].

[1] Available at http://chasen.org/~taku/software/TinySVM/

[2] Available at http://chasen.org/~taku/software/YamCha/

[3] www.nltk.org

- Morphologic features: suffix/prefix of up to 3 characters within a word.
- Orthographic features: information about if a word contains capital letters, digits, special characters etc. We used orthographic features described in (Collier, Nobata, & Tsujii, 2000) and modified some as for medication information such as "digit and percent". We had totally 21 labels for orthographic features.
- Previous history features: Class assignments of preceding words, by the NER system itself.
- Semantic tag features: semantic categories of words. Typical NER systems use dictionary lookup methods to determine semantic categories of a word (e.g., gene names in a dictionary). In this study, we used MedEx, the best rule-based medication extraction system in the i2b2 challenge, to assign medication specific categories into words.

MedEx was originally developed at Vanderbilt University, for extracting medication information from clinical text (Xu et al., 2010). MedEx labels medication related entities with a pre-defined semantic categories, which has overlap with the six entities defined in the i2b2 challenge, but not exactly same. For example, MedEx breaks the phrase *"fluocinonide 0.5% cream"* into *drug nam*e: *"fluocinonide", strength*: *"0.5%",* and *form*: *"cream";* while i2b2 labels the whole phrase as a medication name. There are a total of 11 pre-defined semantic categories which are listed in (Xu et al., 2010c). When the Vanderbilt team applied MedEx to the i2b2 challenge, they customized and extended MedEx to label medication related entities as required by i2b2. Those customizations included:

- Customized Rules to combine entities recognized by MedEx into i2b2 entities, such as combine drug name: *"fluocinonide",* strength: *"0.5%", and* form: *"cream"* into one medication nam*e "fluocinonide 0.5% cream".*
- A new Section Tagger to filter some drug names in sections such as "allergy" and "labs".
- A new Spell Checker to check whether a word can be a misspelled drug names.

In a summary, the MedEx system will produce two sets of semantic tags: 1) initial tags that are identified by the original MedEx system; 2) final tags that are identified by the customized MedEx system for the i2b2 challenge. The initial tagger will be equivalent to some simple dictionary look up methods used in many NER systems. The final tagger is a more advanced method that integrates other level of information such as sections and spellings. The outputs of initial tag include 11 pre-defined semantic tags in MedEx, and outputs of final tags consist of 6 types of NEs as in the i2b2 requirements. Therefore, it is interesting to us to study effects of both types of tags from MedEx in this study. These semantic tags were also converted into the BIO format when they were used as features.

4 Results and Discussions

In this study, we measured Precision, Recall, and

Features	**Pre**	**Rec**	**F-score**
Words (Baseline)	87.09	77.05	81.76
Words + History	90.34	78.17	83.81
Words + History + Morphology	91.72	81.08	86.06
Words + History + Morphology + POS	91.81	81.06	86.10
Words + History + Morphology + POS + Orthographies	91.78	81.29	86.22
Words + Semantic Tags (Original MedEx)	90.15	83.17	86.51
Words + Semantic Tags (Customized MedEx)	92.38	86.73	89.47
Words + History + Morphology + POS + Orthographies + Semantic Tags (Original MedEx)	91.43	84.2	87.66
Words + History + Morphology + POS + Orthographies + Semantic Tags (Customized MedEx)	**93.2**	**87.12**	**90.05**

Table 2. Performance of the SVM-based NER system for different feature combinations.

F-score using the CoNLL evaluation script[4]. Precision is the ratio between the number of correctly identified NE chunks by the system and the total number of NE chunks found by the system; Recall is the ratio between the number of correctly identified NE chunks by the system and the total number of NE chunks in the gold standard. Experiments were run in a Linux machine with 16GB RAM and 8 cores of Intel Xeon 2.0GHz processor. The performance of different types of feature sets was evaluated using 10-fold cross-validation.

Table 2 shows the precision, recall, and F-score of the SVM-based NER system for all six types of entities, when different combinations of feature sets were used. Among them, the best F-score of 90.05% was achieved, when all feature sets were used. A number of interesting findings can be concluded from those results. First, the contribution of different types of features to the system's performance varies. For example, the "previous history feature" and the "morphology feature" improved the performance substantially (F-score from 81.76% to 83.83%, and from 83.81% to 86.06% respectively). These findings were consistent with previous reported results on protein/gene NER (Kazama et al., 2002; Takeuchi and Collier, 2003; Yamamoto et al., 2003). However, "POS" and "orthographic" features contributed very little, not as much as in protein/gene names recognition tasks. This could be related to the differences between gene/protein phrases and medication phrases – more orthographic clues are observed in gene/protein names. Second, the "semantic tags" features alone, even just using the original tagger in MedEx, improved the performance dramatically (from 81.76% to 86.51% or 89.47%). This indicates that the knowledge bases in the biomedical domain are crucial to biomedical NER. Third, the customized final semantic tagger in MedEx had much better performance than the original tagger, which indicated that advanced semantic tagging methods that integrate other levels of linguistic information (e.g., sections) were more useful than simple dictionary lookup methods.

Table 3 shows the precision, recall, and F-score for each type of entity, from the MedEx alone, and the baseline and the best runs of the SVM-based NER system. As we can see, the best SVM-based NER system that combines all types of features (including inputs from MedEx) was much better than the MedEx system alone (90.05% vs. 85.86%). This suggested that the combination of rule-based systems with machine learning approaches could yield the most optimized performance in biomedical NER tasks.

Among six types of medication entities, we noticed that four types of entities (medication names, dosage, mode, and frequency) got very high F-scores (over 92%); while two others (duration and reason) had low F-scores (up to 50%). This finding was consistent with results from i2b2 challenge. Duration and reason are more difficult to identify because they do not have well-formed patterns and few knowledge bases exist for duration and reasons.

This study only focused on the first step of the i2b2 medication extraction challenge – NER. Our next plan is to work on the second step of determining relations between medication names and other entities, thus allowing us to compare our results with those reported in the i2b2 challenge. In addition, we will also evaluate and compare the performance of other ML algorithms such as CRF and ME on the same NER task.

Entity	**MedEx only**			**SVM (Baseline)**			**SVM (Best)**		
	Pre	Rec	F-score	Pre	Rec	F-score	Pre	Rec	F-score
ALL	**87.85**	**83.97**	**85.86**	87.09	77.05	81.76	**93.2**	**87.12**	**90.05**

5 Conclusions

In this study, we developed an SVM-based NER system for medication related entities. We systematically investigated different types of features and our results showed that by combining semantic features from a rule-based system, the ML-based NER system could achieve the best F-score of 90.05% in recognizing medication related entities, using the i2b2 annotated data set. The experiments also showed that optimized usage of external knowledge bases were crucial to high performance ML based NER systems for medical entities such as drug names.

Exploring the Data-Driven Prediction of Prepositions in English

Abstract

Prepositions in English are a well-known challenge for language learners, and the computational analysis of preposition usage has attracted significant attention. Such research generally starts out by developing models of preposition usage for native English based on a range of features, from shallow surface evidence to deep linguistically-informed properties.

While we agree that ultimately a combination of shallow and deep features is needed to balance the preciseness of exemplars with the usefulness of generalizations to avoid data sparsity, in this paper we explore the limits of a purely surface-based prediction of prepositions.

Using a web-as-corpus approach, we investigate the classification based solely on the relative number of occurrences for target n-grams varying in preposition usage. We show that such a surface-based approach is competitive with the published state-of-the-art results relying on complex feature sets.

Where enough data is available, in a surprising number of cases it thus is possible to obtain sufficient information from the relatively narrow window of context provided by n-grams which are small enough to frequently occur but large enough to contain enough predictive information about preposition usage.

1 Introduction

The correct use of prepositions is a well-known difficulty for learners of English, and correspondingly the computational analysis of preposition usage has attracted significant attention in recent years (De Felice and Pulman, 2007; De Felice, 2008; Lee and Knutsson, 2008; Gamon et al., 2008; Chodorow et al., 2007; Tetreault and Chodorow, 2008a, 2008b).

As a point of reference for the detection of preposition errors in learner language, most of the research starts out by developing a model of preposition usage for native English. For this purpose, virtually all previous approaches employ a machine learning setup combining a range of features, from surface-based evidence to deep linguistically-informed properties. The overall task is approached as a classification problem where the classes are the prepositions and the instances to be classified are the contexts, i.e., the sentences with the prepositions omitted.

A focus of the previous literature is on the question which linguistic and lexical features are the best predictors for preposition usage. Linguistic features used include the POS tags of the surrounding words, PP attachment sites, WordNet classes of PP object and modified item. Lexical features used include the object of the PP and the lexical item modified by the PP. Those syntactic, semantic and lexical features are then extracted from the training instances and used by the machine learning tool to predict the missing preposition in a test instance.

While we agree that ultimately a combination of shallow and linguistically informed features is needed to balance the preciseness of exemplars

Coling 2008: Poster Volume, pages 267–275,
Beijing, August 2010

with the usefulness of generalizations to avoid data sparsity problems, in this paper we want to explore the limits of a purely surface-based prediction of prepositions. Essentially, our question is how much predictive information can be found in the immediate distributional context of the preposition. Is it possible to obtain n-gram contexts for prepositions which are small enough to occur frequently enough in the available training data but large enough to contain enough predictive information about preposition usage?

This perspective is related to that underlying the variation-n-gram approach for detecting errors in the linguistic annotation of corpora (Dickinson and Meurers, 2003; Dickinson and Meurers, 2005; Boyd et al., 2008). Under that approach, errors in the annotation of linguistic properties (lexical, constituency, or dependency information) are detected by identifying units which recur in the corpus with sufficient identical context so as to make variation in their annotation unlikely to be correct. In a sense, the recurring n-gram contexts are used as exemplar references for the local domains in which the complex linguistic properties are established. The question now is to what extent basic[1] n-gram contexts can also be successfully used to capture the linguistic properties and relations determining preposition usage, exploring the trade-off expressed in the question ending the previous paragraph.

To address this question, in this paper we make use of a web-as-corpus approach in the spirit of Lapata and Keller (2005). We employ the Yahoo search engine to investigate a preposition classification setup based on the relative number of web counts obtained for target n-grams varying in the preposition used. We start the discussion with a brief review of key previous approaches and the results they obtain for the preposition classification task in native English text. In section 2, we then describe the experimental setup we used for our exploration and discuss our results in section 3.

1.1 Previous work and results

The previous work on the preposition prediction task varied in i) the features selected, ii) the number of prepositions tackled, and iii) the training and testing corpora used.

De Felice (2008) presents a system that (among other things) is used to predict the correct preposition for a given context. The system tackles the nine most frequent prepositions in English: *of, to, in, for, on, with, at, by, from*. The approach uses a wide variety of syntactic and semantic features: the lexical item modified by the PP, the lexical item that occurs as the object of the preposition, the POS tags of three words to the left and three words to the right of the preposition, the grammatical relation that the preposition is in with its object, the grammatical relation the preposition is in with the word modified by the PP, and the WordNet classes of the preposition's object and the lexical item modified by the PP. De Felice (2008) also used a named entity recognizer to extract generalizations about which classes of named entities can occur with which prepositions. Further, the verbs' subcategorization frames were taken as features. For features that used lexical sources (WordNet classes, verbs subcategorization frames), only partial coverage of the training and testing instances is available.

The overall accuracy reported by De Felice (2008) for this approach is 70.06%, testing on section J of the *British National Corpus (BNC)* after training on the other sections. As the most extensive discussion of the issue, using an explicit set of prepositions and a precisely specified and publicly accessible test corpus, De Felice (2008) is well-suited as a reference approach. Correspondingly, our study in this paper is based on the same set of prepositions and the same test corpus.

Gamon et al. (2008) introduce a system for the detection of a variety of learner errors in non-native English text, including preposition errors. For the preposition task, the authors combine the outputs of a classifier and a language model. The language model is a 5-gram model trained on the English Gigaword corpus. The classifier is trained

[1] While Dickinson and Meurers (2005) also employ discontinuous n-grams, we here focus only on contiguous n-gram contexts. Using discontinuous n-gram contexts for preposition prediction could be interesting to explore in the future, once, as a prerequisite for the effective generation of discontinuous n-grams, heuristics have been identified for when which kind of discontinuities should be allowed to arise for preposition classification contexts.

on Encarta encyclopedia and Reuters news text. It operates in two stages: The presence/absence classifier predicts first whether a preposition needs to be inserted at a given location. Then, the choice classifier determines which preposition is to be inserted. The features that are extracted for each possible insertion site come from a six-token window around the possible insertion site. Those features are the relative positions, POS tags, and surface forms of the tokens in that window. The choice classifier predicts one of 13 prepositions: *in, for, of, on, to, with, at, by, as, from, since, about, than,* and *other*. The accuracy of the choice classifier, the part of the system to which the work at hand is most similar, is 62.32% when tested on text from Encarta and Reuters news.

Tetreault and Chodorow (2008a) present a system for detecting preposition errors in learner text. Their approach extracts a total of 25 features from the local contexts: the adjacent words, the heads of the nearby phrases, and the POS tags of all those. They combine word-based features with POS tag features to better handle cases where a word from the test instance has not been seen in training. For each test instance, the system predicts one of 34 prepositions. In training and testing performed on the Encarta encyclopedia, Reuters news text and additional training material an accuracy figure of 79% is achieved.

Bergsma et al. (2009) extract contextual features from the Google 5-gram corpus to train an SVM-based classifier for predicting prepositions. They evaluate on 10 000 sentences taken from the New York Times section of the Gigaword corpus, and achieve an accuracy of 75.4%.

Following De Felice (2008, p. 66), we summarize the main results of the mentioned approaches to preposition prediction for native text in Figure 1.[2] Since the test sets and the prepositions targeted differ between the approaches, such a comparison must be interpreted with caution. In terms of the big picture, it is useful to situate the results with respect to the majority baseline reported by De Felice (2008). It is obtained by always choosing *of* as the most common preposition in section J of the BNC. De Felice also reports another interesting figure included in Figure 1, namely the accuracy of the human agreement with the original text, averaged over two English native-speakers.

Approach	Accuracy
Gamon et al. (2008)	62.32%
Tetreault and Chodorow (2008a)	79.00%
Bergsma et al. (2009)	75.50%
De Felice (2008) system	70.06%
Majority baseline *(of)*	26.94%
Human agreement	88.60%

Figure 1: Preposition prediction results

2 Experiments

2.1 Data

As our test corpus, we use section J of the BNC, the same corpus used by De Felice (2008). Based on the tokenization as given in the corpus, we join the tokens with a single space, which also means that punctuation characters end up as separate, white-space separated tokens. We select all sentences that contain one or more prepositions, using the POS annotation in the corpus to identify the prepositions. The BNC is POS-annotated with the CLAWS-5 tagset, which distinguishes the two tags `PRF` for *of* and `PRP` for all other prepositions.[3] We mark every occurrence of these preposition tags in the corpus, yielding one prediction task for each marked preposition. For example, the sentence (1) yields four prediction tasks, one for each of the prepositions *for, of, from,* and *in* in the sentence.

(1) But **for** the young, it is rather a question **of** the scales falling **from** their eyes, and having nothing to believe **in** any more.

In each task, one preposition is masked using the special marker `-*-MASKED-*-`. Figure 2 shows the four marked-up prediction tasks resulting for example (1).

Following De Felice (2008), we focus our experiments on the top nine prepositions in the BNC: *of, to, in, for, on, with, at, by, from*. For

[2] The Gamon et al. (2008) result differs from the one reported in De Felice (2008); we rely on the original paper.

```

Figure 2: Four prediction tasks for example (1)

each occurrence of these nine prepositions in section J of the BNC, we extract one prediction task, yielding a test set of 522 313 instances.

Evaluating on this full test set would involve a prohibitively large number of queries to the Yahoo search engine. We therefore extract a randomly drawn subset of 10 000 prediction tasks. From this subset, we remove all prediction tasks which are longer than 4000 characters in length, as Yahoo only supports queries up to that length. Finally, in a web-as-corpus setup, the indexing of the web pages performed by the search engine essentially corresponds to the training step in a typical machine learning setup. In order to avoid testing on the training data, we thus need to ensure that the test cases are based on text not indexed by the search engine. To exclude any such cases, we query the search engine with each complete sentence that a prediction task is based on and remove any prediction task for which the search engine returns hits for the complete sentence. The final test set consists of 8060 prediction tasks.[4]

2.2 Experimental Setup

Recall that the general issue we are interested in is whether one can obtain sufficient information from the relatively narrow distributional window of context provided by n-grams which are small enough to occur frequently enough in the training data but large enough to contain enough predictive information about preposition usage for the instances to be classified. By using a web-as-corpus approach we essentially try to maximize the training data size. For the n-gram size, we explore the use of a maximum order of 7, containing the preposition in the middle and three words of context on either side.

For each prediction task, we successively insert one of the nine most frequent prepositions into the marked preposition slot of the 8060 n-grams obtained from the test set. Thus, for each prediction task, we get a *cohort* consisting of nine different individual queries, one query for each potential preposition. For example, the second prediction task of Figure 2 yields the cohort of nine queries in Figure 3 below, where the candidate prepositions replace the location marked by `-*-MASKED-*-of`. The correct preposition *of* is stripped off and kept for later use in the evaluation step.

1. `rather a question` **`of`** `the scales falling`
2. `rather a question` **`to`** `the scales falling`
3. `rather a question` **`in`** `the scales falling`

   ⋮

9. `rather a question` **`from`** `the scales falling`

Figure 3: Cohort of nine queries resulting for the second prediction task of Figure 2

In cases where a preposition is closer than four words to the beginning or the end of the corresponding sentence, a lower-order n-gram results. For example, in the first prediction task in Figure 2, the preposition occurs already as the second word in the sentence, thus not leaving enough context to the left of the preposition for a symmetric 7-gram. Here, the truncated asymmetric 5-gram "`But` **`<prep>`** `the young ,`" including only one word of context on the left would get used.

We issue each query in a cohort to the Yahoo search engine, and determine the number of hits returned for that query. To that end, we use Yahoo's BOSS service, which offers a

[4] For a copy of the test set, just send us an email.

JSON interface supporting straightforward automated queries. As part of its response to a query, the BOSS service includes the `deephits` field, which gives an "approximate count that reflects duplicate documents and all documents from a host".[5] In other words, this number is an approximate measure of how many web pages there are that contain the search pattern.

With the counts for all nine queries in a cohort retrieved from Yahoo, we select the preposition of the query with the highest count. For the cases in which none of the counts in a 7-gram cohort is greater than zero, we use one of two strategies:

In the **baseline** condition, for all n-gram cohorts with zero counts (5160 out of the 8060 cases) we predict the most frequent preposition *of*, i.e., the majority baseline. This results in an overall accuracy of 50%.

In the **full back-off** condition, we explore the trade-off between the predictive power of the n-gram as context and the likelihood of having seen this n-gram in the training material, i.e., finding it on the web. In this paper we never abstract or generalize away from the surface string (e.g., by mapping all proper names to an abstract name tag; but see the outlook discussion at the end of the paper), so the only option for increasing the number of occurrences of an n-gram is to approximate it with multiple shorter n-grams.

Concretely, if no hits could be found for any of the queries in a cohort, we back off to the sum of the hits for the two overlapping 6-grams constructed in the way illustrated in Figure 4.

```
[rather a question of the scales falling]
                    ⇓
[rather a question of the scales]
       [a question of the scales falling]
```

Figure 4: Two overlapping 6-grams approximate a 7-gram for back-off.

If still no hits can be obtained after backing off to 6-grams for any of the queries in a cohort, the system backs off further to overlapping 5-grams, and so on, down to trigrams.[6]

[5]Cited from `http://developer.yahoo.com/search/boss/boss_guide/ch02s02.html`

[6]When backing off, the left-most and the right-most trigram do not include the target preposition of the original 7-gram. However, this only affects 13 cases, cf. Figure 6.

3 Results

Figure 5 shows the results of the **full back-off** approach. Compared to the baseline condition, accuracy goes up significantly to 76.5%. Thus, the back-off strategy is effective in increasing the amount of available data using lower-order n-grams. This increase of data is also reflected in the number of cases with zero counts for a cohort, which goes down to none.

	Full back-off
Correct	6166
Incorrect	1894
Total	8060
Accuracy	76.5%

Figure 5: Overall results of our experiments.

Figure 6 provides a detailed analysis of the back-off experiment. It lists back-off sequences separately for each maximum n-gram order. The prediction tasks for which a full 7-gram can be extracted are displayed in the third column, with back-off orders of 6 down to 3. Prediction tasks for which only asymmetric 6-grams can be extracted follow in column 4, and so on until 4-grams. There are no predictions tasks that are shorter than four words. Therefore, n-grams with a length of less than 4 do not occur.

The "sum" column shows the combined results of the full 7-gram prediction tasks and the prediction tasks involving truncated, asymmetric n-grams of lower orders.

There are 6999 prediction tasks for which full 7-grams can be extracted. The remaining 1061 of the 8060 prediction tasks are the cases where the system extracts only asymmetric lower-order n-grams, for the reasons explained in section 2.2.

For 2195 of the 6999 7-gram prediction tasks, we find full 7-gram contexts on the web, of which 1931 lead to a correct prediction, and 264 to an incorrect one, leaving 4804 prediction tasks still to be solved through the back-off approach. Thus, full 7-gram contexts lead to high-quality predictions at 88% precision, but they are rare and with a recall of 28,7% cover only a fraction of all cases.

Figure 6: The results of our experiments

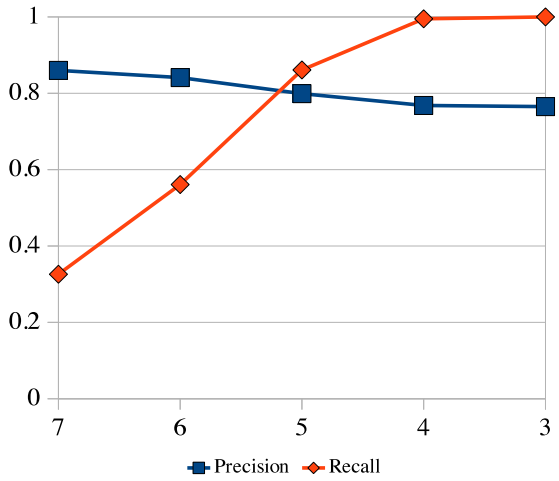

Figure 7: Development of precision and recall in relation to back-off order

Approximating 7-grams with two overlapping 6-grams as the first back-off step provides the evidence needed to correctly predict 1620 additional prepositions, with 408 additional false predictions. The number of correctly solved prediction tasks thus rises to 3551, and the number of incorrect predictions rises to 672. This back-off step almost doubles recall (56.1%). At the same time, precision drops to 84.1%. For 2776 prediction tasks, a further back-off step is necessary since still no evidence can be found for them. This pattern repeats with the back-off steps that follow. To summarize, by adding more data using less restricted contexts, more prediction tasks can be solved. The better coverage however comes at the price of reduced precision: Less specific contexts are worse predictors of the correct preposition than more specific contexts.

Figure 7 visualizes the development of precision and recall with full and truncated 7-grams counted together as in the "sum" column in Figure 6. With each back-off step, more prediction tasks can be solved (as shown by the rising recall curve). At the same time, the overall quality of the predictions drops due to the less specific contexts (as shown by the slightly dropping precision curve). While the curve for recall rises steeply, the curve for precision remains relatively flat. The back-off approach thus succeeds in adding data while preserving prediction quality.

As discussed above, we use the same set of prepositions and test corpus as De Felice (2008), but only make use of 8060 test cases. Figure 8 shows that the accuracy stabilizes quickly after about 1000 predictions, so that the difference in the size of the test set should have no impact on the reported results.

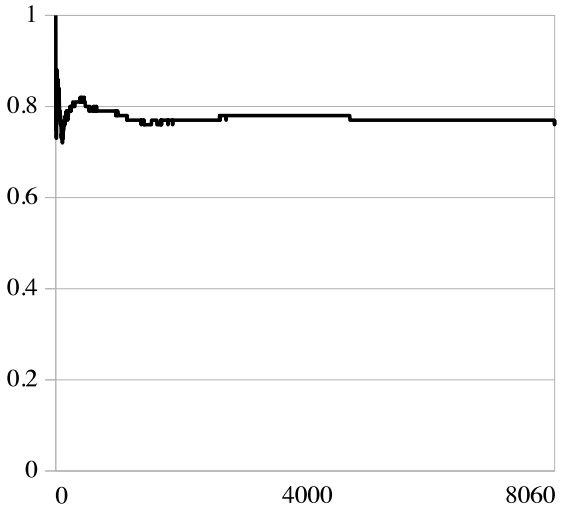

Figure 8: The accuracy of the n-gram prediction stabilizes quickly.

4 Conclusions and Outlook

In this paper, we explored the potential and the limits of a purely surface-based strategy of predicting prepositions in English. The use of surface-based n-grams ensures that fully specific exemplars of a particular size are stored in training, but avoiding abstractions in this way leads to the well-known data sparsity issues. We showed that using a web-as-corpus approach maximizing the size of the "training data", one can work with n-grams which are large enough to predict the occurrence of prepositions with significant precision while at the same time ensuring that these specific n-grams have actually been encountered during "training", i.e., evidence for them can be found on the web.

For the random sample of the BNC section J we tested on, the surface-based approach results in an accuracy of 77% for the 7-gram model with back-off to overlapping shorter n-grams. It thus outperforms De Felice's (2008) machine learning

approach which uses the same set of prepositions and the full BNC section J as test set. In broader terms, the result of our surface-based approach is competitive with the state-of-the art results for preposition prediction in English using machine learning to combine sophisticated sets of lexical and linguistically motivated features.

In this paper, we focused exclusively on the impact of n-gram size on preposition prediction. Limiting ourselves to pure surface-based information made it possible to maximize the "training data" by using a web-as-corpus approach. Returning from this very specific experiment to the general issue, there are two well-known approaches to remedy the data sparseness problem arising from storing large, specific surface forms in training. On the one hand, one can use smaller exemplars, which is the method we used as backoff in our experiments in this paper. This only works if the exemplars contain enough context for the linguistic property or relation that we need to capture the predictive power. On the other hand, one can abstract parts of the surface-based training instances to more general classes. The crucial question this raises is which generalizations preserve the predictive power of the exemplars and can reliably be identified. The linguistically-informed features used in the previous approaches in the literature naturally provide interesting instances of answers to this question. In the future, we intend to compare the results we obtained using the web-as-corpus approach with one based on the Google-5-gram corpus to study using controlled, incremental shallow-to-deep feature development which abstractions or linguistic generalizations best preserve the predictive context while lowering the demands on the size of the training data.

Turning to a linguistic issue, it could be useful to distinguish between lexical and functional prepositions when reporting test results. This is an important distinction because the information needed to predict functional prepositions typically is in the local context, whereas the information needed to predict lexical prepositions is not necessarily present locally. To illustrate, a competent human speaker presented with the sentence *John is dependent ___ his brother* and asked to fill in the missing preposition, would correctly pick *on*. This is a case of a functional preposition where the relevant information is locally present: the adjective *dependent* selects *on*. On the other hand, the sentence *John put his bag ___ the table* is more problematic, even for a human, since both *on* and *under* are reasonable choices; the information needed to predict the omitted preposition in this case is not locally present. In line with the previous research, in the work in this paper we made predictions for all prepositions alike. In the future, it could be useful to annotate the test set so that one can distinguish functional and lexical uses and report separate figures for these two classes in order to empirically confirm their differences with respect to locality.

Abstract

Several sets of explanatory variables – including shallow, language modeling, POS, syntactic, and discourse features – are compared and evaluated in terms of their impact on predicting the grade level of reading material for primary school students. We find that features based on in-domain language models have the highest predictive power. Entity-density (a discourse feature) and POS-features, in particular nouns, are individually very useful but highly correlated. Average sentence length (a shallow feature) is more useful – and less expensive to compute – than individual syntactic features. A judicious combination of features examined here results in a significant improvement over the state of the art.

1 Introduction

1.1 Motivation and Method

Readability Assessment quantifies the difficulty with which a reader understands a text. Automatic readability assessment enables the selection of appropriate reading material for readers of varying proficiency. Besides modeling and understanding the linguistic components involved in readability, a readability-prediction algorithm can be leveraged for the task of automatic text simplification: as simplification operators are applied to a text, the readability is assessed to determine whether more simplification is needed or a particular reading level was reached.

Identifying text properties that are strongly correlated with text complexity is itself complex. In this paper, we explore a broad range of text properties at various linguistic levels, ranging from discourse features to language modeling features, part-of-speech-based grammatical features, parsed syntactic features and well studied shallow features, many of which are inspired by previous work.

We use grade levels, which indicate the number of years of education required to completely understand a text, as a proxy for reading difficulty. The corpus in our study consists of texts labeled with grade levels ranging from grade 2 to 5. We treat readability assessment as a classification task and evaluate trained classifiers in terms of their prediction accuracy. To investigate the contributions of various sets of features, we build prediction models and examine how the choice of features influences the model performance.

1.2 Related Work

Many traditional readability metrics are linear models with a few (often two or three) predictor variables based on superficial properties of words, sentences, and documents. These shallow features include the average number of syllables per word, the number of words per sentence, or binned word frequency. For example, the Flesch-Kincaid Grade Level formula uses the average number of words per sentence and the average number of syllables per word to predict the grade level (Flesch, 1979). The Gunning FOG index (Gunning, 1952) uses average sentence length and the percentage of words with at least three syllables. These traditional metrics are easy to compute and use, but they are not reliable, as demonstrated by several recent studies in the field (Si and Callan, 2001; Petersen and Ostendorf, 2006; Feng et al., 2009).

Coling 2008: Poster Volume, pages 276–284,
Beijing, August 2010

With the advancement of natural language processing tools, a wide range of more complex text properties have been explored at various linguistic levels. Si and Callan (2001) used unigram language models to capture content information from scientific web pages. Collins-Thompson and Callan (2004) adopted a similar approach and used a smoothed unigram model to predict the grade levels of short passages and web documents. Heilman et al. (2007) continued using language modeling to predict readability for first and second language texts. Furthermore, they experimented with various statistical models to test their effectiveness at predicting reading difficulty (Heilman et al., 2008). Schwarm/Petersen and Ostendorf (Schwarm and Ostendorf, 2005; Petersen and Ostendorf, 2006) used support vector machines to combine features from traditional reading level measures, statistical language models and automatic parsers to assess reading levels. In addition to lexical and syntactic features, several researchers started to explore discourse level features and examine their usefulness in predicting text readability. Pitler and Nenkova (2008) used the Penn Discourse Treebank (Prasad et al., 2008) to examine discourse relations. We previously used a lexical-chaining tool to extract entities that are connected by certain semantic relations (Feng et al., 2009).

In this study, we systematically evaluate all above-mentioned types of features, as well as a few extensions and variations. A detailed description of the features appears in Section 3. Section 4 discusses results of experiments with classifiers trained on these features. We begin with a description of our data in the following section.

2 Corpus

We contacted the Weekly Reader[1] corporation, an on-line publisher producing magazines for elementary and high school students, and were granted access in October 2008 to an archive of their articles. Among the articles retrieved, only those for elementary school students are labeled with grade levels, which range from 2 to 5. We selected only this portion of articles (1629 in total) for the study.[2] These articles are intended to build children's general knowledge and help them practice reading skills. While pre-processing the texts, we found that many articles, especially those for lower grade levels, consist of only puzzles and quizzes, often in the form of simple multiple-choice questions. We discarded such texts and kept only 1433 full articles. Some distributional statistics of the final corpus are listed in Table 1.

Table 1: Statistics for the Weekly Reader Corpus

Grade	docs.	words/document		words/sentence	
		mean	std. dev.	mean	std. dev.
2	174	128.27	106.03	9.54	2.32
3	289	171.96	106.05	11.39	2.42
4	428	278.03	187.58	13.67	2.65
5	542	335.56	230.25	15.28	3.21

3 Features

3.1 Discourse Features

We implement four subsets of discourse features: entity-density features, lexical-chain features, coreference inference features and entity grid features. The coreference inference features are novel and have not been studied before. We previously studied entity-density features and lexical-chain features for readers with intellectual disabilities (Feng et al., 2009). Entity-grid features have been studied by Barzilay and Lapata (2008) in a stylistic classification task. Pitler and Nenkova (2008) used the same features to evaluate how well a text is written. We replicate this set of features for grade level prediction task.

3.1.1 Entity-Density Features

Conceptual information is often introduced in a text by entities, which consist of general nouns and named entities, e.g. people's names, locations, organizations, etc. These are important in text comprehension, because established entities form basic components of concepts and propositions, on which higher level discourse processing is based. Our prior work illustrated the importance of entities in text comprehension (Feng et al., 2009).

[1] http://www.weeklyreader.com

[2] A corpus of Weekly Reader articles was previously used in work by Schwarm and Ostendorf (2005). However, the two corpora are not identical in size nor content.

Table 2: New Entity-Density Features

1	percentage of named entities per document
2	percentage of named entities per sentences
3	percentage of overlapping nouns removed
4	average number of remaining nouns per sentence
5	percentage of named entities in total entities
6	percentage of remaining nouns in total entities

We hypothesized that the number of entities introduced in a text relates to the working memory burden on their targeted readers – individuals with intellectual disabilities. We defined entities as a union of named entities and general nouns (nouns and proper nouns) contained in a text, with overlapping general nouns removed. Based on this, we implemented four kinds of entity-density features: total number of entity mentions per document, total number of unique entity mentions per document, average number of entity mentions per sentence, and average number of unique entity mentions per sentence.

We believe entity-density features may also relate to the readability of a text for a general audience. In this paper, we conduct a more refined analysis of general nouns and named entities. To collect entities for each document, we used OpenNLP's[3] name-finding tool to extract named entities; general nouns are extracted from the output of Charniak's Parser (see Section 3.3). Based on the set of entities collected for each document, we implement 12 new features. We list several of these features in in Table 2.

3.1.2 Lexical Chain Features

During reading, a more challenging task with entities is not just to keep track of them, but to resolve the semantic relations among them, so that information can be processed, organized and stored in a structured way for comprehension and later retrieval. In earlier work (Feng et al., 2009), we used a lexical-chaining tool developed by Galley and McKeown (2003) to annotate six semantic relations among entities, e.g. synonym, hypernym, hyponym, etc. Entities that are connected by these semantic relations were linked through the text to form lexical chains. Based on these chains, we implemented six features, listed in Table 3, which we use in our current study. The length of a chain is the number of entities contained in the chain, the span of chain is the distance between the index of the first and last entity in a chain. A chain is defined to be active for a word or an entity if this chain passes through its current location.

[3] http://opennlp.sourceforge.net/

Table 3: Lexical Chain Features

1	total number of lexical chains per document
2	avg. lexical chain length
3	avg. lexical chain span
4	num. of lex. chains with span $\geq$ half doc. length
5	num. of active chains per word
6	num. of active chains per entity

Table 4: Coreference Chain Features

1	total number of coreference chains per document
2	avg. num. of coreferences per chain
3	avg. chain span
4	num. of coref. chains with span $\geq$ half doc. length
5	avg. inference distance per chain
6	num. of active coreference chains per word
7	num. of active coreference chains per entity

3.1.3 Coreference Inference Features

Relations among concepts and propositions are often not stated explicitly in a text. Automatically resolving implicit discourse relations is a hard problem. Therefore, we focus on one particular type, referential relations, which are often established through anaphoric devices, e.g. pronominal references. The ability to resolve referential relations is important for text comprehension.

We use OpenNLP to resolve coreferences. Entities and pronominal references that occur across the text and refer to the same person or object are extracted and formed into a coreference chain. Based on the chains extracted, we implement seven features as listed in Table 4. The chain length, chain span and active chains are defined in a similar way to the lexical chain features. Inference distance is the difference between the index of the referent and that of its pronominal reference. If the same referent occurs more than once in a chain, the index of the closest occurrence is used when computing the inference distance.

3.1.4 Entity Grid Features

Coherent texts are easier to read. Several computational models have been developed to represent and

measure discourse coherence (Lapata and Barzilay, 2005; Soricut and Marcu, 2006; Elsner et al., 2007; Barzilay and Lapata, 2008) for NLP tasks such as text ordering and text generation. Although these models are not intended directly for readability research, Barzilay and Lapata (2008) have reported that distributional properties of local entities generated by their grid models are useful in detecting original texts from their simplified versions when combined with well studied lexical and syntactic features. This approach was subsequently pursued by Pitler and Nenkova (2008) in their readability study. Barzilay and Lapata's entity grid model is based on the assumption that the distribution of entities in locally coherent texts exhibits certain regularities. Each text is abstracted into a grid that captures the distribution of entity patterns at the level of sentence-to-sentence transitions. The entity grid is a two-dimensional array, with one dimension corresponding to the salient entities in the text, and the other corresponding to each sentence of the text. Each grid cell contains the grammatical role of the specified entity in the specified sentence: whether it is a subject (S), object (O), neither of the two (X), or absent from the sentence (-).

We use the Brown Coherence Toolkit (v0.2) (Elsner et al., 2007), based on (Lapata and Barzilay, 2005), to generate an entity grid for each text in our corpus. The distribution patterns of entities are traced between each pair of adjacent sentences, resulting in 16 entity transition patterns[4]. We then compute the distribution probability of each entity transition pattern within a text to form 16 entity-grid-based features.

3.2 Language Modeling Features

Our language-modeling-based features are inspired by Schwarm and Ostendorf's (2005) work, a study that is closely related to ours. They used data from the same data – the Weekly Reader – for their study. They trained three language models (unigram, bigram and trigram) on two paired complex/simplified corpora (Britannica and LiteracyNet) using an approach in which words with high information gain are kept and the remaining words are replaced with their parts of speech. These language models were then used to score each text in the Weekly Reader corpus by perplexity. They reported that this approach was more successful than training LMs on text sequences of word labels alone, though without providing supporting statistics.

It's worth pointing out that their LMs were not trained on the Weekly Reader data, but rather on two unrelated paired corpora (Britannica and LiteracyNet). This seems counter-intuitive, because training LMs directly on the Weekly Reader data would provide more class-specific information for the classifiers. They justified this choice by stating that splitting limited Weekly Reader data for training and testing purposes resulted in unsuccessful performance.

We overcome this problem by using a hold-one-out approach to train LMs directly on our Weekly Reader corpus, which contains texts ranging from Grade 2 to 5. We use grade levels to divide the whole corpus into four smaller subsets. In addition to implementing Schwarm and Ostendorf's information-gain approach, we also built LMs based on three other types of text sequences for comparison purposes. These included: word-token-only sequence (i.e., the original text), POS-only sequence, and paired word-POS sequence. For each grade level, we use the SRI Language Modeling Toolkit[5] (with Good-Turing discounting and Katz backoff for smoothing) to train 5 language models (1- to 5-gram) using each of the four text sequences, resulting in $4 \times 5 \times 4 = 80$ perplexity features for each text tested.

3.3 Parsed Syntactic Features

Schwarm and Ostendorf (2005) studied four parse tree features (average parse tree height, average number of SBARs, noun phrases, and verb phrases per sentences). We implemented these and additional features, using the Charniak parser (Charniak, 2000). Our parsed syntactic features focus on clauses (SBAR), noun phrases (NP), verb phrases (VP) and prepositional phrases (PP). For each phrase, we implement four features: total number of the phrases per document, average number of phrases per sentence, and average phrase length

[4]These 16 transition patterns are: "SS", "SO", "SX", "S-", "OS", "OO", "OX", "O-", "XS", "XO", "XX", "X-", "-S", "-O", "-X", "--".

[5]http://www.speech.sri.com/projects/srilm/

measured by number of words and characters respectively. In addition to average tree height, we implement two non-terminal-node-based features: average number of non-terminal nodes per parse tree, and average number of non-terminal nodes per word (terminal node).

3.4 POS-based Features

Part-of-speech-based grammatical features were shown to be useful in readability prediction (Heilman et al., 2007; Leroy et al., 2008). To extend prior work, we systematically studied a number of common categories of words and investigated to what extent they are related to a text's complexity. We focus primarily on five classes of words (nouns, verbs, adjectives, adverbs, and prepositions) and two broad categories (content words, function words). Content words include nouns, verbs, numerals, adjectives, and adverbs; the remaining types are function words. The part of speech of each word is obtained from examining the leaf node based on the output of Charniak's parser, where each leaf node consists of a word and its part of speech. We group words based on their POS labels. For each class of words, we implement five features. For example, for the adjective class, we implemented the following five features: percent of adjectives (tokens) per document, percent of unique adjectives (types) per document, ratio of unique adjectives per total unique words in a document, average number of adjectives per sentence and average number of unique adjectives per sentence.

3.5 Shallow Features

Shallow features refer to those used by traditional readability metrics, such as Flesch-Kincaid Grade Level (Flesch, 1979), SMOG (McLaughlin, 1969), Gunning FOG (Gunning, 1952), etc. Although recent readability studies have strived to take advantage of NLP techniques, little has been revealed about the predictive power of shallow features. Shallow features, which are limited to superficial text properties, are computationally much less expensive than syntactic or discourse features. To enable a comparison against more advanced features, we implement 8 frequently used shallow features as listed in Table 5.

Table 5: Shallow Features

1	average number of syllables per word
2	percentage of poly-syll. words per doc.
3	average number of poly-syll. words per sent.
4	average number of characters per word
5	Chall-Dale difficult words rate per doc.
6	average number of words per sentence
7	Flesch-Kincaid score
8	total number of words per document

3.6 Other Features

For comparison, we replicated 6 out-of-vocabulary features described in Schwarm and Ostendorf (2005). For each text in the Weekly Reader corpus, these 6 features are computed using the most common 100, 200 and 500 word tokens and types based on texts from Grade 2. We also replicated the 12 perplexity features implemented by Schwarm and Ostendorf (2005) (see Section 3.2).

4 Experiments and Discussion

Previous studies on reading difficulty explored various statistical models, e.g. regression vs. classification, with varying assumptions about the measurement of reading difficulty, e.g. whether labels are ordered or unrelated, to test the predictive power of models (Heilman et al., 2008; Petersen and Ostendorf, 2009; Aluisio et al., 2010). In our research, we have used various models, including linear regression; standard classification (Logistic Regression and SVM), which assumes no relation between grade levels; and ordinal regression/ classification (provided by Weka, with Logistic Regression and SMO as base function), which assumes that the grade levels are ordered. Our experiments show that, measured by mean squared error and classification accuracy, linear regression models perform considerably poorer than classification models. Measured by accuracy and F-measure, ordinal classifiers perform comparable or worse than standard classifiers. In this paper, we present the best results, which are obtained by standard classifiers. We use two machine learning packages known for efficient high-quality multi-class classification: LIBSVM (Chang and Lin, 2001) and the Weka machine learning toolkit (Hall et al., 2009), from which we choose Logistic Regression as classifiers. We train and evaluate various prediction

Table 6: Comparison of discourse features

Feature Set	LIBSVM	Logistic Regress.
Entity-Density	59.63 ± 0.632	57.59 ± 0.375
Lexical Chain	45.86 ± 0.815	42.58 ± 0.241
Coref. Infer.	40.93 ± 0.839	42.19 ± 0.238
Entity Grid	45.92 ± 1.155	42.14 ± 0.457
all combined	60.50 ± 0.990	58.79 ± 0.703

Table 7: Comparison of lang. modeling features

Word/POS pair	60.38 ± 0.820	59.00 ± 0.367
all combined	68.38 ± 0.929	66.82 ± 0.448
IG by Schwarm	52.21 ± 0.832	51.89 ± 0.405

Table 8: Comparison of parsed syntactic features

Feature Set	# Feat.	LIBSVM
Original features	4	50.68 ± 0.812
Expanded features	21	57.79 ± 1.023

models using the features described in Section 3. We evaluate classification accuracy using repeated 10-fold cross-validation on the Weekly Reader corpus. Classification accuracy is defined as the percentage of texts predicted with correct grade levels. We repeat each experiment 10 times and report the mean accuracy and its standard deviation.

4.1 Discourse Features

We first discuss the improvement made by extending our earlier entity-density features (Feng et al., 2009). We used LIBSVM to train and test models on the Weekly Reader corpus with our earlier features and our new features respectively. With earlier features only, the model achieves 53.66% accuracy. With our new features added, the model performance is 59.63%.

Table 6 presents the classification accuracy of models trained with discourse features. We see that, among four subsets of discourse features, entity-density features perform significantly better than the other three feature sets and generate the highest classification accuracy (LIBSVM: 59.63%, Logistic Regression: 57.59%). While Logistic Regression results show that there is not much performance difference among lexical chain, coreference inference, and entity grid features, classification accuracy of LIBSVM models indicates that lexical chain features and entity grid features are better in predicting text readability than coreference inference features. Combining all discourse features together does not significantly improve accuracy compared with models trained only with entity-density features.

4.2 Language Modeling Features

Table 7 compares the performance of models generated using our approach and our replication of Schwarm and Ostendorf's (2005) approach. In our approach, features were obtained from language models trained on the Weekly Reader corpus. Not surprisingly, these are more effective than LMs trained on the Britannica and LiteracyNet corpora, in Schwarm and Ostendorf's approach. Our results support their claim that LMs trained with information gain outperform LMs trained with POS labels. However, we also notice that training LMs on word labels alone or paired word/POS sequences achieved similar classification accuracy to the IG approach, while avoiding the complicated feature selection of the IG approach.

4.3 Parsed Syntactic Features

Table 8 compares a classifier trained on the four parse features of Schwarm and Ostendorf (2005) to a classifier trained on our expanded set of parse features. The LIBSVM classifier with the expanded feature set scored 7 points higher than the one trained on only the original four features, improving from 50.68% to 57.79%. Table 9 shows a detailed comparison of particular parsed syntactic features. The two non-terminal-node-based features (average number of non-terminal nodes per tree and average number of non-terminal nodes per word) have higher discriminative power than average tree height. Among SBARs, NPs, VPs and PPs, our experiments show that VPs and NPs are the best predictors.

4.4 POS-based Features

The classification accuracy generated by models trained with various POS features is presented in Table 10. We find that, among the five word classes investigated, noun-based features gener-

Feature Set	LIBSVM	Logistic Regress.
Non-term.-node ratios	53.02 ± 0.571	51.80 ± 0.171
Average tree height	44.26 ± 0.914	43.45 ± 0.269
SBARs	44.42 ± 1.074	43.50 ± 0.386
NPs	51.56 ± 1.054	48.14 ± 0.408
VPs	53.07 ± 0.597	48.67 ± 0.484
PPs	49.36 ± 1.277	46.47 ± 0.374
all combined	57.79 ± 1.023	54.11 ± 0.473

Table 10: Comparison of POS features

Feature Set	LIBSVM	Logistic Regress.
Nouns	58.15 ± 0.862	57.01 ± 0.256
Verbs	54.40 ± 1.029	55.10 ± 0.291
Adjectives	53.87 ± 1.128	52.75 ± 0.427
Adverbs	52.66 ± 0.970	50.54 ± 0.327
Prepositions	56.77 ± 1.278	54.13 ± 0.312
Content words	56.84 ± 1.072	56.18 ± 0.213
Function words	52.19 ± 1.494	50.95 ± 0.298
all combined	59.82 ± 1.235	57.86 ± 0.547

ate the highest classification accuracy, which is consistent with what we have observed earlier about entity-density features. Another notable observation is that prepositions demonstrate higher discriminative power than adjectives and adverbs. Models trained with preposition-based features perform close to those trained with noun-based features. Among the two broader categories, content words (which include nouns) demonstrate higher predictive power than function words (which include prepositions).

4.5 Shallow Features

We present some notable findings on shallow features in Table 11. Experimental results generated by models trained with Logistic Regression show that average sentence length has dominating predictive power over all other shallow features. Features based on syllable counting perform much worse. The Flesch-Kincaid Grade Level score uses a fixed linear combination of average words per sentence and average syllables per word. Combining those two features (without fixed coefficients) results in the best overall accuracy, while using the Flesch-Kincaid score as a single feature is significantly worse.

Table 11: Comparison of shallow features

Feature Set	Logistic Regress.
Avg. words per sent.	52.17 ± 0.193
Avg. syll. per word	42.51 ± 0.264
above two combined	53.04 ± 0.514
Flesch-Kincaid score	50.83 ± 0.144
Avg. poly-syll. words per sent.	45.70 ± 0.306
all 8 features combined	52.34 ± 0.242

4.6 Comparison with Previous Studies

A trivial baseline of predicting the most frequent grade level (grade 5) predicts 542 out of 1433 texts (or 37.8%) correctly. With this in mind, we first compare our study with the widely-used Flesch-Kincaid Grade Level formula, which is a linear function of average words per sentence and average syllables per word that aims to predict the grade level of a text directly. Since this is a fixed formula with known coefficients, we evaluated it directly on our entire Weekly Reader corpus without cross-validation. We obtain the predicted grade level of a text by rounding the Flesch-Kincaid score to the nearest integer. For only 20 out of 1433 texts the predicted and labeled grade levels agree, resulting in a poor accuracy of 1.4%. By contrast, using the Flesch-Kincaid score as a feature of a simple logistic regression model achieves above 50% accuracy, as discussed in Section 4.5.

The most closely related previous study is the work of Schwarm and Ostendorf (2005). However, because their experiment design (85/15 training/test data split) and machine learning tool (SVM^{light}) differ from ours, their results are not directly comparable to ours. To make a comparison, we replicated all the features used in their study and then use LIBSVM and Weka's Logistic Regression to train two models with the replicated features and evaluate them on our Weekly Reader corpus using 10-fold cross-validation.

Using the same experiment design, we train classifiers with three combinations of our features as listed in Table 12. "All features" refers to a naive combination of all features. "AddOneBest" refers to a subset of features selected by a group-wise add-one-best greedy feature selection. "WekaFS" refers to a subset of features chosen by Weka's feature selection filter.

"WekaFS" consists of 28 features selected au-

Table 12: Comparison with previous work

baseline accuracy (majority class)		37.8	
Flesch-Kincaid Grade Level		1.4	
Feature Set	# Feat.	LIBSVM	Logistic Reg.
Schwarm	25	63.18 ± 1.664	60.50 ± 0.477
All features	273	72.21 ± 0.821	63.71 ± 0.576
AddOneBest	122	74.01 ± 0.847	69.22 ± 0.411
WekaFS	28	70.06 ± 0.777	65.46 ± 0.336

tomatically by Weka's feature selection filter using a best-first search method. The 28 features include language modeling features, syntactic features, POS features, shallow features and out-of-vocabulary features. Aside from 4 shallow features and 5 out-of-vocabulary features, the other 19 features are novel features we have implemented for this paper.

As Table 12 shows, a naive combination of all features results in classification accuracy of 72%, which is much higher than the current state of the art (63%). This is not very surprising, since we are considering a greater variety of features than any previous individual study. Our WekaFS classifier uses roughly the same number of features as the best published result, yet it has a higher accuracy (70.06%). Our best results were obtained by group-wise add-one-best feature selection, resulting in 74% classification accuracy, a big improvement over the state of the art.

5 Conclusions

We examined the usefulness of features at various linguistic levels for predicting text readability in terms of assigning texts to elementary school grade levels. We implemented a set of discourse features, enriched previous work by creating several new features, and systematically tested and analyzed the impact of these features.

We observed that POS features, in particular nouns, have significant predictive power. The high discriminative power of nouns in turn explains the good performance of entity-density features, based primarily on nouns. In general, our selected POS features appear to be more correlated to text complexity than syntactic features, shallow features and most discourse features.

For parsed syntactic features, we found that verb phrases appear to be more closely correlated with text complexity than other types of phrases. While SBARs are commonly perceived as good predictors for syntactic complexity, they did not prove very useful for predicting grade levels of texts in this study. In future work, we plan to examine this result in more detail.

Among the 8 shallow features, which are used in various traditional readability formulas, we identified that average sentence length has dominating predictive power over all other lexical or syllable-based features.

Not surprisingly, among language modeling features, combined features obtained from LMs trained directly on the Weekly Reader corpus show high discriminative power, compared with features from LMs trained on unrelated corpora.

Discourse features do not seem to be very useful in building an accurate readability metric. The reason could lie in the fact that the texts in the corpus we studied exhibit relatively low complexity, since they are aimed at primary-school students. In future work, we plan to investigate whether these discourse features exhibit different discriminative power for texts at higher grade levels.

A judicious combination of features examined here results in a significant improvement over the state of the art.

Abstract

In statistical machine translation, decoding without any reordering constraint is an NP-hard problem. Inversion Transduction Grammars (ITGs) exploit linguistic structure and can well balance the needed flexibility against complexity constraints. Currently, translation models with ITG constraints usually employs the cube-time CYK algorithm. In this paper, we present a shift-reduce decoding algorithm that can generate ITG-legal translation from left to right in linear time. This algorithm runs in a *reduce-eager* style and is suited to phrase-based models. Using the state-of-the-art decoder Moses as the baseline, experiment results show that the shift-reduce algorithm can significantly improve both the accuracy and the speed on different test sets.

1 Introduction

In statistical machine translation, for the diversity of natural languages, the word order of source and target language may differ and searching through all possible translations is NP-hard (Knight, 1999). So some measures have to be taken to reduce search space: either using a search algorithm with pruning technique or restricting possible reorderings.

Currently, beam search is widely used (Tillmann and Ney, 2003; Koehn, 2004) to reduce search space. However, the pruning technique adopted by this algorithm is not risk-free. As a result, the best partial translation may be ruled out during pruning. The more aggressive the pruning is, the more likely the best translation escapes. There should be a tradeoff between the speed and the accuracy. If some heuristic knowledge is employed to guide the search, the search algorithm can discard some implausible hypotheses in advance and focus on more possible ones.

Inversion Transduction Grammars (ITGs) permit a minimal extra degree of ordering flexibility and are particularly well suited to modeling ordering shifts between languages (Wu, 1996; Wu, 1997). They can well balance the needed flexibility against complexity constraints. Recently, ITG has been successfully applied to statistical machine translation (Zens and Ney, 2003; Zens et al., 2004; Xiong et al., 2006). However, ITG generally employs the expensive CYK parsing algorithm which runs in cube time. In addition, the CYK algorithm can not calculate language model exactly in the process of decoding, as it can not catch the full history context of the left words in a hypothesis.

In this paper, we introduce a shift-reduce decoding algorithm with ITG constraints which runs in a left-to-right manner. This algorithm parses source words in the order of their corresponding translations on the target side. In the meantime, it gives all candidate ITG-legal reorderings. The shift-reduce algorithm is different from the CYK algorithm, in particular:

- It produces translation in a left-to-right manner. As a result, language model probability can be calculated more precisely in the light of full history context.

- It decodes much faster. Applied with distor-

Coling 2008: Poster Volume, pages 285–293,
Beijing, August 2010

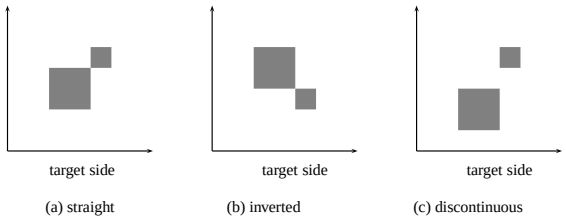

Figure 1: Orientation of two blocks.

tion limit, shift-reduce decoding algorithm can run in linear time, while the CYK runs in cube time.

- It holds ITG structures generated during decoding. That is to say, it can directly give ITG-legal spans, which leads to faster decoding. Furthermore, it can be extended to syntax-based models.

We evaluated the performance of the shift-reduce decoding algorithm by adding ITG constraints to the state-of-the-art decoder Moses. We did experiments on three data sets: NIST MT08 data set, NIST MT05 data set and China Workshop on Machine Translation 2007 data set. Compared to Moses, the improvements of the accuracy are 1.59, 0.62, 0.8 BLEU score, respectively, and the speed improvements are 15%, 24%, 30%, respectively.

2 Decoding with ITG constraints

In this paper, we employ the shift-reduce algorithm to add ITG constraints to phrase-based machine translation model. It is different from the traditional shift-reduce algorithm used in natural language parsing. On one hand, as natural language parsing has to cope with a high degree of ambiguity, it need take ambiguity into consideration. As a result, the traditional one often suffers *shift-reduce* divergence. Nonetheless, the shift-reduce algorithm in this paper does not pay attention to ambiguity and acts in a *reduce-eager* manner. On the other hand, the traditional algorithm can not ensure that all reorderings observe ITG constraints, so we have to modify the traditional algorithm to import ITG constraints.

We will introduce the shift-reduce decoding algorithm in the following two steps: First, we will deduce how to integrate the shift-reduce algorithm and ITG constraints and show its correctness (Section 2.1). Second, we will describe the shift-reduce decoding algorithm in details (Section 2.2).

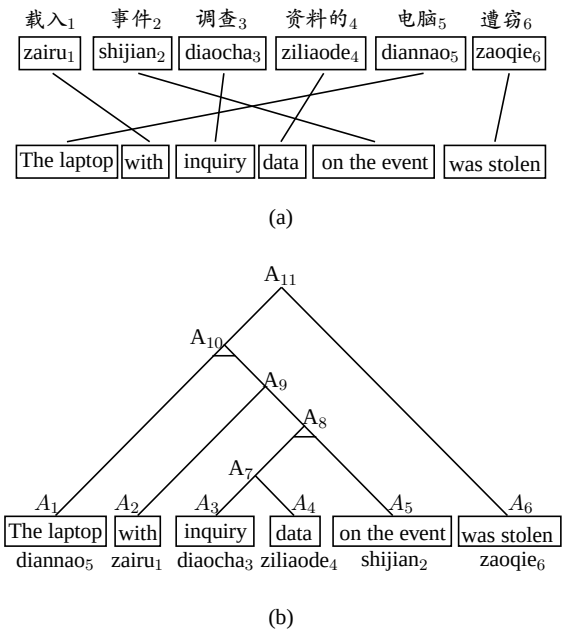

Figure 2: A Chinese-to-English sentence pair and its corresponding ITG tree.

2.1 Adding ITG constraints

In the process of decoding, a source phrase is regarded as a block and a source sentence is seen as a sequence of blocks. The orientation of two blocks whose translations are adjacent on the target side can be straight, inverted or discontinuous, as shown in Figure 1. According to ITG, two blocks which are straight or inverted can be merged into a single block. For parsing, different mergence order of a sequence of continuous blocks may yield different derivations. In contrast, the phrase-based machine translation does not compute reordering probabilities hierarchically, so the mergence order will not impact the computation of reordering probabilities. As a result, the shift-reduce decoding algorithm need not take into consideration the shift-reduce divergence. It merges two continuous blocks as soon as possible, acting in a reduce-eager style.

Every ITG-legal sentence pair has a corre-

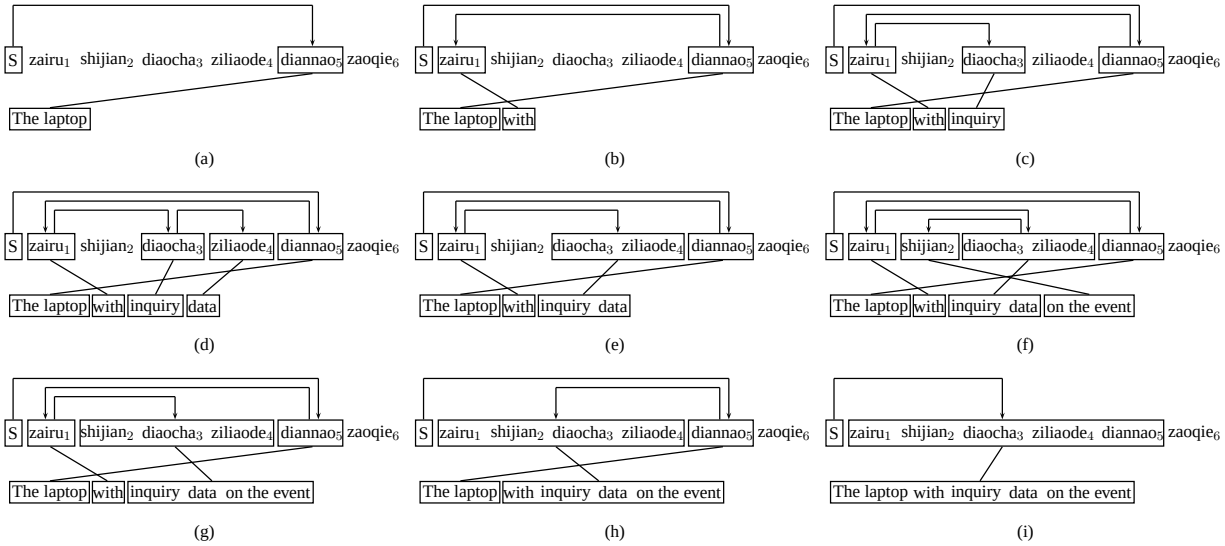

Figure 3: The partial translation procedure of the sentence in Figure 2.

sponding ITG tree, and source words covered by every node (eg. $A1, ..., A_{11}$ in Figure 2(b)) in the ITG tree can be seen as a block. By watching the tree in Figure 2, we can find that a block must be adjacent to the block either on its left or on its right, then they can be merged into a larger block. For example, A_2 matches the block $[zairu_1]$ and A_8 matches the block $[shijian_2\ diaocha_3\ ziliaode_4]$.[1] The two blocks are adjacent and they are merged into a larger block $[zairu_1\ shijian_2\ diaocha_3\ ziliaode_4]$, covered by A_9. The procedure of translating $zairu_1\ shijian_2\ diaocha_3\ ziliaode_4\ diannao_5$ is illustrated in Figure 3.

For a hypothesis during decoding, we assign it three factors: the current block, the left neighboring uncovered span and the right neighboring uncovered span. For example, in Figure 3(c), the current block is $[diaocha_3]$ and the left neighboring uncovered span is $[shijian_2]$ and the right neighboring uncovered span is $[ziliaode_4]$. $[zaoqie_6]$ is not thought of as the right neighboring block, for it is not adjacent to $[diaocha_3]$. The next covered block is $[ziliaode_4]$ (as shown in Figure 3(d)). For $[diaocha_3]$ and $[ziliaode_4]$ are adjacent, they are merged. In Figure 3(e), the current block is $[diaocha_3\ ziliaode_4]$.

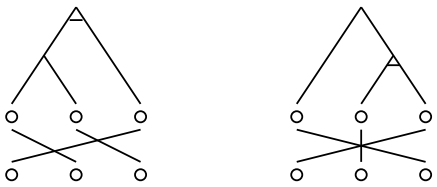
A sentence is translated with ITG constraints iff its source side can be covered by an ITG tree. That is to say, for every hypothesis during decoding, the next block to cover must be selected from the left or right neighboring uncovered span.

First, we show that if the next block to cover is selected in this way, the translation must observe ITG constraints. For every hypothesis during decoding, the immediate left and right words of the current block face the following three conditions:

(1) The immediately left word is not covered and the immediately right word is covered, then the next block to cover must be selected from the left neighboring uncovered span, eg. for the current block $[diaocha_3\ ziliaode_4]$ in Figure 3(e). In this condition, the ITG tree can be constructed in the following two ways: either all words in the left neighboring uncovered span are translated first, then this span is merged with the current span (taking three nodes as an example, this case is shown in Figure 4(a)), or the right part of the left neighboring uncovered span is merged with the current block first, then the new block is merged with the rest part of the left neighboring uncovered span (shown in Figure 4(b)). In a word, only after all words in the left neighboring uncovered span are covered, other words can be covered.

(2) The immediately right word is not covered and the immediately left word is covered. Similarly, only after all words in the right neighboring uncovered span are covered, other words can be

[1]The words within a block are sorted by their order in the source sentence.



(a) (b)

Figure 4: The two ways that the current block is merged with its left neighboring uncovered span. The third node in the first row denotes the current block, the first and second nodes in the first row denote left and right parts of the left neighboring uncovered span, respectively.

covered.

(3) The immediately left and right words are neither covered. The next block can be selected from either the left or the right neighboring uncovered span until the immediate left or right word is covered.

The above operations can be performed recursively until the whole source sentence is merged into a single block, so the reordering observes ITG constraints.

Now, we show that translation which is not generated in the above way must violate ITG constraints.

If the next block is selected out of the neighboring uncovered spans, the current block can be neither adjacent to the last covered block nor adjacent to the selected next block, so the current block can not be merged with any block and the whole sentence can not be covered by an ITG tree. As in Figure 3(b), if the next block to cover is $[zaoqie_6]$, then $[zairu_1]$ is neither adjacent to $[diannao_5]$ nor adjacent to $[zaoqie_6]$.

We can conclude that if we select the next block from the left or right neighboring uncovered span of the current block, then the translation must observe ITG constraints.

2.2 Shift-Reduce Decoding Algorithm

In order to generate the translation with ITG constraints, the shift-reduce algorithm have to keep trace of covered blocks, left and right neighboring uncovered spans. Formally, the shift-reduce decoding algorithm uses the following three stacks:

- S_t: the stack for covered blocks. The blocks are pushed in the order that they are covered, not the order that they are in the source sentence.

- S_l : the stack for the left uncovered spans of the current block. When a block is pushed into S_t, its corresponding left neighboring uncovered span is pushed into S_l.

- S_r :the stack for the right uncovered spans of the current block. When a block is pushed into S_t, its corresponding right neighboring uncovered span is pushed into S_r.

A translation configuration is a triple $c = \langle S_t,\ S_l,\ S_r \rangle$. Given a source sentence $f = f_1, f_2, ..., f_m$, we import a virtual start word and the whole translation procedure can be seen as a sequence of transitions from c_s to c_t, where $c_s = \langle [0],\ \emptyset,\ [1, m] \rangle$ is the initial configuration, $c_t = \langle [0, m],\ \emptyset,\ \emptyset \rangle$ is the terminal configuration. The configuration for Figure 3 (e) is $\langle [0][5][1][3, 4],\ [2],\ [6] \rangle$.

We define three types of transitions from a configuration to another . Assume the current configuration $c = \langle\ [f_{t_1 1}, f_{t_1 2}]...[f_{t_k 1}, f_{t_k 2}],\ [f_{l_1 1}, f_{l_1 2}]...[f_{l_u 1}, f_{l_u 2}],\ [f_{r_v 1}, f_{r_v 2}]...[f_{r 1 1}, f_{r 1 2}]\ \rangle$, then :

- Transitions *LShift* pop the top element $[f_{l_u 1}, f_{l_u 2}]$ from S_l and select a block $[i, j]$ from $[f_{l_u 1}, f_{l_u 2}]$ to translate. In addition, they push $[i, j]$ into S_t, and if $i \neq f_{l_u 1}$, they push $[f_{l_u 1}, i - 1]$ into S_l, and if $j \neq f_{l_u 2}$, they push $[j + 1, f_{l_u 2}]$ into S_r. The precondition to operate the transition is that S_l is not null and the top span of S_l is adjacent to the top block of S_t. Formally, the precondition is $f_{l_u 2} + 1 = f_{t_k 1}$.

- Transitions *RShift* pop the top element $[f_{r_v 1}, f_{r_v 2}]$ of S_r and select a block $[i, j]$ from $[f_{r_v 1}, f_{r_v 2}]$ to translate. In addition, they push $[i, j]$ into S_t, and if $i \neq f_{r_v 1}$, they push $[f_{r_v 1}, i-1]$ into S_l, and if $j \neq f_{r_v 2}$, they push $[j + 1, f_{r_v 2}]$ into S_r. The precondition is that S_r is not null and the top span of S_r is

adjacent to the top block of S_t. Formally, the precondition is $f_{t_k 2} + 1 = f_{r_v 1}$.

- Transitions *Reduce* pop the top two blocks $[f_{t_{k-1}1}, f_{t_{k-1}2}]$, $[f_{t_k 1}, f_{t_k 2}]$ from S_t and push the merged span $[f_{t_{k-1}1}, f_{t_k 2}]$ into S_t. The precondition is that the top two blocks are adjacent. Formally, the precondition is $f_{t_{k-1}2} + 1 = f_{t_k 1}$

The transition sequence of the example in Figure 2 is listed in Figure 5. For the purpose of efficiency, transitions *Reduce* are integrated with transitions *LShift* and *RShift* in practical implementation. Before transitions *LShift* and *RShift* push $[i, j]$ into S_t, they check whether $[i, j]$ is adjacent to the top block of S_t. If so, they change the top block into the merged block directly.

In practical implementation, in order to further restrict search space, distortion limit is applied besides ITG constraints: a source phrase can be covered next only when it is ITG-legal and its distortion does not exceed distortion limit. The distortion d is calculated by $d = |start_i - end_{i-1} - 1|$, where $start_i$ is the start position of the current phrase and end_{i-1} is the last position of the last translated phrase.

Transition	S_t	S_l	S_r
	$[0]$	$\emptyset$	$[1,6]$
RShift	$[0][5]$	$[1,4]$	$[6]$
LShift	$[0][5][1]$	$\emptyset$	$[2,4][6]$
RShift	$[0][5][1][3]$	$[2]$	$[4][6]$
RShift	$[0][5][1][3][4]$	$[2]$	$[6]$
Reduce	$[0][5][1][3,4]$	$[2]$	$[6]$
LShift	$[0][5][1][3,4][2]$	$\emptyset$	$[6]$
Reduce	$[0][5][1][2,4]$	$\emptyset$	$[6]$
Reduce	$[0][5][1,4]$	$\emptyset$	$[6]$
Reduce	$[0][1,5]$	$\emptyset$	$[6]$
Reduce	$[0,5]$	$\emptyset$	$[6]$
RShift	$[0,5][6]$	$\emptyset$	$\emptyset$
Reduce	$[0,6]$	$\emptyset$	$\emptyset$

3 Related Work

Galley and Manning (2008) present a hierarchical phrase reordering model aimed at improving non-local reorderings. Via the hierarchical mergence of two blocks, the orientation of long distance words can be computed. Their shift-reduce algorithm does not import ITG constraints and admits the translation violating ITG constraints.

Zens et al. (2004) introduce a left-to-right decoding algorithm with ITG constraints on the alignment template system (Och et al., 1999). Their algorithm processes candidate source phrases one by one through the whole search space and checks if the candidate phrase complies with ITG constraints. Besides, their algorithm checks validity via cover vector and does not formalize ITG structure. The shift-reduce decoding algorithm holds ITG structure via three stacks. As a result, it can offer ITG-legal spans directly and decode faster. Furthermore, with the help of ITG structure, it can be extended to syntax-based models easily.

Xiong et al. (2006) propose a BTG-based model, which uses the context to determine the orientation of two adjacent spans. It employs the cube-time CYK algorithm.

4 Experiments

We compare the shift-reduce decoder with the state-of-the-art decoder Moses (Koehn et al., 2007). The shift-reduce decoder was implemented by modifying the normal search algorithm of Moses to our shift-reduce algorithm, without cube pruning (Huang and Chiang, 2005). We retained the features of Moses: four translation features, three lexical reordering features (straight, inverted and discontinuous), linear distortion, phrase penalty, word penalty and language model, without importing any new feature. The decoding configurations used by all the decoders, including beam size, phrase table limit and so on, were the same, so the performance was compared **fairly**.

First, we will show the performance of shift-reduce algorithm on three data sets with large training data sets (Section 4.1). Then, we will analyze the performance elaborately in terms of accuracy, speed and search ability with a smaller

training data set (Section 4.2). All experiments were done on Chinese-to-English translation tasks and all results are reported with case insensitive BLEU score. Statistical significance were computed using the sign-test described in Collins et al. (Collins et al., 2005).

4.1 Performance Evaluation

We did three experiments to compare the performance of the shift-reduce decoder, Moses and the decoder with ITG constraints using cover vector (denoted as CV). [2] The shift-reduce decoder decoded with two sets of parameters: one was tuned by itself (denoted as SR) and the other was tuned by Moses (denoted as SR-same), using MERT (Och, 2003). Two searching algorithms of Moses are considered: one is the normal search algorithm without cubing pruning (denoted as Moses), the other is the search algorithm with cube pruning (denoted as Moses-cb). For all the decoders, the distortion limit was set to 6, the nbest size was set to 100 and the phrase table limit was 50.

In the first experiment, the development set is part of NIST MT06 data set including 862 sentences, the test set is NIST MT08 data set and the training data set contains 5 million sentence pairs. We used a 5-gram language model which were trained on the Xinhua and AFP portion of the Gigaword corpus. The results are shown in Table 1(a).

In the second experiment, the development data set is NIST MT02 data set and the test set is NIST MT05 data set. Language model and the training data set are the same to that of the first experiment. The result is shown in Table 1(b).

In the third experiment, the development set is China Workshop on Machine Translation 2008 data set (denoted as CWMT08) and the test set is China Workshop on Machine Translation 2007 data set (denoted as CWMT07). The training set contains 2 Million sentence pairs and the language model are a 6-gram language model trained on the Reuter corpus and English corpus. Table 1(c) gives the results.

In the above three experiments, SR decoder improves the accuracy by 1.59, 0.62, 0.8 BLEU score ($p < .01$), respectively, and improves the speed by 15%, 24%, 30%, respectively. we can see that SR can improve both the accuracy and the speed while SR-same can increase the speed significantly with a slight improvement on the accuracy. As both SR and CV decode with ITG constraints, they match each other on the accu-

[2]The decoder CV is implemented by adding the ITG constraints to Moses using the algorithm described in (Zens et al., 2004).

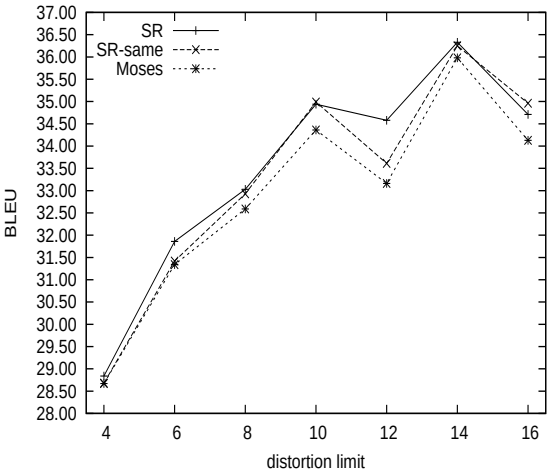
racy. However, the speed of SR is faster than CV. Cube pruning can improve decoding speed dramatically, but it is not risk-free pruning technology, so the BLEU score declines obviously.

4.2 Performance Analysis

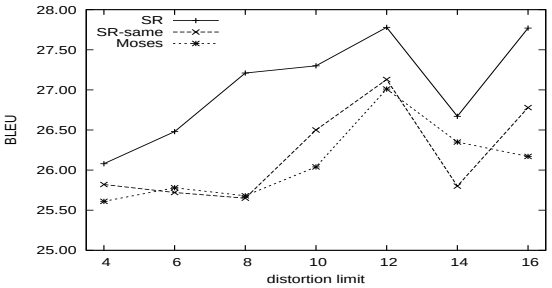
We make performance analysis with the same experiment configuration as the second experiment in Section 4.1, except that the training set in the analysis experiment is FBIS corpus, including 289k sentence pairs. In the following experiments, Moses employs the normal search algorithm without cube pruning.

For the decoders employ the linear distortion feature, the distortion limit will influence the translation accuracy. Besides, with different distortion limit, the proportion of ITG-legal translation generated by Moses will differ. The smaller the distortion limit is, the greater the proportion is. So we first compare the performance with different distortion limit.

We compare the shift-reduce decoder with Moses using different distortion limit. The results are shown in Figure 6. When distortion limit is set to 6, every decoder gets a peak value and SR has an improvement of 0.66 BLEU score over Moses. From the curves, we can see that the BLEU score of SR-same with distortion limit 8



(a) ITG set



(b) rest set

Figure 7: Accuracy comparison on the ITG set and rest set of NIST05. The ITG set includes the sentences the translations of which generated by Moses are ITG-legal, and the rest set contains the rest sentences. distortion limit $= 16$ denotes no distortion limit.

is lower than that of Mose with distortion limit 6. This is because the decoding speed of SR-same with distortion limit 8 is not faster than that of Moses with distortion limit 6. On the whole, compared to Moses, SR-same can improve the accuracy slightly with much faster decoding speed, and SR can obtain improvements on both the accuracy and the speed.

We split the test set into two sets: one contains the sentences, the translations of which generated by Moses are ITG-legal (denoted as ITG set) and the other contains the rest (denoted as rest set). From Figure 7, we can see that no matter on the ITG set or on the rest set, SR decoder can gain obvious accuracy improvements with all distortion

d	ITG						rest					
	Moses	SR-same	total	$<$	$=$	$>$	Moses	SR-same	total	$<$	$=$	$>$
4	28.67	28.68	1050	8	1042	0	25.61	25.82	32	0	0	32
6	31.34	31.42	758	51	705	2	25.78	25.72	324	32	2	290
8	32.59	32.93*	594	72	516	6	25.68	25.65	488	82	3	403
10	34.36	34.99**	456	80	365	11	26.04	26.50*	626	147	3	476
12	33.16	33.61**	454	63	380	11	27.01	27.13	628	165	1	462
14	35.98	36.25*	383	60	316	7	26.35	26.67*	699	203	1	495
-1	34.13	34.96**	351	39	308	4	26.17	26.78**	731	154	0	577

Table 2: Search ability comparison. The ITG set and the rest set of NIST05 were tested, respectively. On the ITG set, the following six factors are reported from left to right: BLEU score of Moses, BLEU score of SR-same, the number of sentences in the ITG set, the number of sentences the translation probabilities of which computed by Moses, compared to that computed by SR, is lower, equal and greater. The rest set goes similarly. *: significance at the .05 level, **: significance at the .01 level.

limit. While SR-same decoder only gets better results on the ITG set with all distortion limit. This may result from the use of the linear distortion feature. Moses may generate hypotheses the distortion of which is forbidden in the shift-reduce decoder. This especially sharpens on the rest set. So SR-same may suffer from an improper linear distortion parameter.

The search ability of Moses and the shift-reduce decoder are evaluated, too. The translation must be produced with the same set of parameters. In our experiments, we employed the parameters tuned by Moses. The test was done on the ITG and the rest set, respectively. The results are shown in Table 2. As the distortion limit becomes greater, the number of the ITG-legal translation generated by Moses becomes smaller. On the ITG set, translation probabilities from the shift-reduce decoder is either greater or equal to that from Moses on most sentences, and BLEU scores of shift-reduce decoder is greater than that of Moses with all distortion limit. Although the search space of shift-reduce decoder is smaller than that of Moses, shift-reduce decoder can give the translation that Moses can not reach. On the rest set, for most sentences, the translation probabilities from Moses is greater than that from shift-reduce decoder. But only when distortion limit is 6 and 8, the BLEU score of Moses is greater than that of the shift-reduce decoder. We may conclude that greater score does not certainly lead to greater BLEU score.

5 Conclusions and Future Work

In this paper, we present a shift-reduce decoding algorithm for phrase-based translation model that can generate the ITG-legal translation in linear time. The algorithm need not consider shift-reduce divergence and performs *reduce* operation as soon as possible. We compare the performance of the shift-reduce decoder with the state-of-the-art decoder Moses. Experiment results show that the shift-reduce algorithm can improve both the accuracy and the speed significantly on different test sets. We further analyze the performance and find that on the ITG set, the shift-reduce decoder is superior over Moses in terms of accuracy, speed and search ability, while on the rest set, it does not display advantage, suffering from improper parameters.

Next, we will extend the shift-reduce algorithm to syntax-based translation models, to see whether it works.

Abstract

A new approach has been developed for acquiring bilingual web pages from the result pages of search engines, which is composed of two challenging tasks. The first task is to detect web records embedded in the result pages automatically via a clustering method of a sample page. Identifying these useful records through the clustering method allows the generation of highly effective features for the next task which is high-quality bilingual web page acquisition. The task of high-quality bilingual web page acquisition is a classification problem. One advantage of our approach is that it is search engine and domain independent. The test is based on 2516 records extracted from six search engines automatically and annotated manually, which gets a high precision of 81.3% and a recall of 94.93%. The experimental results indicate that our approach is very effective.

1 Introduction

There have been extensive studies on parallel resource extraction from parallel monolingual web pages of some bilingual web sites (Chen and Nie, 2000; Resnik and Smith, 2003; Zhang et al., 2006; Shi et al., 2006). Candidate parallel web pages are acquired by making use of URL strings or HTML tags, then the translation equivalence of the candidate pairs are verified via content-based features.

However, we observe that bilingual resources may exist not only in two parallel monolingual web pages, but also in single bilingual web pages. For example, many news web pages and English learning pages are bilingual. Based on this observation, researchers have proposed methods to improve parallel sentences extraction within a bilingual web page. Jiang (2009) uses an adaptive pattern-based method to mine interesting bilingual data based on the observation that bilingual data usually appears collectively following similar patterns. Because the World Wide Web is composed of billions of pages, it is a challenging task to locate valuable bilingual pages.

To acquire bilingual web pages automatically, a novel and effective method is proposed in this paper by making use of search engines, such as Baidu (http://www.baidu.com). By submitting parallel sentence pairs to the given search engine, lots of result pages with web records are returned, most of which are linked to bilingual web pages. We first identify and extract all result records automatically by selecting and analyzing a sample page with a clustering method, and then select high-quality bilingual web pages from candidates with classification algorithms.

Our method has the following advantages:

1. Former researchers extract parallel corpus from specific bilingual web sites. Since search engines index amounts of web pages, and we aim to acquire bilingual pages based on them, our method expands the corpus source greatly.

2. For one search engine, only one sample result page is used to generate the record wrapper. Then the wrapper is used to identify web records from other result pages of the same search engine. Compared with existing data record extraction technologies, such as MDR (Liu et al., 2003; Zhai and Liu, 2006), our method is more effective and efficient.

Coling 2008: Poster Volume, pages 294–302,
Beijing, August 2010

3. We model the issue of verification bilingual pages as a binary-class classification problem. The records acquired automatically and annotated manually are utilized to train and test the classifier. This work is domain and search engine independent. That is to say, the records acquired from any search engine in any domain are used indiscriminately as training and testing dataset.

The rest of the paper is organized as follows. Related works are introduced in section 2. Section 3 provides an overview of our solution. The work about bilingual page acquisition and verification is introduced in section 4 and 5. Section 6 presents the experiments and results. Finally section 7 concludes the paper.

2 Related Work

As far as we know, there is no publication available on acquiring bilingual web pages. Most existing studies, such as Nie (1999), Resnik and Smith (2003) and Shi (2006), mine parallel web documents within bilingual web sites first and then extract bilingual sentences from mined parallel documents using sentence alignment method.

In this paper, the candidate bilingual web pages are acquired by analyzing web records embedded in the search engines' result pages. Therefore, record extraction from result pages is a critical technique in our method. Many researches, such as Laender (2002), have been developed various solutions in web information extraction from kinds of perspectives.

Earlier web information extraction systems (Baumgartner et al., 2001; Liu et al., 2000; Zhai and Liu, 2005) require users to provide labeled data so that the extraction rules could be learned. Yet such semi-automatic methods are not scalable enough to the whole Web which changes at any time. That's why more and more researchers focus on fully or nearly fully automatic solutions.

Structured data objects are normally database records retrieved from underlying web databases and displayed on the web pages with some fixed templates, so automatic extraction methods try to find such patterns and use them to extract more data. Several approaches have succeeded to address the problem automatically without human assistance. IEPAD (Chang and Lui, 2001) identifies sub-strings that appear many times in a document. By traversing the DOM tree of the Web page, MDR extracts the data-rich sub-tree indirectly by detecting the existence of multiple similar generalized-nodes. The key limitation is its greedy manner of identifying a data region. DEPTA (Zhai and Liu, 2005) uses visual information (locations on the screen at which the tags are rendered) to infer the structural relationship among tags and to construct a tag tree. NET (Liu and Zhai, 2005) extracts flat or nested data records by post-order or pre-order traversal of the tag tree. ViNTs (Zhao et al., 2005) considers the web page as a tag tree, and utilizes both visual content features as well as tag tree structures. It assumes that data records are located in a minimum data-rich sub-tree and separated by separators of tag forests. Zhao (2006) explicitly aims at extracting all dynamic sections from web pages, and extracting records in each section, whereas ViNTs focuses on record extraction from a single section. Miao (2009) figures out how tag paths format the whole page. Compared with the previous method, it compares pairs of tag path occurrence patterns to estimate how likely these tag paths represent the same list of objects instead of comparing one pair of individual sub-trees in the record. It brings some noise. We follow this method and make appropriate improvement for our task.

3 Basic Concepts and Overview

3.1 Basic Concepts

Some basic concepts are introduced below.

Figure 1. An example of search engine return

Tag Path: The path of a tag consists of all nodes from the tree root <html> to itself. We use tag path to specify the location of the tag. The tag paths are classified into two types: text tag paths and non-text tag paths.

Data Record: When a page is considered as strings of tokens, data records are enwrapped by one or more tag paths, which compose the visually repeating pattern in a page. This paper aims to extract such structured data records that are produced by computer programs following some fixed templates, while whose contents are usually retrieved from backend databases. For example, there are four records in Figure 1.

3.2 Method Overview

We can get much more bilingual web pages by submitting parallel sentence pairs to the search engine than submitting monolingual queries. Based on this observation, our work is as shown in Figure 2. The algorithm consists of two steps: 1) Record wrapper generation. By submitting parallel sentence pairs to search engines, result pages containing lots of web records are returned. In order to generate record wrappers, we select and analyze a sample page and then apply clustering method to tag paths with similar patterns. We apply these wrappers to extract more records, which are linked to candidate bilingual web pages. 2) High-quality bilingual page acquisition. In order to acquire high-quality bilingual pages from candidates, a binary classifier is constructed to decide whether the candidate pages are bilingual or not. In order to improve the classifier, some useful resources are used, such as a dictionary and translation equivalents.

However, a result page often contains some information irrelevant to the query, such as information related to the hosting site of the search engine, which increases the difficulty of record extraction. Besides, there are also many irrelevant records irrelevant to the query. So our focus is to acquire plenty of features to filter out the irrelevant pages from the candidates.

In this paper, the first result page is chosen as the sample page and Affinity Propagation (AP) clustering is used. The reason lies in Frey and Dueck (2007), which proves that to produce the groups of tag paths; the AP algorithm does not require the three restrictions: 1) the samples must be of a specific kind, 2) the similarity values must be in a specific range, and 3) the similarity matrix must be symmetric. In order to decide the type of a page, the Support Vector Machines (SVM) (Cortes and Vapnik, 1995) classifier on Fuzzy C-means is constructed combining with word-overlap, length and frequency measures. SVM is well-fitted to treat such classification problems that involve interrelated features likes ours, while most probabilistic classifiers, such as Naïve Bayes classifier, strongly assume feature independence (DuVerle and Prendinger, 2009).

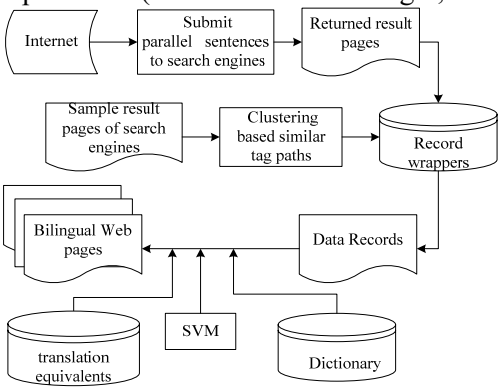

Figure 2. Overview of the method

4 Bilingual Page Acquisition

4.1 Result Page Extraction

The result pages of a search engine consist of a ranked list of document summaries linked to the actual documents or web pages. A web document summary typically contains the title and URL of the web page, links to live and cached versions of the page and, most importantly, a short text summary, or a snippet, to convey the contents of the page. Such snippets embedded in result pages of search engines are query-dependent summaries. White (2001) finds the result pages are sensitive to the content and language of the query. If the query is monolingual, the returned search results are mostly monolingual, while the result pages are bilingual if the query is bilingual. In order to acquire more bilingual web pages, we submit parallel translation pairs. Figure 1 gives an example result page from Baidu, in which the snapshot consists of four records related to the query, which consists of "I see." and its translation "我明白了。". The results have

more effective advantages than submitting the query "I see." or "我明白了。" respectively.

4.2 Clustering With Path Similarity

Given a web page, we get the occurrence positions of each tag path the same as the sequence in the preorder traversal of the page's DOM tree. Certainly, there are many tag paths which appear several times in the whole page. So an inverted mapping from HTML tag paths to their positions is built easily. For example, there are 599 tag paths formatting the sample page in Figure 1, and after the inverted mapping, we acquire 86 unique tag paths in all. Only tick off one part of the results as shown in Table 1, where P_i represents the *ith* unique tag path, and the vector S_i is defined to store the occurrence positions of P_i in the third column.

As introduced above, detecting visually repeating tag paths is a clustering problem. Above all, a factor in determining the clustering performance is the choice of similarity functions, which captures the likelihood that two data samples belong to the same cluster. In our case, the similarity scores between two tag paths aim to capture how their positions are close to each other and how they interleave each other.

With the purpose of characterizing how close two tag paths appear, we only acquire the distance between paths' average positions, which is easy to obtain by the acquired occurrence vectors. For example, the average position of P_{11} and P_{15} in Table 1 is 227 and 215, so the distance between them is 12.

i	Unique Tag Path (P_i)	Occurrences (S_i) of P_i
1	\html	1
3	\html\head\#text	3,4,7,8,9
9	\html\body\table	84,93,115,146,180, 217,258,292,335,372, 406,437
11	\html\body\table\tr	15,85,94,116,147,181, 218,259,293,336,373, 407,438
14	\html\body\table\tr \td\#text	18,21,24,27,55,79,87, 91,97,111,113
15	\html\body\table\tr \td\a	19,88,118,149,183, 220,261,295,338,375, 409,440

Table 1. Unique tag paths of the sample page

However, the most difficult problem is how to capture the interleaving characteristic between two tag paths. Before doing that, another vector O_i is produced. $O_i(k)$ indicates whether the tag path P_i occurs in the position k or not by its value. In addition, the value is binary that 0 or 1, and 0 shows P_i doesn't occur in the position k, while 1 shows the opposite. Of particular note, the length of each O_i is equal to the total number of HTML tags that formatting the whole web page. Take the tag path P_3 ("\html\head\#text") in Table 1 as an example, whose position vector O_3 is (0, 0, 1, 1, 0, 0, 1, 1, 1, 0… 0), and the vector's length is 599, because there are totally 599 tag paths formatting the sample page in Figure 1.

Based on the position vectors, we capture how tag path P_i and P_j interleave each other by a segment D_{O_i/O_j} of O_i divided by O_j. We aim to find such tag paths that divide each other in average. In other words if the variance of counts in the segment D_{O_i/O_j} is stable, they are likely to be grouped in the same cluster. So, we define the interleaving measure μ in terms of the variances of D_{O_i/O_j} and D_{O_j/O_i} as:

$$\mu(O_i,O_j)=\max\{Var(D_{O_i/O_j}),Var(D_{O_j/O_i})\} \quad (1)$$

where D_{O_i/O_j} is acquired by O_j as follows: if value of $O_j(k)$ is 1, $O_i(k)$ is a separator to segment itself into several regions. The value of every element in the segment is the count of P_i that occurs in every region, which is the number of 1 in the region.

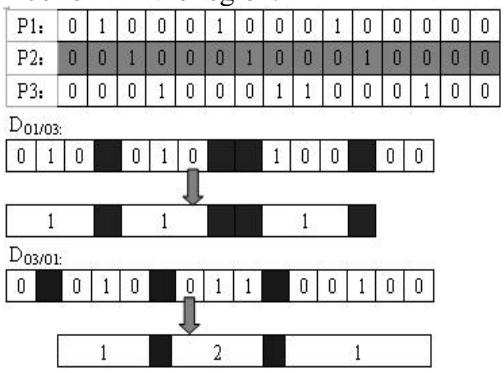

Figure 3. An Example of tag paths

In addition, there may be many consecutive separators in O_i, and we integrate them into one. Besides, the segment is a non-empty set. So if there is no occurrence of P_i in one region, we

will ignore this special region. Figure 3 shows three tag paths. P_1 and P_2 are likely to belong to the same cluster because of their regular occurrences, whereas the occurrences of P_3 are comparatively irregular. By our method, D_{O_1/O_3} = {1, 1, 1} and D_{O_3/O_1} = {1, 2, 1}. We integrate separators once and ignore an empty region in the process of getting D_{O_1/O_3}.

Both the score of the closeness measure and the interleaving measure for any two tag paths are non-negative real numbers. And a smaller value of either measure indicates a high frequency that the two tag paths appear regularly. The measure $\sigma(P_i, P_j)$ defined below is inversely proportional of these two measures.

$$\sigma(P_i, P_j) = \frac{\varepsilon}{c(S_i, S_j) \times \mu(O_i, O_j) + \varepsilon} \quad (2)$$

where ε is a non-negative term that avoids dividing by 0 and normalizes the similarity value so that it falls into the range (0, 1]. In our experiment, we choose ε = 10. By Equation 2, we calculate the similarity value of any pair of tag paths. As expected, the pairwise similarity matrix is fed into the AP clustering algorithm directly, and each cluster acquired from AP clustering contains *n* tag paths, which indicates that those *n* paths appear repeatedly together with high frequency, and the tag paths that have no remarkable relation are spilt into different clusters. For the given sample page in Figure 1, the number of identified clusters is 16.

We observe that HTML code of most data records contain more than three HTML tags, so we only examine the clusters containing four or more visual signals. In the clustering result of sample page in Figure 1, there are three clusters' sizes less than four. Meanwhile, we also note that:

1. The feature page of a common search engine usually contains 10 or more web records with similar layout pattern. So we define a threshold T=3. If an ancestor tag path doesn't occur more than T times, we believe these tag path dose not lead a record.
2. Usually the content of the result pages returned by search engines is completely related to the queries, which means the data records that we are interested in are distributed in the whole page as main component. So the occurrence position of valuable tag paths must be global optimization. In this paper, the scope between beginning and ending occurrence must be wider than three quarters of the length of the web page.

Thus, we get essential clusters fit with above observations, which is denoted by C= {C_1, C_2…C_M}. Once we have the essential clusters, we apply them in new web page of the same search engine to identify data records.

4.3 Data Record Extraction

Based on the essential clusters, we extract the exact data records from the real content of text tag path that follow the ancestor tag path.

In order to describe the extraction process in details, we firstly define D_{aI} as the child tag paths of an ancestor tag path P_a, and suppose that (Pos_1… Pos_i… Pos_m) is the occurrence vector of P_a, which means at each position Pos_i the tag path P_i occurs. $D_{a(i)}$ is such a tag path set that the position Pos of every path in it is $Pos_i < Pos < Pos_{i+1}$. In the meantime, such path strings must begin with the same prefix of P_a. Such as in Table 2, $D_{a\ (i)}$ contains tag paths from Pos_i to Pos_{i+1}-1, and we obtain the *ith* records embedded in the result pages by acquiring the real content of all text tag paths in $D_{a(i)}$.

Occurrence of P_a	D_{aI} of P_a	Child tag path
Pos_1		P_a:\html\body\table\tr
Pos_1+1	$D_{a(1)}$	P_t:\html\body\table\tr\…
……		……
Pos_2-1		P_k: ……

5 Bilingual Web Page Verification

Based on the previous work, we capture a list of records based on a holistic analysis of a result page, and each record contains snippets and URLs related to the query. In this section, we aim to decide whether the candidate pages that returned records are linked to are bilingual or not by putting some statistical features (collected from snippets) into an effective SVM classification.

To the acquired snippets, some necessary preprocessing is made before we acquire useful features. We remove most of the noise that affect the precision and robustness of the entire system by such methods as recovery of abbreviation words, deletion of noisy words, amendment for half or full punctuations and simplified or traditional characters, and so on.

The snippet is described with more regular contents after preprocessing. We cut the snippet into several segments by its language. Each segment of the snippet is just represented in one language, which is either English or Chinese in this paper and different from its adjacent segments. So the source snippets are transferred into such language strings that consist of C and E, where C stands for Chinese and E stands for English. It is unlikely that continuous C or E exists in the same language string. We store the real text T_c (T_e) that each C (E) stands for. We take the snippet "I see. 我明白了。I quit! 我不干了！" as example, its language string is "ECEC" and real text string is $T_eT_cT_eT_c$, where the two T_e stand for "I see" and "I quit", the two T_c stand for "我明白了" and "我不干了".

Note that different feature functions for the classifier will lead to different results, it is important to choose feature functions that will help to discriminate different classes. In this paper, the SVM classifier involves word-overlap, length and frequency features. We define these three features based on the snippet itself as follows:

(1) Word-Overlap measure

Word overlap judges the similarity of Chinese term and English term. In this paper, we acquire the word-overlap score between any two adjacent language segments. The similarity *Score(c_res,e_res)* of Chinese term and English term is based on word-overlap as following:

$$Score(c\_res, e\_res) = \frac{\sum_{i=1}^{p} Max_{1\le j\le q}(Sim(c_i, e_j))}{\phi} \quad (3)$$

where the denominator is normalization factor, and in our experiment we select $p+q$ as its value, where p stands for the length of Chinese term and q stands for the length of English term. In addition, c_i stands for the *ith* word of Chinese term and e_j stands for the *jth* word of English term. $Sim(c_i,e_j)$ in Liu (2003) and Deng (2004) stands for the similarity of Chinese word c_i and English word e_j.

In our experiment, the Chinese and English sub-snippets are equivalent to Chinese and English sentences of the bilingual pages. In the segmented snippet, with regard to each sub-snippet *T*, which is at even position in the language string, we separately evaluate the intermediate score for snippet *T* with its left and right neighbors by Equation 3. Especially when *T* doesn't have right or left neighbor, the score for *T* with its null neighbor is 0. So for every sub-snippet that needs to be scored the word-overlap score, there are two candidate scores with its adjacent neighbors. Then we choose the higher value as one item of an intermediate result vector. Either the length of the language string is $2 \times n$ or $2 \times n+1$, the length of intermediate vector is n, and the final score is computed as follows:

$$Score(s) = \frac{\sum_{k=1}^{n} InV_k}{n \times m} \quad (4)$$

where *Score(s)* stands for the final score of snippet s on the word-overlap measure, and vector *InV* is the intermediate result vector as mentioned before. The length of the vector *InV* is n, and m is the number of its items that is not equal to zero. *m/n* is used as a useful measure of length, because it indicates how many parallel pairs are there in the same snippet.

(2) Length-Based measure

We acquire three scores about length measure. Take the language string "ECECEC" as example, we use "$E_1C_1E_2C_2E_3C_3$" to replace it for simple description. We acquire one score of the length measure as follows:

$$Score\ (s) = \frac{\sum_{i=1}^{m} (Len\ (c) + Len\ (e))}{Len\ (s)} \quad (5)$$

where *s* and *m* stand for the same as in Equation 4. In addition, *c* and *e* stands for such sub-snippet that *Score(c,e)* contributes to $\sum_{k=1}^{n} InV_k$. The function *Len(s)* is to compute the number of words in the sentence.

We acquire the length of language string. If the length is too long or too short, the associated web page is unlikely to be a bilingual page. At the same time, we are not interested in some language strings although the lengths of them are appropriate. So we also store the variances of lengths about each sub-snippet.

(3) Frequency-Based measure

According to the result pages, queries often occur in the title, snippet, or advertisements. They are highlighted to make them easier to identify. Hence we aim to acquire the frequency of the query in one whole snippet as a feature.

Based on the three measures above, a number of records (containing snippets and URLs) for training and testing can be converted them into a 6-dimensional feature space. In our experiments, nonlinear SVM with Gaussian Radial Basis Function (RBF) kernel is used. The performance of the SVM classifier indicates that it is a reliable way to verify whether the page is bilingual or not by the content of snippet.

6 Experiments and Results

6.1 The Data Set

To acquire enough experimental data, we collect from Google, Baidu, Yahoo, Youdao, Bing and Tecent Soso, and the effectiveness of our algorithm is evaluated based on the data set from these six search engines.

Result records of search engines are collected by program and by human beings with submitting different queries respectively. They are used for checking the performance of record extraction. When evaluating the method of verification bilingual web pages, 2300 records (60% are positive instances) are chosen for training the SVM classifier, and other 230 are selected randomly as test records from the whole record set.

The training data is annotated by human in two methods. The first method is motivated by the content of each source snippet. The annotators assign the type of web pages by scanning the text of every snippet. If the snippet contains many parallel term pairs, we annotate the page as bilingual or monolingual if not parallel. We also use another annotation method, which is to reach the URL by the Internet Explorer. By checking the content of the real web page, annotators decide the type of the candidate pages. And the biggest difference between the two public hand-classified dataset appears when some snippets of candidate pages have no clues in their content to predict classifications.

6.2 Evaluation On Bilingual Page Acquisition

The entire system is evaluated by measuring the performance of the binary SVM classifier. And how the classifier performance changes with three features is shown in Table 3, where W, L and F separately stand for the word-overlap, length and frequency measures.

In order to improve the performance of word-overlap measure, we use not only the bilingual dictionary but also translation equivalents, which are extracted from parallel corpora. Because the bilingual dictionary doesn't contain all necessary entries, the classifier with only word-overlap measure accepts many wrong pairs.

Feature	W	W +L	W +L+F
Precision	70.2%	81.02%	85.10%

Table 3. SVM Classifier Performance changes with more features added to the classifier

Table 3 shows that the length feature and the frequency feature have a significant effect on bilingual web page verification because of the natural relationship among queries, snippets and true web pages.

N	#1		#2	
	P(%)	R(%)	P(%)	R(%)
1	85.1	92.3	75%	84.8
2	80.7	95.1	72.8	85.7
3	78.1	97.4	71.0	93.0
aver	81.3	94.93	72.93	87.83

Table 4. Performance versus training data types

Three experiments of verification bilingual web pages based on two different training datasets are conducted whose results are shown in Table 4. #1 stands for the data set annotated by snippets, and #2 stands for the training data annotated by URLs. Precision and recall are used to evaluate our method. The average precision based on training dataset #2 is 73%, which is lower than the precision of 81.3% resulting from the dataset #1, because in many cases, some snippets are weakly related with real text in the real pages introduced by search engine summarization algorithm. From the table, we also see that the recalls in dataset #1 and #2 are both relatively high, which means our classifier can select high-quality bilingual pages with high accuracy.

6.3 Evaluation On Web Record Extraction

Record extraction has significant effect on bilingual web page collection. A useful intermediate evaluation of the whole scheme is conducted by measuring the performance of record extraction.

We built a prototype system to test the algorithm of record extraction based on the clustering of similar records. On a laptop with a Pentium M 1.7G processor, the process of constructing records wrapper for a given search engine is done in 10 to 30 seconds. Once the wrapper is built, the record extraction from a new result page is done in a small fraction of a second.

In order to test the robustness of the generated wrapper, we compare the records extracted by our method with the test records acquired manually. The precision and recall measures are used to evaluate the result. 98% of all the records are extracted by program, with a precision of 99%. The precision indicates that the generated wrappers in our experiment are quite robust to acquire records. The recall is lower than the precision, which indicates that it sometimes misses a few records. The reason for this is that in the extraction step, the records different from more common ones are eliminated.

We compare our performance with the work in Zhao (2006), which addresses the issue of differentiating dynamic sections and records based on the sample result pages. It generates section wrappers by identifying section boundary markers in nine steps. It is more complicated in computation than ours because it renders each result page and extracts its content lines by a traversal of the DOM tree, while we use tag structure of a page. The accordance is making full use of the sample pages for given search engines. The method also gets a high precision of 98.8% and a recall of 98.7%.

7 Conclusion

The paper presents a novel method to acquire bilingual web pages automatically via search engines. In order to improve the efficiency and effectiveness, the snippets of search engines rather than the contents of the massive pages are analyzed to locate bilingual pages. Bilingual web page verification is modeled as a classification problem with word-overlap, length and frequency measures. Based on the similarity of HTML structures, AP clustering is used to extract web records from result pages of search engines. Experiments show that our algorithm has good performance in precision and recall.

As a valuable resource for up-to-date bilingual terms and sentences, bilingual web pages are counterpart to parallel monolingual web pages. Our method brings an efficient and effective solution to bilingual language engineering.

Building Systematic Reviews Using Automatic Text Classification Techniques

Oana Frunza, **Diana Inkpen**, and **Stan Matwin**
School of Information Technology and Engineering
University of Ottawa
{ofrunza,diana,stan}@site.uottawa.ca

Abstract

The amount of information in medical publications continues to increase at a tremendous rate. Systematic reviews help to process this growing body of information. They are fundamental tools for evidence-based medicine. In this paper, we show that automatic text classification can be useful in building systematic reviews for medical topics to speed up the reviewing process. We propose a per-question classification method that uses an ensemble of classifiers that exploit the particular protocol of a systematic review. We also show that when integrating the classifier in the human workflow of building a review the per-question method is superior to the global method. We test several evaluation measures on a real dataset.

1 Introduction

Systematic reviews are the result of a tedious process which involves human reviewers to manually screen references of papers to determine their relevance to the review. This process often entails reading thousands or even tens of thousands of abstracts from prospective articles. As the body of available articles continues to grow, this process is becoming increasingly difficult.

Common systematic review practices stipulate that two reviewers are used at the screening phases of a systematic review to review each abstract of the documents retrieved after a simple query-based search. After a final decision is made for each abstract (the two reviewers decide if the abstract is relevant or not to the topic of review), in the next phase further analysis (more strict screening steps) on the entire article is done. A systematic review has to be complete, articles that are published on a certain topic and are clinically relevant need to be part of the review. This requires near-perfect recall since the accidental exclusion of a potentially relevant abstract can have a significantly negative impact on the validity of the overall systematic review (Cohen *et al*., 2006). Our goal in this paper is to propose an automatic system that can help human judges in the process of triaging articles by looking only at abstracts and not the entire documents. This decision step is known as the initial screening phase in the protocol of building systematic reviews, only the abstracts are used as source of information.

One reviewer will still read the entire collection of abstracts while the other will benefit from the help of the system; this reviewer will have to label only the articles that will be used to train the classifier (ideally a small proportion for workload reduction), the rest of the articles will be labeled by the classifier.

In the systematic review preparation, if at least one reviewer agrees to include an abstract, the abstract will have the labeled included and it will pass to the next screening phase; otherwise, it will be discarded. Therefore, the benefit of doubt plays an important role in the decision process. When we replace one reviewer with the automatic classifier, because we keep one human judge in the process, the confidence and reliability of the review is still higher while the overall workload is reduced. The reduction is from the time required for two passes through the collection (for the two humans) to only one pass and the smaller part labeled by the reviewer which is assisted by the classifier. Figure 1 presents on overview of our proposed workflow.

Coling 2008: Poster Volume, pages 303–311,
Beijing, August 2010

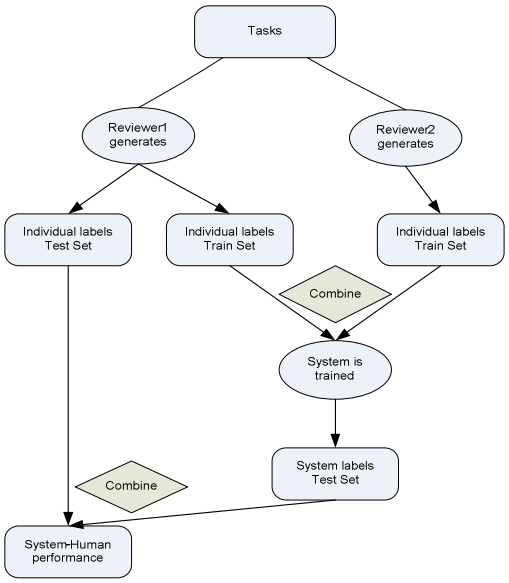

Figure 1. Embedding automatic text classification in the process of building a systematic review.

The task that needs to be solved in order to help the systematic review process is a text classification task intended to classify an abstract as relevant or not relevant to the topic of review.

The hypothesis that guides our research is that it is possible to save time for the human reviewers and obtain good performance levels, similar to the ones obtained by humans. In this current study we show that we can achieve this by building a classification model that is based on the natural human workflow used for building systematic reviews. We show, on a real data set, that a human-machine system obtains the best results when an ensemble of classifiers is used as the classification model.

2 Related Work

The traditional way to collect and triage the abstracts from a systematic review consists in using simple query search techniques based on MeSH[1] or keywords terms. The queries are usual Boolean-based and are optimized either for precision or for recall. The studies done by Haynes *et al.* (1994) show that it is difficult to obtain high performance for both measures.

The research done by Aphinyanaphongs and Aliferis (2005) is probably the first application of automatic text classification to the task of creating systematic reviews. In that paper the authors experimented with a variety of text classification techniques using the data derived from the ACP Journal Club as their corpus. They found that support vector machine (SVM) was the best classifier according to a variety of measures. Further work for systematic reviews was done by Cohen et al. (2006). Their work is mostly focused on the elimination of non relevant documents. As their main goal is to save work for the reviewers involved in systematic review preparation, they define a measure, called work saved over sampling (WSS) that captures the amount of work that the reviewers will save with respect to a baseline of just sampling for a given value of recall. The idea is that a classifier returns, with high recall, a set of abstracts, and only those abstracts need to be read to weed out the non-relevant ones. The savings are measured with respect to the number of abstracts that would have to be read if a random baseline classifier was used. Such baseline corresponds to uniformly sampling a given percentage of abstracts (equal to the desired recall) from the entire set. In Cohen *et al.* (2006), the WSS measure is applied to report the reduction in reviewer's work when retrieving 95% of the relevant documents; the precision was very low.

We focus on developing a classifier for systematic review preparation, relying on characteristics of the data that were not included in the Cohen et *al.'s* (2006), because the questions asked in the preparation of the reviews are not available, Therefore we cannot perform a direct comparison of results here. Also, the data sets that they used in their experiments are significantly smaller than the one that we used.

3 The Data Set

A set of 47,274 abstracts with titles were collected from MEDLINE[2] as part of a systematic review done by the McMaster University's Evidence-Based Practice Center using TrialStat Corporation's Systematic Review System[3], a web-based software platform used to conduct systematic reviews.

The initial set of abstracts was collected using a set of Boolean search queries that were run for

[1] http://www.nlm.nih.gov/mesh/

[2] http://medline.cos.com

[3] http://www.trialstat.com/

the specific topic of the systematic review: "*the dissemination strategy of health care services for elderly people of age 65 and over*".

In the protocol applied, two reviewers work in parallel. They read the entire collection of 47,274 abstracts and answer a set of questions to determine if an abstract is relevant or not to the topic of review. Examples of questions present in the protocol: *Is this article about a dissemination strategy or a behavioral intervention?; Is this a primary study?; Is this a review?; etc.* An abstract is not considered to pass to the next screening phase, when the entire article is available, if the two reviewers respond negative to the same question for a certain abstract. All other cases of possible responses suggest that the abstract will be part of the next screening phase. In this paper we focus on the initial screening phase, the only source of information is the abstract and the title of the article, with the main goal to achieve an acceptable level of recall not to mistakenly exclude relevant abstracts.

From the entire collection of labeled abstracts only 7,173 are relevant. Usually in the process of building systematic reviews the number of non-relevant documents is much higher than the number of relevant ones. The initial retrieval query is purposefully very broad, so as not to miss any relevant papers.

4 Methods

The machine learning techniques that could be used in the process of automating the creation of systematic reviews need to take into account some issues that can arise when dealing with such tasks. *Imbalanced data* sets are usually what we deal with when building reviews, the proportion of relevant articles that end up being present in the review is significantly lower compared with the original data set. The benefit of doubt will affect the quality of the data used to train the classifier, since a certain amount of *noise* is introduced: abstracts that are in fact non-relevant can be labeled as being relevant in the first screening process. The relatively high number of abstracts involved in the process will make the classification algorithms deal with a high number of features and the *representation* technique should try to capture aspects pertaining of the medical domain.

4.1 Representation Techniques

In our current research, we use three representation techniques: bag-of-words (BOW), concepts from the Unified Medical Language System (UMLS), and a combination of both.

The **bag-of-words** representation is commonly used for text classification and we have chosen to use binary feature values. Binary feature values were shown to out-perform weighted values for text classification tasks in the medical domain as shown by Cohen et *al.* (2006) and binary values tend to be more stable in results than frequency values for a task similar to ours, as shown by Ma (2007).

We considered feature words delimitated by space and simple punctuation marks that appeared at least three times in the training data, were not part of a stop words list[4], and had a length greater than three characters. 30,000 word features were extracted. No stemming was used.

UMLS concepts which are part of the U.S. National Library of Medicine[5] (NLM) knowledge repository are identified and extracted form the collection of abstracts using the MetaMap[6] system. This conceptual representation helped us overcome some of the shortcomings of BOW representation, and allowed us to use multi-word features, medical knowledge, and higher-level meanings of words in context. As Cohen (2008) shows, multi-word and medical concept representations are suitable to use.

4.2 Classification Algorithms

As a classification algorithm we have chosen to use the complement naive Bayes (CNB) (Frank and Bouckaert, 2006) classifier from the Weka[7] tool. The reason for this choice is that the CNB classifier implements state-of-the-art modifications of the standard multinomial naïve Bayes (MNB) classifier for a classification task with highly skewed class distribution (Drummond and Holte, 2003). As the systematic reviews data usually contain a large majority of not relevant abstracts, resulting in a skewness reaching even below 1%, it is important to use appropriate classifiers. Other classifiers, such as decision tress,

[4] http://www.site.uottawa.ca/~diana/csi5180/StopWords
[5] http://www.nlm.nih.gov/pubs/factsheets/umls.html
[6] http://mmtx.nlm.nih.gov/
[7] www.cs.waikato.ac.nz/machine learning/weka/

support vector machine, instance-based learning, and boosting, were used but the results obtained with CNB were always better.

4.3 Global Text Classification Method

The first method that we propose in order to solve the text classification task that is intended to help a systematic review process is a straightforward machine learning approach. We trained a classifier, CNB, on a collection of abstracts and then evaluated the classifier's performance on a separate test data set. The power of this classification technique stands in the ability to use a suitable classification algorithm and a good representation for the text classification task; Cohen *et al.* (2006) also used this approach. We randomly split the data set described in Section 3, into a training set and a test set. The two possible classes are **Included (relevant)** or **Excluded (non relevant)**. We decided to work with a training set smaller than the test set because ideally good results need to be obtained without using too much training data. We have to take into consideration that training a classifier for a particular topic, human effort is required for annotation.

Table 1 presents a summary of the data along with the class distribution in the training and test data sets. We randomly sampled the data to build the training and test data sets, and the original distribution of 1:5.6 between the two classes holds in both sets.

Data set	No. of abstracts	Class distribution Included : Excluded (ratio)
Training	20,000	3,056 : 16,944 (1:5.6)
Testing	27,274	4,117 : 23,157 (1:5.6)

Table 1. Training and test data sets.

4.3.1 Feature Selection

Using the global method, we performed experiments with several feature selection algorithms. We used only the BOW representation.

Chi^2 is a measure that evaluates the worth of an attribute by computing the value of the chi-squared statistic with respect to the class. We selected the top k_1 CHI^2 features that are exclusively included (appeared only in the training abstracts that are classified as **Included**) and the top k_2 CHI^2 features that are exclusively excluded (appeared only in the training abstracts that are classified as **Excluded**) and used them as a representation for our data set. We varied the k_1 parameter from 10 to 150 and k2 from 5 to 150 We used a minimum of 20 features and a maximum of 300.

InfoGain evaluates the worth of an attribute by measuring the information gain with respect to the class. We run experiments when we varied the number of selected features from 50 to 500. We used a number of 50, 100, 150, 250, 300 and 500 top features.

Bi-Normal Separation (**BNS**) is a feature selection technique that measures the separation between the threshold occurrences of a feature in one of the two classes. The latter measure is described in detail in Forman (2002). We used a ratio of features that varies from 10 to 150 for the most representative features for the **Included** class and from 5 to 150 for the **Excluded** class. For some experiments the number of features for the **Included** class is higher than the number of features for the **Excluded** class. We have chosen to do so because we wanted to re-balance the imbalance of classes in the training data set. After selecting the number of **Included** and **Excluded** features, we used the combination to represent our entire collection of abstracts.

We used the implementation from the Weka package for the **Chi^2** and **InfoGain** and the BNS implementation done by Ma (2007).

4.4 Per-Question Classification Method

The second method that we propose for solving the task takes into account the specifics of the systematic review process. It takes advantage of the set of questions the reviewers use in the process of deciding if an abstract is relevant or not. These questions are created in the design step of the systematic review and almost all systematic reviews have them. By using these questions we better emulate how the human judges work when building systematic reviews.

We have chosen to use only the questions that have inclusion/exclusion criteria, there were also some opened answer questions involved in the review, because they are the ones that are important for reviewers to make a decision. To collect training data for each question, we used the same training and test data set as in the previous method (but note that not all the abstracts

have answers for all the questions; therefore the training set sizes differ for each question). Table 2 presents the questions and data sets used.

When we created a training data set for each question we removed the abstracts for which we had a disagreement between the human experts – two different answers for a specific question, they represent noise in the training data. For each of the questions from Table 2, we trained a CNB classifier on the corresponding data set.

Question (Training : Included class : Excluded class)
Q1 - Is this article about a dissemination strategy or a behavioural intervention? **(14,057:1,145:12,912)**
Q2 - Is the population in this article made of individuals 65-year old or older or does it comprise individuals who serve the elderly population needs (i.e. health care providers, policy makers, organizations, community)? **(15,005:7,360:7,645)**
Q3 - Is this a primary study? **(8,825:6,895:1,930)**
Q4 - Is this a review? **(6,429:5,640:789)**

Table 2. Data sets for the per-question classification method.

We used the same representation for the per-question classifiers as we did for the global classifier: BOW, UMLS (the concepts that appeared only in the new question-oriented training data sets), and the combination BOW+UMLS. We used each trained model to obtain a prediction for each instance from the test set; therefore each test instance was assigned four prediction values of 0 or 1. To assign a final class for each test instance, from the prediction of all four classifiers, the class of a test instance is decided according to one of the following four schemes:

1. If any one vote is **Excluded**, the final class of a test instance is **Excluded**. This is a 1-vote scheme.

2. If any two votes are **Excluded**, the final class of a test instance is **Excluded**. This is a 2-vote scheme.

3. If any three votes are **Excluded**, the final class of a test instance is **Excluded**. This is a 3-vote scheme.

4. If all four votes are **Excluded**, the final class of a test instance is **Excluded.** This is a 4-vote scheme.

When we combined of the classifiers, we gave each classifier an equal importance.

5 Evaluation Measures and Results

When performing the evaluation for the task of classifying an abstract into one of the two classes **Included (relevant)** or **Excluded (non relevant)**, two objectives are of great importance: **Objective 1** - ensure the completeness of the systematic review (maximize the number of relevant documents included); **Objective 2** - reduce the reviewers' workload (maximize the number of irrelevant documents excluded).

We observe that objective 1 is more important than objective 2 and this is why we decided to report recall and precision for the **Included** class. We also report F-measure, since we are dealing with imbalanced data sets.

Besides the standard evaluation measures, we report WSS[8] measure as well in order to give a clearer view of the results we obtain.

As baseline for our methods we consider: two extreme baselines and a random-baseline classifier that takes into account the distribution of the two classes in the training data set. The baselines results are: *Include_All* – a baseline that classifies everything in the majority class: Recall = 100%, Precision = 15%, F-measure = 26.2%; WSS = 0% *Exclude_All* – a baseline that classifies everything as **Excluded**: Recall = 0%, Precision = 100%, F-measure = 64.2%; WSS = 0% *Random baseline*: Recall = 8.9%, Precision = 15.4%, F-measure = 67.8%; WSS = 0.23%.

5.1 Results for the Global Method

In this subsection, we present the results obtained using our global method with the three representation techniques and CNB as classification algorithm. To get a clear image of the results we show the confusion matrix in Table 3 for the reader to better understand the workload reduction when using classifiers to help the process of building systematic reviews.

BOW features were identified following the guidelines presented in Section 3.4 and a number of 23,906 features were selected. UMLS concepts were identified using the MetaMap system.

[8] WSS = (TE + FE)/(TE + FE + TI + FI) – 1+ TI/(TI + FE) where T stands for true; F – false I – Included class; E- Excluded class.

	BOW	UMLS	BOW+UMLS
True Inc.	*2,692*	*2,793*	*2,715*
False Inc.	*5,022*	*8,922*	*5,086*
True Exc.	*18,135*	*14,235*	*18,071*
False Exc.	*1,425*	*1,324*	*1,402*
Recall	65.3%	67.8%	65.9%
Precision	34.9%	23.8%	34.8%
F-measure	45.5%	35.2%	45.5%
WSS	37.1%	24.9%	37.3%

Table 3. Results for the global method.

From the whole training abstracts collection, a number of 459 UMLS features were identified. Analyzing the results from Table 5, in terms of recall, the UMLS representation obtained the best recall results, 67.8% for the global method but much lower precision, 23.8% than BOW representation, 34.9%. The hybrid representation, BOW+ UMLS features had similar results with the BOW alone. Recall increased a bit for the hybrid representation compared to BOW alone, 0.6% but its value is still not acceptable. We conclude that the levels of recall, our main objective for this task, were not acceptable for a classifier to be used as replacement of a human judge in the workflow of building a systematic review. The levels of precision that we obtained with the global method are acceptable but they cannot substitute the low level of recall. Since our major focus is recall, we investigated more and we further improved our precision scores with the per-question classification method.

5.1.1 Results for Feature Selection

Table 4 presents the results obtained with our feature selection techniques. We decided to report only representative results using CNB as a classifier and a specific representation setting. The number of features used in the experiment is presented in the round brackets. The first number represents the number of features extracted from the **Included** class data set while the second from the **Excluded** class data set.

Similar experiments were performed when using Naïve Bayes as classifier. The results obtained were opposite to ones obtained for CNB, all abstracts were classified as **Excluded**. We believe that this is the case because the CNB classifier tries to compensate for the class imbalance and gives more credit to the minority class,

	Chi^2 (150:150)	InfoGain (300)	BNS (10:8)
True Inc.	*3,819*	*3,875*	*2,690*
False Inc.	*19,233*	*19,638*	*13,905*
True Exc.	*3,924*	*3,518*	*9,253*
False Exc.	*298*	*242*	*1,427*
Recall	92.8%	94.1%	65.3%
Precision	16.6%	16.5%	16.2%
F-measure	28%	28%	25%
WSS	8.2%	7.9%	4.5%

Table 4. Representative results obtained for various feature selection techniques.

while the Naïve Bayes classifier will let the majority class overwhelm the classifier.

Besides the results presented in Table 4, we also tried to boost the representative features for the **Included** class hoping to re-balance the imbalance present in the training data set. To perform these experiments we selected the top k CHI^2 word features and then added to this set of features the top k_1 CHI^2 representative features only for the **Included** class. The parameter k varied from 50 to 100 and the parameter k_1 from 30 to 70. We performed experiments when using the original imbalanced training data set and using a balanced data set as well, with both CNB and Naïve Bayes classifier. The results obtained for these experiments were similar to the ones when we used the previous feature selection techniques. There was no significant difference in the results compared to the ones in Table 5.

5.2 Results for the Per-Question Method

The results for our second method using the four voting schemes are presented in Table 5.

Compared with the global method the results obtained by the per-question method, especially the ones for 2 votes are the best so far in terms of the balance between the two objectives. A large number of abstracts that should be excluded are classified as **Excluded** whereas wrongly excluding very few abstracts that should have been included (a lot fewer than in the case of the global classification method).

The 2-votes scheme performs better than the 1-vote schemes because of potential classification errors. When the classifiers for two different questions (that look at two different aspects of the systematic review topic) are confident that the abstract is not relevant, the chance of correct

prediction is higher; a balance between excluding an article and keeping it as relevant is achieved. When using the classifiers for 3 or 4 questions the performance goes down in terms of precision; a higher number of abstracts get classified as **Included** - some abstracts do not address all target question of the review topic.

1-Vote	BOW	UMLS	BOW+UMLS
True Inc.	*1,262*	*1,222*	*1,264*
False Inc.	*745*	*2,266*	*741*
True Exc.	*22,412*	*20,891*	*22,416*
False Exc.	*2,855*	*2,895*	*2,853*
Recall	30.6%	29.6%	30.7%
Precision	62.8%	35.0%	63.0%
F-measure	41.2%	32.1%	41.2%
WSS	23.2%	16.8%	23.3%
2-Vote	**BOW**	**UMLS**	**BOW+UMLS**
True Inc.	*3,181*	*2,603*	*3,283*
False Inc.	*9,976*	*9,505*	*10,720*
True Exc.	*13,181*	*13,652*	*12,437*
False Exc.	*936*	*1,514*	*834*
Recall	77.2%	63.2%	79.7%
Precision	24.1%	21.5%	23.4%
F-measure	36.8%	32.0%	36.2%
WSS	29.0%	18.8%	28.4%
3-Vote	**BOW**	**UMLS**	**BOW+UMLS**
True Inc.	*3,898*	*3,480*	*3,890*
False Inc.	*18,915*	*16,472*	*18,881*
True Exc.	*4,242*	*6,685*	*4,276*
False Exc.	*219*	*637*	*227*
Recall	94.6%	84.5%	94.4%
Precision	17.0%	17.4%	17.0%
F-measure	28.9%	28.9%	28.9%
WSS	11.0%	11.3%	11.0%
4-Vote	**BOW**	**UMLS**	**BOW+UMLS**
True Inc.	*4,085*	*3,947*	*4,086*
False Inc.	*21,946*	*20,869*	*21,964*
True Exc.	*1,211*	*2,288*	*1,193*
False Exc.	*32*	*170*	*31*
Recall	99.2%	95.8%	99.2%
Precision	15.6%	15.9%	15.6%
F-measure	27.1%	27.2%	27.0%
WSS	3.7%	4.8%	3.7%

Table 5. Results for the per-question method for the **Included** class.

For the per-question technique the recall value peaked at 99.2% with the 4-vote method BOW and BOW+UMLS representation technique. In the same time the lowest values of precision for the per-question technique, 15.6% is obtained with the same experimental setting. It is important to aim for a high recall but not to dismiss the precision values. The difference of even less than 2% in precision values can cause the reviewers to read additional thousands of documents, as observed in the confusion matrices for 2-vote, 3-vote and 4-vote methods in Table 5.

From the confusion matrix in Table 5 for the 2-vote method and the 3- and 4-vote method we observe the high difference in the number of documents a reviewer will have to read (the falsely included documents). The difference in precision from 24.1% for the 2-vote method to 15.6% for the 4-vote method makes the reviewer go through 11,988 additional abstracts.

The best value for the WSS measure for the per-question method is achieved by the 2-vote scheme. The result is lower than the one obtained by the global method but the recall level is higher therefore, we still keep as a potential winner the 2-vote scheme.

5.3 Results for Human-Machine Workflow

In Figure 1, we envisioned the way we can use the automatic classifier in the workflow of building a systematic review. In order to determine the performance of the human-machine workflow that we propose we computed the recall values when the human reviewer's labels are combined with the labels obtained from the classifier. The same labeling technique is applied as for the human-human workflow: if at least one decision for an abstract is to include it in the systematic review, then the final label is **Included**.

We also calculated the evaluation measures for the two reviewers. The evaluation measures for the human judge that is kept in the human-machine workflow, Reviewer 1 in Figure 1, are 64.29% for recall and 15.20% for precision. The evaluation measures for the reviewer that is to be replaced in the human-machine classification, Reviewer 2 in Figure 1 are 59.66% for recall and 15.09% for precision. The recall value for the two human judges combined is 85.26% and the precision value is 100%. As we can observe the recall value for the second reviewer, the one that is replaced in the human-classifier workflow is low. In Table 6 we present precision and recall results for the symbiotic model for both our methods. In these results we can clearly see that the 2-vote technique is superior to the other voting techniques and to the global method. For almost the same level of precision the level or recall it is much higher. These observations support the fact

that the extra effort spent in identifying the most suitable methodology pays off.

The fact that we keep a human in the loop makes our method acceptable as a workflow for building a systematic review.

Method	BOW	UMLS	BOW+ UMLS
Global	17.9/87.7%	17.0/88.6%	17.9/87.7%
1-Vote	17.1/75.3%	16.5/74.8%	17.1/75.4%
2-Vote	17.1/91.6%	16.4/86.6%	17.1/92.7%
3-Vote	15.8/97.9%	15.8/94.2%	15.8/97.8%
4-Vote	15.3/99.6%	15.4/98.3%	15.3/99.6%

Table 6. Precision/recall results for the human-classifier workflow for the **Included** class.

6 Discussion

The global method achieves good results in terms of precision while the best recall is obtained by the per-question method.

The best results for the task were obtained using the per-question method with the 2-vote scheme with or without UMLS features. The 3-vote scheme with UMLS representation is close to the 2-vote scheme but looking at F-measure and WSS results the 2-vote scheme is better. The clear distinction between the methods comes when we combined the classifiers with the human judge in the workflow of building reviews.

The per-question technique is more robust and it offers the possibility to choose the desired type of performance. If the reviewers are willing to read almost the entire collection of documents, knowing that the recall is high, then a 3 or 4-vote scheme can be the set-up (though the 3 or 4-vote method is not likely to achieve 100% recall because it is very rare that an abstract contain answers to three or four of the questions associated with the systematic review). If the reviewers will like to read a small collection being confident that almost all the abstracts are relevant, then a 1-vote scheme can be the set-up required. The per-question method confirms the fact that an ensemble of classifiers is better than one classifier; (Dietterich, 1997).

When we combine the human and the system results we obtain a major improved in terms of recall. We base our discussion for the human-machine results for the experiment that obtained the best results, the 2-vote scheme with a BOW+UMLS representation technique. When combining the human and classifier decisions, the precision level decreased a bit compared to the one that the machine obtained. We believe that this is the case because some of the abstracts that the classifier excluded were included by the first human reviewer and, with this decision process in place, the level of precision dropped.

Our goal of improving the recall level from the first level of screening is achieved, since when both the classifier and the human judge are integrated in the workflow, the recall level jumps from 79.7% to 92.7%.

We believe that the low level of precision that is obtained for the human reviewer, for the human-classifier workflow, and for the classifier, is due to the fact that we are running experiments for the first screening phase when we use only the abstracts as source of information and not the entire articles.

We believe that further investigations are required to fully replace a human reviewer with an automatic classifier but the results obtained with the per-question method encourage us to believe that this is a suitable solution for reaching our final goal.

7 Conclusions and Future Work

In this paper, we looked at two methods by which we envision the way automatic text classification techniques could help the workflow of building systematic reviews.

The first method is a straight-forward application of the representations and learning algorithms that capture the specifics of the data: medical domain, huge number of features, misclassification, and imbalanced classes.

We showed that the specifics of the human protocol in which systematic reviews are built have a positive effect when deployed in an automatic way. We believe that the tedious process that is currently used for building systematic reviews can be lightened by the use of a classifier in combination with only one human judge. By having a human judge in the loop, we ensure that the workflow is reliable and that the system can be easily integrated in the workflow.

In future work we would like to look into ways of improving the results by the way we chose the training data set and by integrating more domain specific knowledge. We would also like to investigate ways by witch we can update systematic reviews.

Chinese Sentence-Level Sentiment Classification Based on Fuzzy Sets

Guohong Fu and Xin Wang
School of Computer Science and Technology, Heilongjiang University
ghfu@hlju.edu.cn,wangxincs@hotmail.com

Abstract

This paper presents a fuzzy set theory based approach to Chinese sentence-level sentiment classification. Compared with traditional topic-based text classification techniques, the fuzzy set theory provides a straightforward way to model the intrinsic fuzziness between sentiment polarity classes. To approach fuzzy sentiment classification, we first propose a fine-to-coarse strategy to estimate sentence sentiment intensity. Then, we define three fuzzy sets to represent the respective sentiment polarity classes, namely positive, negative and neutral sentiments. Based on sentence sentiment intensities, we further build membership functions to indicate the degrees of an opinionated sentence in different fuzzy sets. Finally, we determine sentence-level polarity under maximum membership principle. We show that our approach can achieve promising performance on the test set for Chinese opinion analysis pilot task at NTCIR-6.

1 Introduction

With the explosive growth of the user-generated content on the web over the past years, opinion mining has been attracting an ever-increasing amount of attention from the natural language processing community. As a key issue in opinions mining, sentiment classification aims to classify opinionated documents or sentences as expressing positive, negative or neutral opinions, and plays a critical role in many opinion mining applications such as opinion summarization and opinion question answering.

Although recent years have seen a great progress in sentiment analysis, it is still challenging to develop a practical sentiment classifier for open applications. This is largely due to the particularities of subjective languages. Unlike factual text, opinion text is usually expressed in a more subtle or arbitrary manner (Pang and Lee, 2008). Moreover, the sentiment orientation of a subjective expression is often context, domain and/or even order-dependent (Pang and Lee, 2008). This makes it hard to explore informative cues for sentiment classification. In particular, the final semantic orientation of an opinionated sentence often depends on the synthetic effects of all sentiment units (e.g. sentiment words or phrases) within it. Therefore, sentiment granularity selection and polarity aggregation are two important factors that affect sentiment classification performance.

In addition, real opinion texts do not contain precisely-defined criteria of membership with respect to polarity classes. Most current work employs supervised machine learning techniques like naive Bayesian models and support vector machines to perform sentiment classification. While they have shown a good performance in traditional topic-based text classification tasks (Wang, 2006), their applications in sentiment classification are far from satisfactory (Pang *et al.*, 2002). The reason might be the intrinsic fuzziness between sentiment polarity classes. Relative to the concept of objective topics like *sports* and *politics* in traditional text classification, the division between *positive sentiments* and *negative sentiments* is rather vague, which does not make clear boundary between their conceptual extensions. Such vague conceptual extension in sentiment polarity inevitably raises another challenge to sentiment classification.

Coling 2008: Poster Volume, pages 312–319,
Beijing, August 2010

To address the above problems, in this paper we exploit fuzzy set theory to perform Chinese sentiment classification at sentence level. To approach this task, we first consider multiple sentiment granularities, including sentiment morphemes, sentiment words and sentiment phrases, and develop a fine-to-coarse strategy for computing sentence sentiment intensity. Then, we reformulate the three classes of sentiment orientations, namely positive, negative and neutral sentiments, as three fuzzy sets, respectively. To describe the membership of an opinion sentence in a special sentiment fuzzy set, we further construct membership functions based on sentence sentiment intensity, and thus determine the final semantic orientation of a given opinionated sentence under the principle of maximum membership. We show that the proposed approach can achieve a promising performance on the test set for Chinese opinion analysis pilot task at NTCIR-6.

The remainder of the paper is organized as follows: Section 2 provides a brief review of the literature on sentiment classification. In Section 3, we describe the fine-to-coarse strategy for estimating sentiment intensity of opinionated sentences. Section 4 details how to apply fuzzy set theory in sentiment classification. Section 5 reports our experimental results on NTCIR-6 Chinese opinion data. Finally, section 6 concludes our work and discusses some possible directions for future research.

2 Related Work

Sentiment classification has been extensively studied at different granularity levels. At lexical level, Andreevskaia and Bergler (2006) exploit an algorithm for extracting sentiment-bearing adjectives from the WordNet based on fuzzy logic. Following (Turney, 2002), Yuen *et al.* (2004) investigate the association between polarity words and some strongly-polarized morphemes in Chinese, and present a method for inferring sentiment orientations of Chinese words. More recently, Ku *et al.* (2009) consider eight morphological types that constitute Chinese opinion words, and develop a machine learning based classifier for Chinese word-level sentiment classification. They show that using word structural features can improve performance in word-level polarity classification. At phase level, Turney (2002) presents a technique for inferring the orientation and intensity of a phrase according to its PMI-IR statistical association with a set of strongly-polarized seed words. More recently, Wilson *et al.* (2009) distinguish prior and contextual polarity, and thus describe a method to phrase-level sentiment analysis. At sentence level, Yu and Hatzivassiloglou (2003) propose to classify opinion sentences as positive or negative in terms of the main perspective being expressed in opinionated sentences. Kim and Hovy (2004) try to determine the final sentiment orientation of a given sentence by combining sentiment words within it. However, their system is prone to produce error sentiment classification because they only consider sentiment words near opinion holders and ignore some important words like adversative conjunctions. To compute sentiment intensity of opinionated sentences, in this study we propose a fine-to-coarse strategy, which take into account multiple granularity sentiments, from sentiment morphemes, sentiment words to sentiment phrases, and can thus handle both unknown lexical sentiments and contextual sentiments in sentiment classification.

Most recent studies apply machine learning techniques to perform sentiment classification. Pang *et al.* (2002) attempt three machine learning methods, namely naive Bayesian models, maximum entropy and support vector machines in sentiment classification. They conclude that the traditional machine learning methods do not perform well enough in sentiment analysis. Wilson *et al.* (2009) further employ several machine learning algorithms to explore important features for contextual polarity identification. Different from most existing works that focus on traditional text classification techniques, in this study we attempt to resolve sentiment classification problems under the framework of fuzzy set theory. We choose fuzzy set theory because it provides a more straightforward way to represent the intrinsic fuzziness in sentiment.

3 Sentence-Level Sentiment Intensity

In this section, we describe a fine-to-coarse strategy to compute sentence-level sentiment intensity. After a brief discussion of the relationship between Chinese sentiment words and their component morphemes in Section 3.1,

we extract a dictionary of sentiment morphemes from a sentiment lexicon, and compute their opinion scores using a modified chi-square technique. Then, we develop two rule-based strategies for word-level and phrase-level polarity identification, respectively. Finally, we calculate the final sentiment intensity of an opinionated sentence by summing the opinion score of all phrases within it.

3.1 Sentiment words and morphemes

As shown in Table 1, Chinese sentiment words can be categorized into static polar words and dynamic polar words. The polarity of a static polar word remains unchanged while a dynamic polar word may have different polarity in different contexts or domains.

Type		Example
Static polar word	Positive	美丽 'beautiful', 温柔 'gentle'
	Negative	卑劣 'beggary', 错误'wrong'
	Neutral	还可以 'acceptable'
Dynamic polar words		大'big', 高'high'

Table 1. Types of Chinese sentiment words

For a static polar word, its polarity can be easily determined by referring to a sentiment lexicon. However, a precompiled dictionary cannot cover all sentiment words in real text, which raises an issue of predicting the polarity of out-of-vocabulary (OOV) sentiment words. To address this problem, we introduce sentiment morphemes. As Table 2 shows, here we consider two types of sentiment morphemes, namely positive morphemes and negative morphemes.

Morpheme types	Sentiment morphemes	Sentiment words composed by sentiment morphemes
Positive morphemes	美'beauty'	精美 'exquisite'
		优美 'graceful'
	爱'love'	喜爱 'like'
		爱慕 'adoration'
Negative morphemes	污'dirty'	污染 'pollution'
		贪污 'corruption'
	败'fail'	腐败 'corruption'
		败坏 'undermine'

Table 2. Types of Chinese sentiment morphemes

In most cases, the polarity of a sentiment word is closely related to the semantic orientation of its component morphemes. In other words, word-level polarity can often be determined by some key component sentiment morphemes within sentiment words. Take the following three sentiment words for example, 败坏 'undermine', 腐败 'corruption', and 败类 'degenerate'. They share a same negative sentiment morpheme 败 'fail', and thus have the same negative orientation. Based on this observation, here we use morpheme-level polarity, rather than a sentiment lexicon, to predict the polarity of static sentiment words, particularly the OOV sentiment words in real text.

As for dynamic sentiment words, traditional lexicon-based methods do not work for their real polarity changes with contexts. We will discuss the problem of dynamic polarity identification in Section 3.4.

3.2 Identifying morpheme-level polarity

Sentiment morphemes prove to be helpful in dealing with OOV polarity (Ku et al, 2009). However, there is not a dictionary of sentiment morphemes available for sentiment analysis. To avoid this, we propose to automatically extract sentiment morphemes from some existing sentiment lexicon using chi-square (χ^2) technique. Formula (1) presents the χ^2 of a morpheme m within a sentiment word of category c.

$$\chi^2(m,c) = \frac{n \times (n_{11} \times n_{22} - n_{12} \times n_{21})^2}{(n_{11}+n_{12})(n_{21}+n_{22})(n_{11}+n_{21})(n_{12}+n_{22})} \quad (1)$$

where m denotes a sentiment morpheme. $c \in$ {positive, negative} denotes the polarity of a certain sentiment word w that contain m. n is the total number of sentiment words in the lexicon. To calculate χ^2, we need to construct a 2×2 contingency table from the sentiment lexicon. As shown in Table 3, n_{11}, n_{12}, n_{21} and n_{22} denote the observed frequencies, respectively.

Polar word w	belong to c	not belong to c
contain m	n_{11}	n_{12}
not contain m	n_{21}	n_{22}

Table 3. The 2×2 contingency table for χ^2

The traditional χ^2 statistics in Formula (1) can demonstrate the degree of contributions that a sentiment morpheme forms a special group of sentiment words. However, it cannot indicate whether the morpheme and the sentiment category are either positively- or anti-correlated.

Such information is very important for inferring word-level polarity from sentiment morphemes. To compensate for this deficiency, we modify the traditional χ^2 by injecting positive correlation and anti-correlation. Following (Wang, 2006), we introduce the following two rules in determining the sign of correlation between the sentiment category of words and their component sentiment morphemes.

- If $n_{11}\times n_{22}-n_{12}\times n_{21}>0$, the morpheme and the sentiment category are positively correlated. In this case, a larger χ^2 implies a higher likelihood that the morpheme belongs to the sentiment category.
- If $n_{11}\times n_{22}-n_{12}\times n_{21}<0$, the morpheme and the sentiment category are anti-correlated. In this case, a larger χ^2 value implies a higher likelihood that the morpheme does not belong to the sentiment category.

Thus, we obtain a modified χ^2 statistics as follows.

$$\chi^{2\prime}=sign(n_{11}\times n_{22}-n_{12}\times n_{21})\frac{n\times(n_{11}\times n_{22}-n_{12}\times n_{21})^2}{(n_{11}+n_{12})(n_{21}+n_{22})(n_{11}+n_{21})(n_{12}+n_{22})} \quad (2)$$

With the $\chi^{2\prime}$ statistic, we can build a dictionary of sentiment morphemes from a source sentiment lexicon, and further determine the polarity of each sentiment morpheme using the two rules as shown in Definitions 1 and 2.

Definition 1 (positive sentiment morphemes). If the $\chi^{2\prime}$ statistic between a morpheme *m* and positive sentiment words is greater than zero, then *m* can be identified as positive.

Definition 2 (negative sentiment morphemes). If the $\chi^{2\prime}$ statistic between a morpheme *m* and positive sentiment words is smaller than zero, then *m* can be identified as is negative.

Table 4 illustrates some extracted sentiment morphemes and their $\chi^{2\prime}$ values.

Types of morphemes	Examples	$\chi^{2\prime}$
Positive morphemes	美'beautiful'	111.78
	爱'love'	65.88
	喜'happy'	40.72
Negative morphemes	死'die'	-104.97
	败'failed'	-45.28
	恶'evil'	-72.37

Table 4. $\chi^{2\prime}$ values of sentiment morphemes

3.3 Identifying word-level polarity

To determine word-level polarity, we employ morpheme-based rules. First of all, we normalize the $\chi^{2\prime}$ value of each sentiment morpheme *m* into [-1, 1] by dividing it with the maximum absolute value. Such normalized chi-square, denoted by *chi*(*m*), is further viewed as the opinion score of the sentiment morpheme *m*. Thus, we can determine whether a word is a sentiment or not using a simple rule: if a word contains sentiment morphemes, it is a sentiment word. Finally, we can calculate the opinion score of a word *w* consisting of morphemes m_i, $(1\le i\le 2)$[1], using the following two rules.

- If m_1 is a negation, e.g. 不 'not' and 非 'non-', then $Score(w)= -1\times chi(m_2)$.
- If m_1 is not a negation morpheme, then $Score(w)=Sign(chi(m_i))\times Max(|chi(m_i)|)$. Where, $Max(|chi(m_i)|)$ is the largest absolute value among the opinion scores of morphemes within a word *w*, $Sign(chi(m_i))$ denotes the positive or negative sign of *m*, namely '-' and '+'.

3.4 Identifying phrase-level polarity

To handle contextual polarity, we apply lexical polarity to determine the sentiment orientation of phrases within an opinionated sentence. Based on (Hatzivassiloglou and Wiebe, 2000) and (Turney, 2002), we consider four types of structures (as shown in Table 5) during sentiment phrase extraction. To simplify the process, we reduce some function words like 的 ''s' and 与 'and' from the input sentences before extraction in that they have no influence on sentiment orientation determination, and focus on extracting two consecutive words. Different from (Turney, 2002), we consider phrases with negations as their initial words. In this way, we can handle the local negation that may reverse polarity.

Phrase structures	Examples
Phases containing a adjective	成功率高 'high success rate'
Phrases containing a verb	详细讨论'carefully discuss'
Phrase containing an idiom	企图掩人耳目/'intent to deceive the public'
Phrases beginning with a negation	没有证据'no evidence'

Table 5. Structures of opinion phrases

[1] For words that contain three or more characters, particularly the four-character idioms, their polarity can be determined using the second rule.

After opinion phrase extraction, we continue to calculate the opinion score of the extracted phrases using rules that are similar to (Hu and Liu, 2004). Before going to the details of phrase-level opinion score calculation, we need to give some definitions in advance.

Definition 3 (increased dynamic polar words). An increased dynamic polarity word can increase the orientation strength of sentiment words that it modifies without changing their polarity. For example, the word 大 'serious' in the phrase 污染大 'serious pollution' and the word 高 'high' in the phrase 效益高 'high benefit'.

Definition 4 (decreased dynamic polar word). A decreased dynamic polarity word can decrease the orientation strength of sentiment words that it modifies and at the same time, reverse their polarity. For example, the word "小" 'little' in the phrase 污染小 'little pollution' and the word 低 'low' in the phrase 效益低 'low benefit'.

To calculate phrase-level opinion scores, we construct a dictionary of dynamic polar words by extracting adjectives and verbs that contain a single-character seed morpheme like 少 'little' from the training corpus. Table 6 illustrates some increased and decreased dynamic polar words and their signs for changing polarity.

Dynamic polar word	Example	Polarity sign
Increased	高 'high' 增加 'increase' 提升 'upgrade' 下降 'down'	*Sign*(increased)=1
Decreased	减少 'reduce' 缩小 'diminish'	*Sign*(decreased)=−1

Table 6. Dynamic words and their polarity sign

With these dynamic polar words, we can then calculate the opinion score of a given opinion phrase p_i that consists of two words (denoted by w_j, $j \in \{1,2\}$), using three rules as follows.

- If w_1 is a negation, e.g. 不 'no' and 没有 'without', then $Score(p_i) = -1 \times Score(w_2)$.
- If p_i involves a dynamic word w_d, then $Score(p_i) = Sign(w_d) \times Score(w_j)$. Where, $Sign(w_d)$ denotes the polarity sign of dynamic words shown in Table 6.
- Otherwise, $Score(p_i) = Sign(w_j) \times Max(|Score(w_j)|)$. *Where* $Max(|Score(word_j)|)$ is the largest absolute value among the word-level opinion scores.

4 Sentence Sentiment Classification

4.1 Sentiment fuzzy sets and membership functions

As we have mentioned above, sentiment polarity is vague with regard to its conceptual extension. There is not a clear boundary between the concepts of "positive", "neutral" and "negative". To better handle such intrinsic fuzziness in sentiment polarity, we apply the fuzzy set theory by (Zadeh, 1965) to sentiment classification. To do so, we first redefine sentiment classes as three fuzzy sets, and then apply existing fuzzy distributions to construct membership functions for the three sentiment fuzzy sets.

In our formulation, all the opinionated sentences under discussion are represented as a sorted set, denoted by X, in terms of their opinion scores. Thus, we have $X = [Min(Opinion\ Score(S_i)), \ldots, Max(Opinion\ Score(S_i))]$. Where, $i=\{1,\ldots,n\}$, $Min(Opinion\ Score(S_i))$ and $Max(Opinion\ Score(S_i))$ denotes the respective minimum and maximum opinion scores. The details of the fuzzy sets and their membership functions are given in Definitions 5, 6 and 7, respectively.

Definition 5 (positive sentiment fuzzy set). if X is a collection of sentiment opinions (denoted by x), then a positive sentiment fuzzy set $\tilde{P}$ in X can be defined as a set of ordered pairs, namely

$$\tilde{P} = \{(x, \mu_{\tilde{P}}(x)) \mid x \in X\},$$

where $\mu_{\tilde{P}}(x)$ denotes the membership function of x in $\tilde{P}$ that maps X to the membership space M.

We choose the rise semi-trapezoid distribution (Zimmermann, 2001) as the membership function of the positive sentiment fuzzy set, namely

$$\mu_{\tilde{P}}(x) = \begin{cases} 0, & x < a \\ \dfrac{x-a}{b-a}, & a \le x \le b \\ 1, & x > b \end{cases} \quad (3)$$

where x denotes the opinion score of a sentence under discussion. The adjustable parameters a and b can be defined as $a = Min(x_i) + \lambda_1(Max(x_i) - Min(x_i)/k)$ and $b = Min(x_i) + \lambda_2(Max(x_i) - Min(x_i)/k)$, respectively. $Max(x_i)$ and $Min(x_i)$

denote the respective minimum and maximum values within X. λ_1, λ_2 and k are parameters. Here we set λ_1= 5.2, λ_2 = 5.4, and k = 10.

Definition 6 (neutral sentiment fuzzy set). if X is a collection of sentiment opinions (denoted by x), then a neutral sentiment fuzzy set $\tilde{E}$ in X can be defined as a set of ordered pairs, namely

$$\tilde{E} = \{(x, \mu_{\tilde{E}}(x)) \mid x \in X\},$$

where $\mu_{\tilde{E}}(x)$ denotes the membership function of x in $\tilde{E}$ that maps X to the membership space M.

As shown in Formula (4), we also select the semi-trapezoid distribution (Zimmermann, 2001) as the membership function of the neutral sentiment fuzzy set.

$$\mu_{\tilde{E}}(x) = \begin{cases} 0, & x < a \\ \dfrac{x-a}{b-a}, & a \le x < b \\ 1, & b \le x < c \\ \dfrac{d-x}{d-c}, & c \le x < d \\ 0, & x \ge d \end{cases} \quad (4)$$

where x denotes the opinion score of a sentence under test. a, b, c and d are adjustable parameters that can be defined as a = Min(xi) + λ1(Max(xi)-Min(xi)/k), b=Min(xi) +m1(Max(xi) - Min(xi)/k), c = Min(xi) + m2(Max(xi) - Min(xi)/k) and d= Min(xi) + λ2(Max(xi) - Min(xi)/k), respectively. Max(xi) and Min(xi) denotes the respective minimum and maximum values within X. λ1, λ2, m1, m2 and k are parameters, Here we set λ1 = 5.2, λ2 = 5.5, m1 = 5.26, m2 = 5.33, and k = 10.

Definition 7 (negative sentiment fuzzy set). if X is a collection of sentiment opinions (denoted by x), then a negative sentiment fuzzy set $\tilde{N}$ in X can be defined as a set of ordered pairs, namely

$$\tilde{N} = \{(x, \mu_{\tilde{N}}(x)) \mid x \in X\},$$

where $\mu_{\tilde{N}}(x)$ denotes the membership function of x in $\tilde{N}$ that maps X to membership space M.

To represent the membership function of the negative sentiment fuzzy set, we employ the drop semi-trapezoid distribution (Zimmermann, 2001), namely

$$\mu_{\tilde{N}}(x) = \begin{cases} 1, & x < a \\ \dfrac{b-x}{b-a}, & a \le x \le b \\ 0, & x > b \end{cases} \quad (5)$$

where x denotes the opinion score of a subjective sentence under discussion. The adjustable parameters a and b can be defined as $a = Min(x_i) + \lambda_1(Max(x_i) - Min(x_i)/k)$ and $b = Min(x_i) + \lambda_2(Max(x_i) - Min(x_i)/k)$, respectively. $Max(x_i)$ and $Min(x_i)$ refer to the corresponding minimum and maximum values in X. λ_1, λ_2, and k are parameters. Here we set λ_1=5.2, λ_2=5.3 and k=10.

4.2 Determining sentence polarity

Based on the above membership functions, we can now calculate the grade of membership of a given opinionated sentence in each sentiment fuzzy set, and thus determine its polarity under the principle of maximum membership. The basic idea is as follows: Let $\tilde{A}_1, \tilde{A}_2, \ldots, \tilde{A}_n$ be the fuzzy sets of X. $\exists x_0 \in X$, if

$$\tilde{A}_k(x_0) = \max_{1 \le i \le n} \{\tilde{A}_i(x_0)\}$$

then x_0 is a membership of the fuzzy set $\tilde{A}_k$.

5 Experiments and Results

To assess the effectiveness of our approach, we implemented a classification system for Chinese sentence-level sentiment analysis. The system involves three main modules, namely a lexical analysis module, a subjectivity detection module and a sentiment classification module. To explore lexical cues for sentiment analysis, the morpheme-based chunking technique by (Fu, Kit and Webster, 2008) is employed in the lexical analysis module to carry out word segmentation and part-of-speech tagging tasks. To conform to the NTCIR-6 evaluation, a sentiment density-based naive Bayesian classifier is also embedded in the second module to perform opinionated sentence detection. The details of this classifier can be seen in (Wang and Fu, 2010). To evaluate our system, we conducted experiments on the NTCIR-6 Chinese opinion data. This section reports the experimental results.

5.1 Experimental setup

In our experiments, we use the same test set for the Chinese opinion analysis tasks at NTCIR-6. The basic statistics is presented in Table 7. For comparison, the performance is reported in terms of the same metrics as used in NTCIR-6. They are F-score (F), recall (R), precision (P) under the LWK evaluation with lenient standard.

Item	Number
Topics	32
Documents	843
Sentences	11907
Opinionated sentences under the lenient standard	62%

Table 7. Basic statistics of the test set for Chinese opinion tasks at NTCIR-6

The basic sentiment lexicon used in our system contains a total of 17138 sentiment words, which is built from the CUHK and NTU sentiment lexica by excluding some derived opinion words like 不美丽 'not beautiful'. In addition, we also construct a list of 95 dynamic polarity words using the method described in Section 3.4.

5.2 Experimental results

The experiments are designed to examine the following two issues:

(1) As we have discussed above, it is a key issue to select a proper granularity for sentiment classification. To determine the sentiment orientation of an opinionated sentence, we use a fine-to-coarse strategy that considers three types of sentiment units, namely sentiment morphemes, sentiment words and sentiment phrases. Therefore, the first intention of our experiments is to investigate how the use of different sentiment granularity affects the performance of Chinese sentence-level sentiment classification. To do this, we take the above three sentiment granularity as the basic units for computing sentence-level sentiment intensity, respectively, and examine the relevant sentiment classification results.

(2) To the best of our knowledge, this study may be the first attempt to apply the fuzzy set theory in Chinese sentiment classification. Therefore, our second motivation is to examine whether it is feasible to apply fuzzy set theory in sentiment classification by comparing our system with other public systems for Chinese opinion analysis pilot task at NTCIR-6.

Table 8 presents the experimental results with different sentiment granularities. It can be observed that the system with word as the basic sentiment units slightly performs better than the system based on sentiment morphemes. But a prominent improvement of performance can be obtained after using sentiment phrases. This reason may be that under the fine-to-coarse framework, sentiment classification based on sentiment phrases can handle both internal and external contextual sentiment information, and can thus result in performance improvement.

Granularity	P	R	F
Morpheme	0.389	0.480	0.430
Word	0.393	0.485	0.434
Phrase	0.415	0.512	0.458

Table 8. Performance on sentiment classification with different sentiment granularity

Table 9 illustrates the comparison of our system with the best system for Chinese opinion analysis pilot task at NTCIR-6, namely the CUHK system (Seki *et al.*, 2007; Xu, Wong and Xia, 2007). As can be seen from Table 9, our system outperforms the CUHK system by 5 percents with regard to F-score, showing the feasibility of using fuzzy set theory in sentiment classification.

System	P	R	F
CUHK	0.522	0.331	0.405
Our system	0.415	0.512	0.458

Table 9. Comparison of our system with the best system at NTCIR-6 under lenient standard

6 Conclusion and Future Work

In this paper, we have described a fuzzy set theory based framework for Chinese sentence-level sentiment classification. To handle unknown polarity and contextual polarity as well, we consider three types of sentiment granularities, namely sentiment morphemes, words and phrases in calculating sentiment intensity of opinionated sentenced. Furthermore, we define three fuzzy sets to represent polarity classes and construct the relevant membership functions, respectively. Compared with most existing work, the proposed approach provides a straightforward way to model the vagueness in conceptual division of sentiment polarity. The experimental results show that our system outperforms the best system for Chinese opinion analysis pilot task at NTCIR-6 under the lenient evaluation standard.

The encouraging results of the fuzzy set-based approach suggest several possibilities for future

research. Our experiments demonstrate that the incorporation of multiple granularity polarity has a positive effect on sentiment classification performance. To further enhance our system, in future we intend to exploit more tailored techniques for aggregating multiple-granularity polarity within opinionated sentences. Moreover, we plan to optimize the proposed membership functions for fuzzy sentiment classification.

Monolingual Distributional Profiles for Word Substitution in Machine Translation

Rashmi Gangadharaiah rgangadh@cs.cmu.edu

Carnegie Mellon University

Abstract

Out-of-vocabulary (OOV) words present a significant challenge for Machine Translation. For low-resource languages, limited training data increases the frequency of OOV words and this degrades the quality of the translations. Past approaches have suggested using stems or synonyms for OOV words. Unlike the previous methods, we show how to handle not just the OOV words but *rare* words as well in an Example-based Machine Translation (EBMT) paradigm. Presence of OOV words and rare words in the input sentence prevents the system from finding longer phrasal matches and produces low quality translations due to less reliable language model estimates. The proposed method requires only a monolingual corpus of the source language to find candidate replacements. A new framework is introduced to score and rank the replacements by efficiently combining features extracted for the candidate replacements. A lattice representation scheme allows the decoder to select from a beam of possible replacement candidates. The new framework gives statistically significant improvements in English-Chinese and English-Haitian translation systems.

1 Introduction

An EBMT system makes use of a parallel corpus to translate new sentences. Each input sentence is matched against the source side of a training corpus. When matches are found, the corresponding translations in the target language are obtained through sub-sentential alignment. In our EBMT system, the final translation is obtained by combining the partial target translations using a statistical target Language Model. EBMT systems, like other data-driven approaches, require large amounts of data to function well (Brown, 2000).

Having more training data is beneficial resulting in log-linear improvement in translation quality for corpus-based methods (EBMT, SMT). Koehn (2002) shows translation scores for a number of language pairs with different training sizes translated using the Pharaoh SMT toolkit (Koehn et al., 2003). However, obtaining sizable parallel corpora for many languages is time-consuming and expensive. For rare languages, finding bilingual speakers becomes especially difficult.

One of the main reasons for low quality translations is the presence of large number of OOV and rare words (low frequency words in the training corpus). Variation in domain and errors in spelling increase the number of OOV words. Many of the present translation systems either ignore these unknown words or leave them untranslated in the final target translation. When data is limited, the number of OOV words increases, leading to the poor performance of the translation models and the language models due to the absence of longer sequences of source word matches and less reliable language model estimates.

Approaches in the past have suggested using stems or synonyms for OOV words as replacements (Yang and Kirchhoff, 2006). Similarity measures have been used to find words that are closely related (Marton et al., 2009). For morpho-

Coling 2008: Poster Volume, pages 320–328,
Beijing, August 2010

logically rich languages, the OOV word is morphologically analyzed and the stem is used as its replacement (Popović and Ney, 2004).

This paper presents a simpler method inspired by the Context-based MT approach (Carbonell et al., 2006) to improve translation quality. The method requires a large source language monolingual corpus and does not require any other language dependent resources to obtain replacements. Approaches suggested in the past only concentrated on finding replacements for the OOV words and not the rare words. This paper proposes a unified method to find possible replacements for OOV words as well as rare words based on the context in which these words appear. In the case of rare words, the translated sentence is traced back to find the origin of the translations and the target translations of the replacements are replaced with the translations of the rare words. In the case of OOV words, the target translations are replaced by the OOV word itself. The main idea for adopting this approach is the belief that the EBMT system will be able to find longer phrasal matches and that the language model will be able to give better probability estimates while decoding if it is not forced to fragment text at OOV and rare-word boundaries. This method is highly beneficial for low-resource languages that do not have morphological analysers or Part-of-Speech (POS) taggers and in cases where the similarity measures proposed in the past do not find closely related words for certain OOV words.

The rest of the paper is organized as follows. The next section (Section 2) discusses related work in handling OOV words. Section 3 describes the method adopted in this paper. Section 4 describes the experimental setup. Section 5 reports the results obtained with the new framework for English-Chinese and English-Haitian translation systems. Section 6 concludes and suggests possible future work.

2 Related Work

Orthographic and morpho-syntactic techniques for preprocessing training and test data have been shown to reduce OOV word rates. Popović and Ney (2004) demonstrated this on rich morphological languages in an SMT system. They introduced different types of transformations to the verbs to reduce the number of unseen word forms. Habash (2008) addresses spelling, name-transliteration OOVs and morphological OOVs in an Arabic-English Machine Translation system. Phrases with the OOV replacements in the phrase table of a phrase-based SMT system were "recycled" to create new phrases in which the replacements were replaced by the OOV words.

Yang and Kirchhoff (2006) proposed a back-off model for phrase-based SMT that translated word forms in the source language by hierarchical morphological phrase level abstractions. If an unknown word was found, the word was first stemmed and the phrase table entries for words sharing the same stem were modified by replacing the words with their stems. If a phrase entry or a single word phrase was found, the corresponding translation was used, otherwise the model backed off to the next level and applied compound splitting to the unknown word. The phrase table included phrasal entries based on full word forms as well as stemmed and split counterparts.

Vilar et al. (2007) performed the translation process treating both the source and target sentences as a string of letters. Hence, there are no unknown words when carrying out the actual translation of a test corpus. The word-based system did most of the translation work and the letter-based system translated the OOV words.

The method proposed in this work to handle OOV and rare words is very similar to the method adopted by Carbonell et al. (2006) to generate word and phrasal synonyms in their Context-based MT system. Context-based MT does not require parallel text but requires a large monolingual target language corpus and a fullform bilingual dictionary. The main principle is to find those n-gram candidate translations from a large target corpus that contain as many potential word and phrase translations of the source text from the dictionary and fewer spurious content words. The overlap decoder combines the target n-gram translation candidates by finding maximal left and right overlaps with the translation candidates of the previous and following n-grams. When the overlap decoder does not find coherent sequences of overlapping target n-grams, more candidate transla-

tions are obtained by substituting words or phrases in the target n-grams by their synonyms.

Barzilay and McKeown (2001) and Callison-Burch et al. (2006) extracted paraphrases from monolingual parallel corpus where multiple translations were present for the same source. The synonym generation in Carbonell et al. (2006) differs from the above in that it does not require parallel resources containing multiple translations for the same source language. In Carbonell et al. (2006), a list of paired left and right contexts that contain the desired word or phrase are extracted from the monolingual corpus. The same corpus is used to find other words and phrases that fit the paired contexts in the list. The idea is based on the distributional hypothesis which states that words with similar meanings tend to appear in similar contexts (Harris, 1954). Hence, their approach performed synonym generation on the target language to find translation candidates that would provide maximal overlap during decoding.

Marton et al. (2009) proposed an approach similar to Carbonell et al. (2006) to obtain replacements for OOV words, where monolingual distributional profiles for OOV words were constructed. Hence, the approach was applied on the source language side as opposed to Carbonell et al. (2006) which worked on the target language. Only similarity scores and no other features were used to rank the paraphrases (or replacements) that occured in similar contexts. The high ranking paraphrases were used to augment the phrase table of phrase-based SMT.

All of the previously suggested methods only handle OOV words (except Carbonell et al. (2006) which handles low frequency target phrases) and no attempt is made to handle rare words. Many of the methods explained above directly modify the training corpus (or phrase table in phrase-based SMT) increasing the size of the corpus. Our method clusters words and phrases based on their context as described by Carbonell et al. (2006) but uses the clustered words as replacements for not just the OOV words but also for the rare words on the source language side. Our method does not make use of any morphological analysers, POS taggers or manually created dictionaries as they may not be available for many rare or low-resource languages. The translation of the replacements in the final decoded target sentence is replaced by the translation of the original word (or the source word itself in the OOV case), hence, we do not specifically look for synonyms. The only condition for a word to be a candidate replacement is that its left and right context need to match with that of the OOV/rare-word. Hence, the clustered words could have different semantic relations. For example,

$(cluster1)$:"laugh, giggle, chuckle, cry, weep"
where "laugh, giggle, chuckle" are synonyms and "cry, weep" are antonyms of "laugh".

Clusters can also contain hypernyms (or hyponyms), meronyms (or holonyms), troponyms and coordinate terms along with synonyms and antonyms. For example,

$(cluster2)$:"country, region, place, area, district, state, zone, United States, Canada, Korea, Malaysia".
where "country" is a hypernym of "United States/Canada/Korea/Malaysia". "district" is a meronym of "state". "United States, Canada, Korea, Malaysia" are coordinate terms sharing "country" as their hypernym.

The contributions made by the paper are threefold: first, replacements are found for not just the OOV words but for the *rare* words as well. Second, the framework used allows scoring replacements based on multiple features to permit optimization. Third, instead of directly modifying the training corpus by replacing the candidate replacements by the OOV words, a new representation scheme is used for the test sentences to efficiently handle a beam of possible replacements.

3 Proposed Method

Like Marton et al. (2009), only a large monolingual corpus is required to extract candidate replacements. To retrieve more replacements, the monolingual corpus is pre-processed by first generalizing numbers, months and years by NUMBER, MONTH and YEAR tags, respectively.

3.1 OOV and Rare words

Words in the test sentence (new source sentence to be translated) that do not appear in the training corpus are called OOV words. Words in the test sentence that appear less than K times in the training corpus are considered as rare words (in this paper $K = 3$). The method presented in the following sections holds for both OOV as well as rare words. In the case of rare words, the final translation is postprocessed (Section 3.7) to include the translation of the rare word.

The procedure adopted will be explained with a real example T (the rest of the sentence is removed for the sake of clarity) encountered in the test data with "hawks" as the OOV word,

T:a mobile base , *hitting three* **hawks** *with one arrow* over the past few years ...

3.2 Context

As the goal is to obtain longer target phrasal translations for the $test\ sentence$ before decoding, only words that fit the left and right context of the OOV/rare-word in the test sentence are extracted. Unlike Marton et al. (2009) where a context list for each OOV is generated from the contexts of their replacements, this paper uses only the left and right context of the OOV/rare-word. The default window size for the context is five words (two words to the left and two words to the right of the OOV/rare-word). If the windowed words contain only function words, the window is incremented until at least one content word is present in the resulting context. This enables one to find sensible replacements that fit the context well. The contexts for T are:

Left-context (L): hitting three
Right-context (R): with one arrow

The above contexts are further processed to generalize the numbers by a $NUMBER$ tag to produce more candidate replacements. The resulting contexts are now:

Left-context (L): hitting $NUMBER$
Right-context (R): with $NUMBER$ arrow

As a single $L - R$ context is used, a far smaller number of replacements are extracted.

3.3 Finding Candidate replacements

The monolingual corpus (ML) of the source language is used to find words and phrases (X_k) that fit LX_kR i.e., with L as its left context and/or R as its right context. The maximum length for X_k is set to 3 currently. The replacements are further filtered to obtain only those replacements that contain at least one content word. As illustrated earlier, the resulting replacement candidates are not necessarily synonyms.

3.4 Features

A local context of two to three words to the left of an OOV/rare-word ($word_i$) and two to three words to the right of $word_i$ contain sufficient clues for the word, $word_i$. Hence, local contextual features are used to score each of the replacement candidates ($X_{i,k}$) of $word_i$. Each $X_{i,k}$ extracted in the previous step is converted to a feature vector containing 11 contextual features. Certainly more features can be extracted with additional knowledge sources. The framework allows adding more features, but for the present results, only these 11 features were used.

As our aim is to assist the translation system in finding longer target phrasal matches, the features are constructed from the occurrence statistics of $X_{i,k}$ from the bilingual training corpus (BL). If a candidate replacement does not occur in the BL, then it is removed from the list of possible replacement candidates.

Frequency counts for the features of a particular replacement, $X_{i,k}$, extracted in the context of $L_{i,-2}L_{i,-1}$ (two preceding words of $word_i$) and $R_{i,+1}R_{i,+2}$ (two following words of $word_i$) (the remaining words in the left and right context of $word_i$ are not used for feature extraction) are obtained as follows:

f_1: frequency of $X_{i,k}R_{i,+1}$
f_2: frequency of $L_{i,-1}X_{i,k}$
f_3: frequency of $L_{i,-1}X_{i,k}R_{i,+1}$
f_4: frequency of $L_{i,-2}L_{i,-1}X_{i,k}$
f_5: frequency of $X_{i,k}R_{i,+1}R_{i,+2}$
f_6: frequency of $L_{i,-2}L_{i,-1}X_{i,k}R_{i,+1}$

f_7: frequency of $L_{i,-1}X_{i,k}R_{i,+1}R_{i,+2}$
f_8: frequency of $L_{i,-2}L_{i,-1}X_{i,k}R_{i,+1}R_{i,+2}$
f_9: frequency of $X_{i,k}$ in ML
f_{10}: frequency of $X_{i,k}$ in BL
f_{11}: number of feature values $(f_1, ..f_{10}) > 0$

f_{11} is a vote feature which counts the number of features (f_1 ... f_{10}) that have a value greater than zero. The features are normalized to fall within $[0, 1]$. The sentences in ML, BL and test data are padded with two begin markers and two end markers for obtaining counts for OOV/rare-words that appear at the beginning or end of a test sentence.

3.5 Representation

Before we go on to explaining the lattice representation, we would like to make a small clarification in the terminalogy used. In the MT community, a lattice usually refers to the list of possible partially-overlapping target translations for each possible source $n-$gram phrase in the input sentence. Since we are using the term lattice to also refer to the possible paths through the input sentence, we will call the lattice used by the decoder, the "*decoding lattice*". The lattice obtained from the input sentence representing possible replacement candidates will be called the "*input lattice*".

An input lattice (Figure 1) is constructed with a beam of replacements for the OOV and rare words. Each replacement candidate is given a score (Eqn 1) indicating the confidence that a suitable replacement is found. The numbers in Figure 1 indicate the start and end indices (based on character counts) of the words in the test sentence. In T, two replacements were found for the word *"hawks"*: *"homers"* and *"birds"*. However, "homers" was not found in the BL and hence, it was removed from the replacement list.

The input lattice also includes the OOV word with a low score (Eqn 2). This allows the EBMT system to also include the OOV/rare-word during decoding. In the Translation Model of the EBMT system, this test lattice is matched against the source sentences in the bilingual training corpus. The matching process would now also look for phrases with "birds" and not just "hawks". When a match is found, the corresponding translation in the target language is obtained through sub-sentential alignment (Section 3.7). The scores on the input lattice are later used by the decoder (Section 3.7). Each replacement $X_{i,k}$ for the OOV/rare-word ($word_i$) is scored with a logistic function (Bishop, 2006) to convert the dot product of the features and weights ($\vec{\lambda} \cdot \vec{f_{i,k}}$) to a score between 0 and 1 (Eqn 1 and Eqn 2).

T : a mobile base , hitting three hawks with one arrow .....

input lattice:

0	0	(" a ")
1	6	(" mobile ")
7	10	(" base ")
11	11	(",")
12	18	(" hitting ")
13	17	(" three ")
18	22	(" *hawks* " 0.0026)
18	22	(" **birds** " 0.9974)
23	26	(" with ")
27	29	(" one ")
30	34	(" arrow ")

OOV/Rare word	Candidate Replacements
Spelling errors	
krygyzstan	kyrgyzstan,...
yusukuni	yasukuni,..
kilomaters	kilometers, miles, km, ...
	Coordinate terms
somoa	india, turkey, germany, russia, japan,...
ear	body, arms, hands, feet, mind, car, ...
buyers	dealer, inspector, the experts, smuggler,.
	Synonyms
plummet	drop, dropped, fell, ...
	Synonyms and Antonyms
optimal	worse, better, minimal,....

Figure 2: Sample English candidate replacements obtained.

$$p_\lambda(X_{i,k}|word_i) = \frac{exp(\vec{\lambda}\vec{f_{i,k}})}{1+\sum_{j=1...S} exp(\vec{\lambda}\vec{f_{i,j}})} \quad (1)$$

$$p_\lambda(word_i) = \frac{1}{1 + \sum_{j=1...S} exp(\vec{\lambda} \cdot \vec{f_{i,j}})} \quad (2)$$

where, $\vec{f_{i,j}}$ is the feature vector for the j^{th} replacement candidate of $word_i$, S is the number of replacements, $\vec{\lambda}$ is the weight vector indicating the importance of the corresponding features.

3.6 Tuning feature weights

We would like to select those feature weights ($\vec{\lambda}$) which would lead to the least expected loss in translation quality (Eqn 3). $-log(BLEU)$ (Papineni et al., 2002) is used to calculate the expected loss over a development set. As this objective function has many local minima and is piecewise constant, the surface is smoothed using the L2-norm regularization. Powell's algorithm (Powell, 1964) with grid-based line optimization is used to find the best weights. 7 different random guesses are used to initialize the algorithm.

$$\min_{\lambda} E_\lambda[L(t_{tune})] + \tau * ||\lambda||^2 \quad (3)$$

The algorithm assumes that partial derivates of the function are not available. Approximations of the weights ($\lambda_1, ..\lambda_N$) are generated successively along each of the N standard base vectors. The procedure is iterated with a stopping criteria based on the amount of change in the weights and the change in the loss. A cross-validation set (in addition to the regularization term) is used to prevent overfitting at the end of each iteration of the Powell's algorithm. This process is repeated with different values of τ, as in Deterministic Annealing (Rose, 1998). τ is initialized with a high value and is halved after each process.

3.7 System Description

The EBMT system finds phrasal matches for the test (or input) sentence from the source side of the bilingual corpus. The corresponding target phrasal translations are obtained through subsentential alignment. When an *input lattice* is given instead of an input sentence, the system performs the same matching process for all possible phrases obtained from the input lattice. Hence, the system also finds matches for source phrases that contain the replacements for the OOV/rare-word. Only the top C ranking replacement candidates for every OOV/rare word are used in building the input lattice. The optimal value of C was empirically found to be 2. On examining the obtained input lattices, the proposed method found replacements for at the most 3 OOV/rare words in each test sentence (Section 4). Hence, the number of possible paths through the input lattice is not substantially large.

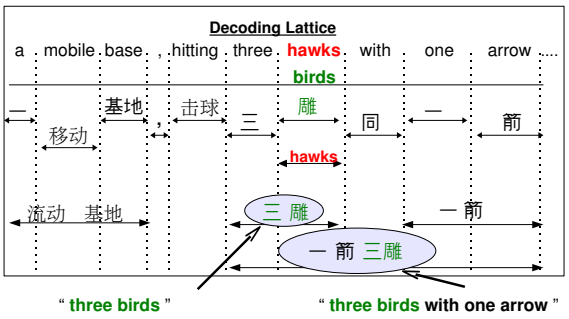

Figure 3: Lattice containing possible phrasal target translations for the test sentence T.

The target translations of all the source phrases are placed on a common decoding lattice. An example of a decoding lattice for example T is given in Figure 3. The system is now able to find longer matches (*" three birds with one arrow "* and *" three birds "*) which was not possible earlier with the OOV word, *"hawks"*. The local ordering information between the translations of "three birds" and "with one arrow" is well captured due to the retrieval of the longer source phrasal match, "three birds with one arrow". Our ultimate goal is to obtain translations for such longer $n-$gram source phrases boosting the confidence of both the translation model and the language model.

The decoder used in this paper (Brown, 2003) works on this *decoding lattice* of possible phrasal target translations (or fragments) for source phrases present in the *input lattice* to generate the target translation. Similar to Pharaoh (Koehn et al., 2003), the decoder uses multi-level beam search with a priority queue formed based on the number of source words translated. Bonuses are given for paths that have overlapping fragments. The total score (TS) for a path (Eqn 4) through the translation lattice is the arithmetic average of the scores for each target word in the

path. The EBMT engine assigns each candidate phrasal translation a quality score computed as a log-linear combination of alignment score and translation probability. The alignment score indicates the engine's confidence that the right target translation has been chosen for a source phrase. The translation probability is the proportion of times each distinct alternative translation was encountered out of all the translations. If the path includes a candidate replacement, the log of the score, $p_\lambda(w_i)$, given for a candidate replacement is incorporated into TS as an additional term with a weight wt_5.

$$TS = \frac{1}{t}\sum_{i=1}^{t}[wt_1 \log(b_i) + wt_2 \log(pen_i) + wt_3 \log(q_i) + wt_4 \log(P(w_i|w_{i-2}, w_{i-1})) + \mathbb{1}_{(w_i=replacement)} wt_5 \log(p_\lambda(w_i)) \ ] \quad (4)$$

where, t is the number of target words in the path, wt_j indicates the importance of each score, b_i is the bonus factor given for long phrasal matches, pen_i is the penalty factor for source and target phrasal-length mismatches, q_i is the quality score and $P(w_i|w_{i-2}, w_{i-1})$ is the LM score. The parameters of the EBMT system (wt_j) are tuned on a development set.

The target translation is postprocessed to include the translation of the OOV/rare-word with the help of the best path information from the decoder. In the case of OOV words, since the translation is not available, the OOV word is put back into the final output translation in place of the translation of its replacement. In the output translation of the test example T, the translation of *"birds"* is replaced by the word, *"hawks"*. For rare words, knowing that the translation of the rare word may not be correct (due to poor alignment statistics), the target translation of the replacement is replaced by the translation of the rare word obtained from the dictionary. If the rare word has multiple translations, the translation with the highest score is chosen.

4 Experimental Setup

As we are interested in improving the performance of low-resource EBMT, the English-Haitian (Eng-Hai) newswire data (Haitian Creole, CMU, 2010) containing 15,136 sentence-pairs was used. To test the performance in other languages, we simulated sparsity by choosing less training data for English-Chinese (Eng-Chi). For the Eng-Chi experiments, we extracted 30k training sentence pairs from the FBIS (NIST, 2003) corpus. The data was segmented using the Stanford segmenter (Tseng et al., 2005). Although we are only interested in small data sets, we also performed experiments with a larger data set of 200k. 5-gram Language Models were built from the target half of the training data with Kneser-Ney smoothing. For the monolingual English corpus, 9 million sentences were collected from the Hansard Corpus (LDC, 1997) and FBIS data.

EBMT system without OOV/rare-word handling is chosen as the Baseline system. The parameters of the EBMT system are tuned with 200 sentence pairs for both Eng-Chi and Eng-Hai. The tuned EBMT parameters are used for the Baseline system and the system with OOV/rare-word handling. The feature weights for the proposed method are then tuned on a seperate development set of 200 sentence-pairs with source sentences containing at least 1 OOV/rare-word. The cross-validation set for this purpose is made up of 100 sentence-pairs. In the OOV case, 500 sentence pairs containing at least 1 OOV word are used for testing. For the rare word handling experiments, 500 sentence pairs containing at least 1 rare word are used for testing.

To assess the translation quality, 4-gram word-based BLEU is used for Eng-Hai and 3-gram word-based BLEU is used for Eng-Chi. Since BLEU scores have a few limitations, the NIST and TER metrics are also used. The test data used for comparing the system handling OOV words and the Baseline (without OOV word handling) is different from the test data used for comparing the system handling rare words and the Baseline system (without rare word handling). In the former case, the test data handles only OOV words and in the latter, the test data only handles rare words. Hence, the test data for both the cases do not completely overlap. As we are interested in determining whether handling rare words in test sentences is useful, we keep both the test data sets seperate and assess the improvements obtained by only

OOV/Rare	system	TER	BLEU	NIST
OOV	Baseline	77.89	18.61	4.8525
	Handling OOV	76.95	19.32	4.9664
Rare	Baseline	74.23	22.84	5.3803
	Handling Rare	74.02	23.12	5.4406

Table 1: Comparison of translation scores of the Baseline system and system handling OOV and Rare words for Eng-Hai.

handling OOV words and by only handling rare words over their corresponding Baselines. As future work, it would be interesting to create one test data set to handle both OOV and rare words to see the overall gain.

The test set is further split into 5 files and the Wilcoxon (Wilcoxon, 1945) Signed-Rank test is used to find the statistical significance.

5 Results

Sample replacements found are given in Figure 2. For both Eng-Chi and Eng-Hai experiments, only the top C ranking replacement candidates were used. The value of C was tuned on the development set and the optimal value was found to be 2. Translation quality scores obtained on the test data with 30k and 200k Eng-Chi training data sets are given in Table 2. Table 1 shows the results obtained on Eng-Hai. Statistically significant improvements ($p < 0.0001$) were seen by handling OOV words as well as rare words over their corresponding baselines.

As the goal of the approach was to obtain longer target phrasal matches, we counted the number of n-grams for each value of n present on the decoding lattice in the 30k Eng-Chi case. The subplots: A and B in Figure 4, shows the frequency of n-grams for higher values of n (for $n > 5$) when handling OOV and rare words. The plots clearly show the increase in number of longer target phrases when compared to the phrases obtained by the baseline systems.

Since the BLEU and NIST scores were computed only up to 3-grams, we further found the number of n-gram matches (for $n > 3$) in the final translation of the test data with respect to the reference translations (subplots: C and D). As expected, a larger number of longer $n-$gram matches were found. For the OOV case, matches

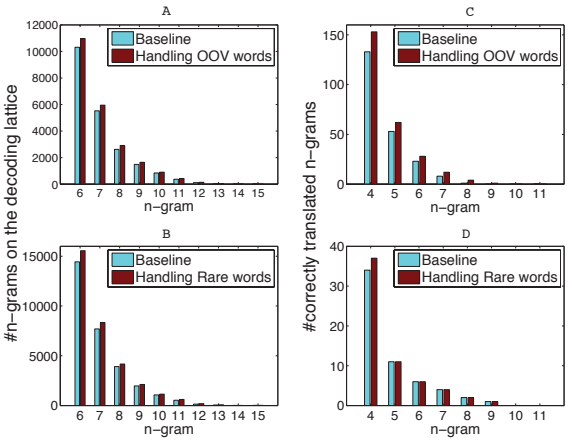

Figure 4: A, B: number of n-grams found for increasing values of n on the decoding lattice. C, D: number of target n-gram matches for increasing values of n with respect to the reference translations.

OOV/Rare	Training data size	system	TER	BLEU	NIST

	30k	Handling OOV	80.97	14.78	4.1798
	200k	Baseline	79.41	19.90	4.6822
	200k	Handling OOV	77.66	20.50	4.7654
Rare	30k	Baseline	82.09	15.36	4.3626
	30k	Handling Rare	80.02	16.03	4.4314
	200k	Baseline	78.04	20.96	4.9647
	200k	Handling Rare	77.35	21.17	5.0122

Table 2: Comparison of translation scores of the Baseline system and system handling OOV and Rare words for Eng-Chi.

up to 9-grams were found where the baseline only found matches up to 8-grams.

6 Conclusion and Future Work

A simple approach to improve translation quality by handling both OOV and rare words was proposed. The framework allowed scoring and ranking each replacement candidate efficiently.

The method was tested on two language pairs and statistically significant improvements were seen in both cases. The results showed that rare words also need to be handled to see improvements in translation quality.

In this paper, the proposed method was only applied on words, as future work we would like to extend it to OOV and rare-phrases as well.

Abstract

Precision-oriented search results such as those typically returned by the major search engines are vulnerable to issues of polysemy. When the same term refers to different things, the dominant sense is preferred in the rankings of search results. In this paper, we propose a novel technique in the context of web search that utilizes contextual terms provided by users for query disambiguation, making it possible to prefer other senses without altering the original query.

1 Introduction

World Wide Web and search engines have become an indispensable part of everyone's everyday life. While web search has come a long way over the past 10 years, it still has a long way to go to respond to the ever-increasing size of the web and needs of web surfers. Today, web search is under intensive and active research, drawing unparalleled attention from both industry and academia.

Need of disambiguation. One of the major challenges in web search lies in unsatisfactory relevance of results caused by ambiguity. Query terms are inherently ambiguous due to polysemy, and most queries are short containing 1 to 3 terms only (Jansen et al., 2000). Thus queries are in general prone to ambiguity of user intent or information needs, resulting in retrieval of enormous irrelevant pages. As the web increases in size at an increasing rate, ambiguity becomes ubiquitous and users are in increasing need of effective means of disambiguation. The ambiguity issue and its consequences are demonstrated in Example 1.

Example 1 *There are 17 entries in Wikipedia for different renown individuals under the same name of "Jim Gray", including a computer scientist, a sportscaster, a zoologist, a politician, a film director, a cricketer, and so on. Suppose we intend to find information about* `Jim Gray`*, the Turing award winner, we can issue a query of "Jim Gray" in Yahoo!For this extremely famous name in computer science, only 3 are relevant in the top 10 results. They are his Wikipedia entry, homepage at Microsoft Research, and DBLP entry.*

Straightforward approach. One intuitive way of disambiguation would be to apply available domain knowledge and refine the query by adding some confining contextual terms. This would generally improve precision. However, there are several inevitable problems in this approach. First, the improvement on precision is at the sacrifice of recall. For example, many `Jim Gray` pages may not contain the added contextual terms and are thus excluded from the search results.

Second, the query is altered, leading to unfavorable ranking of results. Term proximity matters significantly in ranking (Manning et al., 2008). Some good pages w.r.t. the original query may be ranked low in the new search results because of worsened term proximity and relevance w.r.t. the new query. Thus, with this straightforward approach only limited success can be expected at best, as demonstrated in Example 2.

Example 2 *Suppose we know that* `Jim Gray` *is a computer scientist, we can issue a query of "Jim Gray computer". All the top 10 results are about* `Jim Gray` *and relevant. However, many of them are trivial pages, failing to include 2 of the 3 most important ones. His DBLP entry appears as the*

Coling 2008: Poster Volume, pages 329–337,
Beijing, August 2010

27th result, and his homepage at Microsoft Research appears as the 51st result.

This limited success is achieved by using a carefully selected contextual term. "Computer" is a very general term appearing on most of the `Jim Gray` pages. Also, there are no other competitively known computer people with the same name. Most other contextual terms would perform much worse. Thus a third problem of this straightforward query refinement approach is that only few contextual terms, which may not be available to users, would possibly achieve the limited success. Often, much of our domain knowledge would cause more damage than repair and is practically unusable, as demonstrated in Example 3.

Example 3 *Suppose we know that* `Jim Gray` *has David DeWitt as a close friend and colleague, we can issue a query of "Jim Gray David DeWitt". Again, all the top 10 results are about* `Jim Gray` *and relevant. However, the theme of the query is almost completely altered. Evidently, the 1st result "Database Pioneer Joins Microsoft to Start New Database Research Lab", among many others, talks about David DeWitt. It is relevant to* `Jim Gray` *only because the lab is named "Jim Gray Systems Lab" in honor of him.*

The `Bobo` approach. Can we freely apply our domain knowledge to effectively disambiguate search intent and improve relevance of results without altering the original query? For this purpose, we propose and implement `Bobo`.[1]

For conceptual clarity, the `Bobo` interface features two boxes. Besides a regular query box, an additional box is used to take *contextual terms* from users that capture helpful domain knowledge. Contextual terms are used for disambiguation purposes. They do not alter the original query defined by query terms. Particularly, unlike in the straightforward approach, positive contextual terms are not required to be included in search results and negative contextual terms are not required to be excluded from search results. Contextual terms help estimate relevance of search results, routing them towards a user intended domain, filtering out those not-in-domain, or irrelevant, results.

`Bobo` works in two rounds. In round I, a query is issued using by default the combination of query terms and contextual terms, or just the contextual terms if the query returns too few results. Then from the results, some top-ranked high-quality pages are (automatically) selected as *seeds*. In round II, a query is issued using the query terms. Then the results are compared with the seeds and their similarities are computed. The similarity values reflect the degree of relevance of search results to the user intent, based on which the results are re-ranked.

Example 4 reports the `Bobo` experiment using the same contextual terms as in Example 3.

Example 4 *As in Example 3, suppose we know* `Jim Gray` *has David DeWitt as a colleague. Then with* `Bobo`*, we can enter "Jim Gray" in the query box and "David DeWitt" in the auxiliary box. As a result with default preferences, all the top 10 results are relevant including all the top 3 important* `Jim Gray` *pages. From the top 10, only 1 page, the DBLP entry, contains "David DeWitt" as they coauthored papers. The theme of the query is not altered whereas in Example 3, all the top 10 results contain "David DeWitt".*

In Example 4, the selected seeds are relevant to `Jim Gray`. Observe that seeds can be useful if they are relevant to the user-intended domain, not only the user-intended query. `Bobo` works effectively with such seeds and thus can utilize a much expanded range of domain knowledge. Helpful contextual terms do not even need to co-occur with query terms on any page. They only need to occur, possibly separately, on some pages of the same domain, as demonstrated in Example 5.

Example 5 *Using the criteria of being in the same community as* `Jim Gray` *but co-occuring on no web pages, we randomly chose a student name, Flavia Moser. In* `Bobo`*, we entered "Jim Gray" in the query box, "Flavia Moser" in the auxiliary box, and used only the contextual terms for the round I query. As a result, 11 of the top 12 results were relevant including all the top 3 important* `Jim Gray` *pages. Of course, none of the returned pages contains "Flavia Moser".*

[1] `Bobo` has been implemented using Yahoo! web search API and maintained at http://dmlab.cs.txstate.edu/bobo/.

2 Related Work

Disambiguating search intent, capturing information needs and improving search performance have been a fundamental research objective in information retrieval and studied from different perspectives. Voorhees (1993) shows that disambiguation cannot be easily resolved using thesauruses. The filtering problem (Baeza-Yates and Ribeiro-Neto, 1999; Schapire et al., 1998) views disambiguation as a binary text classification task assigning documents into one of the two categories, relevant and irrelevant. The routing problem (Schutze et al., 1995; Singhal et al., 1997) differs from text classification in that search results need to be ranked instead of just classified (Gkanogiannis and Kalamboukis, 2008).

Contextual search (Lawrence, 2000; Finkelstein et al., 2002; Kraft et al., 2006), personalized search (Haveliwala, 2002; Teevan et al., 2005; Zhu et al., 2008), and implicit relevance feedback (Kelly and Teevan, 2003; Joachims et al., 2005; White et al., 2004) generally utilize long-term search history to build user profiles. These profiles are used on a regular basis to guide *many* queries. Such approaches entail little extra user involvement in search, but need to manage profiles, face the privacy issue, and swallow the inflexibility in context switch.

Explicit and pseudo relevance feedback (RF) techniques (Ruthven and Lalmas, 2003; Baeza-Yates and Ribeiro-Neto, 1999; Manning et al., 2008) are more related to Bobo in the sense that they do not build long-term profiles. Instead, they construct a one-time search context that are used only once to guide a *single* query each time. Such approaches enjoy the flexibility to switch spontaneously from one domain to another in response to different information needs.

RF is regarded as the most popular query reformation strategy (Baeza-Yates and Ribeiro-Neto, 1999). It iterates in multiple rounds, typically two, to modify a query step by step. Explicit RF asks explicit feedback from users, whereas pseudo (or blind) RF assumes relevance of top-ranked results. The problem of explicit RF is that it requires too much user involvement. Users are often reluctant to provide explicit feedback, or do not wish to prolong the search interaction. Web search engines of today do not provide this facility. Excite.com initially included but dropped it due to the lack of use (Manning et al., 2008).

Pseudo RF, first suggested by Croft and Harper (1979) and since widely investigated, automates the manual part of RF, so that users get improved search performance without extended interactions. Psuedo RF has been found to improve performance in the TREC ad hoc task and Cornell SMART system at TREC 4 (Buckley et al., 1995). Unfortunately, pseudo RF suffers from a major flaw, the so-called *query drift* problem. Query drift occurs when the feedback documents contain few or no relevant ones. In this case, search results will be routed farther away from the search intent, resulting in even worse performance. Different approaches (Mitra et al., 1998; Yu et al., 2003; Lee et al., 2008)have been proposed to alleviate query drift but with little success. Some queries will be improved, others will be harmed (Ruthven and Lalmas, 2003).

Similarly to RF, Bobo works in two rounds. Similarly to pseudo RF, it makes use of top-ranked round I results. However, Bobo and RF differ fundamentally in various aspects.

Firstly, Bobo is not a query reformation technique as RF. In RF, the *automatically generated* additional terms become part of the reformed query to be issued in round II, while in Bobo, the *user-input* contextual terms are *not* used in round II. The terms generated by RF may work well as contextual terms for Bobo but not the other way around. In general, effective contextual terms form a much larger set.

In query reformation, it is often hard to understand why a particular document was retrieved after applying the technique (Manning et al., 2008). In Bobo, the original query is kept intact and only the ranking of search results is changed.

Secondly, in RF, only query terms are used in round I queries. In Bobo, by default the combination of query terms and contextual terms, both entered by users, is used, leading to much more relevant seeds that are comparable to explicit RF. In this sense, Bobo provides a novel and effective remedy for query drift.

Beyond that, Bobo can use contextual terms

only to obtain seeds that are relevant to the user-intended domain and not necessarily the user-intended query, leading to effective utilization of a largely expanded range of domain knowledge.

Thirdly, RF can have practical problems. The typically long queries (usually more than 20 terms) generated by RF techniques are inefficient for IR systems, resulting in high computing cost and long response time (Manning et al., 2008). In Bobo, however, both query terms (1 to 3) and contextual terms (1 to 2) are short. A round I query combining the two would typically contain 2 to 5 terms only.

3 Overview

Bobo uses the vector space model, where both documents and queries are represented as vectors in a discretized vector space. Documents used in similarity comparison can be in the form of either full pages or snippets. Documents are preprocessed and transformed into vectors based on a chosen term weighting scheme, e.g., TF-IDF.

The architecture of Bobo is shown in Figure 1. Without input of contextual terms, Bobo works exactly like a mainstream search engine and the dashed modules will not be executed. Input of contextual terms is optional in need of disambiguation of user intent. Domain knowledge, directly or indirectly associated with the query, can be used as "pilot light" to guide the search towards a user-intended domain.

With input of contextual terms, Bobo works in two rounds. In round I, a query is issued using by default the combination of query terms and contextual terms, or just the contextual terms if they are unlikely to co-occur much with the query terms. Then from the results, the top k documents (full pages or snippets) satisfying certain quality conditions, e.g., number of terms contained in each seed, are selected as seeds. Optionally, seeds can be *cleaned* by removing the contained query terms to reduce background noise of individual seeds, or *purified* by removing possibly irrelevant seeds to improve overall concentration. Contextual terms themselves can be used as an *elf seed*, which is a special document allowing negative terms, functioning as an explicit feedback.

In round II, a query is issued using the query

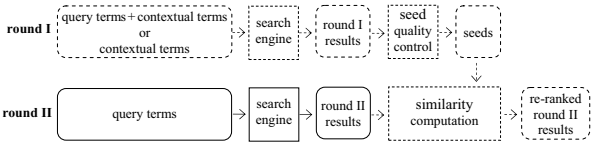

Figure 1: Architecture of Bobo.

terms. Then, each returned result (full page or snippet) is compared to the seeds to compute a similarity using a designated similarity measure, Jaccard coefficient or Cosine coefficient. In the computation, seeds can be *combined* to form a prototype as in Rocchio, or not combined using none generalization as in instance-based lazy learning to better capture locality and handle polymorphic domains. Based on the assumption that seeds are highly relevant, the similarity values estimate the closeness of search results to the user intent, based on which the results are re-ranked.

Bobo was implemented using Yahoo! web search API. For each query, Bobo retrieves 30 HTML pages from the API. If snippets are used for seeding and comparison, the response time of Bobo is sufficiently fast. If full pages are used, page downloading and preprocessing are prohibitively time-consuming. However, the goal of Bobo is to illustrate the promise of the novel disambiguation approach. If Bobo were implemented at the server (search engine) side, response time would not be an issue.

4 Principles and Preferences

In this section, we introduce in detail the design principles and preferences of Bobo regarding the various key issues. We also discuss possible improvements in these aspects.

4.1 Use of Contextual Terms

How to use contextual terms has a fundamental impact on the behavior and performance of Bobo.

In round I. By default, the combination of query terms and contextual terms are used in round I queries. This produces seeds that are relevant to the user-intended query. For instance, in Example 4, the seeds are relevant to Jim Gray. This usage of contextual terms actually provides a novel and effective remedy for query drift, thanks to the input of domain knowledge.

Generally, a large portion of domain knowledge cannot be utilized in a straightforward manner, due to the fact that contextual terms may co-occur with query terms in very few or none web pages. However, as shown in Example 5, Bobo allows using only contextual terms for round I queries, enabling utilization of indirectly associated domain knowledge.

As elf seed. Contextual terms can be considered forming a pseudo document, which can be optionally used as a seed. We call such a seed *elf seed* as it is actually a piece of explicit relevance feedback. Unlike normal seeds, an elf seed may contain positive as well as negative terms, providing a way of collecting positive as well as negative explicit feedback.

Discussion. The option of combing query terms and contextual terms in round I queries can be automated. The idea is to combine the terms first, then test the k^{th} result to see whether it contains all the terms. If not, only the contextual terms should be used in the query.

4.2 Quality of Seeds

As in pseudo relevance feedback, quality of seeds plays an critical role in search performance. The difference is that in Bobo, input of contextual terms is largely responsible for the much improved relevance of seeds. To provide further quality control, Bobo accepts several user-input thresholds, e.g., number of seeds and number of terms contained in each seed. Beyond that, Bobo also provides the following options.

Removing query terms. By default, Bobo uses a combination of contextual terms and query terms in round I queries. Thus usually all the seeds contain the query terms. Round II results contain the query terms as well. Then, in similarity computation against the seeds, those query terms contribute almost equally to each round II result. This amount of contribution then becomes background noise, reducing the sensitivity in differentiating round II results.

By default, Bobo removes query terms from seeds. Although a simple step, this option significantly improves performance in our experiments.

Purifying seeds. Different approaches have been proposed to alleviate query drift by improving relevance of pseudo feedback, but with limited success (Ruthven and Lalmas, 2003). In Bobo, due to the input of domain knowledge, we can well assume that the majority of seeds are relevant, based on which, we can design simple mechanisms to purify seeds. Briefly, we first calculate the centroid of seeds. Then, we compute the similarity of each seed against the centroid, and remove those outlying seeds with poor similarities.

Discussion. Current search engines take into account link-based popularity scores in ranking search results. In Bobo, round I search results are not used to directly meet information needs of users. They are never browsed by users. Thus, different search engines with alternative ranking schemes may be used to better fulfill the purpose of round I queries.

Round I queries do not need to be issued to the same region as round II queries either. Working in a more quality region may help avoid spamming and retrieve better candidates for seed selection.

4.3 Term Weighting

Bobo uses two term weighting schemes. The default one is the conventional TF-IDF. The other scheme, TF-IDF-TAI, uses term association to favor terms that show high co-occurrence with query terms. It is tailored to Bobo, where documents are not compared in isolation, but being "watched" by a query. While TF-IDF can be considered global weighting independent of queries, TF-IDF-TAI can be considered local weighting. Here we omit the details due to the page limit.

IDF estimation. To estimate the IDF values of terms, Bobo used 664, 103 documents in the Ad-hoc track of TREC dataset.[2] These documents can produce a reasonable approximation as they cover various domains such as newspapers, U.S. patents, financial reports, congressional records, federal registers, and computer related contents.

In particular, for a term A, $IDF(A) = \log_2 \frac{n}{DF(A)}$, where $DF(A)$ is the document frequency of A in the TREC data set and n = 664,103.

[2] http://trec.nist.gov/data/docs_eng.html.

4.4 Similarity Computation

By computing similarities between round II results and seeds, Bobo estimates how close different results are to the search intent.

Document type. Seeds can either be in type of snippets (including titles) or full pages. So it is with round II results. White et al. (2007) reported that snippets performed even better than full texts for the task of pseudo RF. In our experiments, snippets also performed comparably to full pages. Thus, Bobo uses "snippet" as the default option for fast response time.

Similarity measure. Bobo uses two standard similarity measures, Cosine coefficient (default) and Jaccard coefficient. Both performed very well in our experiments, with the default option slightly better.

Prototype-based similarity. Bobo implements two types of similarity computation methods, prototype-based or instance-based, with the latter as the default option.

The prototype-based method is actually a form of the well-known Rocchio algorithm (Rocchio, 1971; Salton and Buckley, 1997), which is efficient but would perform poorly in the presence of polymorphic domains. In this method, the seeds are combined and the centroid of seeds is used in similarity computation. Given a set S of seeds, the centroid $\vec{u}$ is calculated as $\vec{u} = \frac{1}{|S|}\sum_{s\in S}\vec{s}$, where $\vec{s}$ is the vector space representation of seed $s \in S$.

Recall that the original Rocchio algorithm for query reformation is defined as follows,

$$\vec{q_e} = \alpha\vec{q} + \beta\frac{1}{|D_r|}\sum_{\vec{d_j}\in D_r}\vec{d_j} - \gamma\frac{1}{|D_{ir}|}\sum_{\vec{d_j}\in D_{ir}}\vec{d_j}$$

where q is the original query vector, q_e is the modified query vector, and D_r and D_{ir} represent the sets of known relevant and irrelevant document vectors respectively. α, β, and γ are empirically-chosen tuning parameters.

If we assign $\alpha = 0$ and $\gamma = 0$, the Rocchio formula agrees with our definition of centroid of seeds. We assign $\alpha = 0$ because Bobo does not target query reformation. We assign $\gamma = 0$ not because of the lack of negative feedback, which is not hard to identify from low-ranked round I search results. The reason is that even in explicit RF, there is no evidence that negative feedback improves performance (Schutze et al., 1995).

Figure 2: A Polymorphic Domain.

Instance-based similarity. Rocchio is simple and efficient. However, it over-generalizes training data and is inaccurate in the presence of polymorphic, or disjunctive, domains. In Figure 2, the 10 seeds labeled by "+" are split into two separate and rather distant sub-domains. The centroid of seeds labeled by "⊕" is not local to any sub-domain. Search result 1 is close to the centroid whereas result 2 is not. Rocchio would give high relevance score to result 1 and poor score to result 2. However, result 2 actually belongs to one of the two sub-domains whereas result 1 does not.

To handle polymorphic domains and capture locality, Bobo uses an instance-based approach, where the similarity of a document against each individual seed is computed, weighted, and aggregated. Let $sim(d, S)$ denote the similarity between a document d and a set S of seeds, then,

$$sim(d, S) = \sum_{s\in S} sim(d, s) \times sim(d, s)$$

Using this approach, result 2 will receive much higher relevance score than result 1 in Figure 2.

Note that, this approach resembles instance-based lazy learning such as k-nearest neighbor classification. Lazy learning generally has superior performance but would suffer from poor classification efficiency. This, however, is not a critical issue in our application because we do not have many seeds. The default number of seeds in Bobo is set to 10.

Discussion. While Bobo adopts rather standard approaches, we are aware of the many other approaches proposed in the literature for pairwise web page similarity computation. An interesting direction to investigate would be a link-based or hybrid approach. For example, Vassilvitskii and Brill (2006) uses web-graph distance for relevance feedback in web search.

5 Empirical Evaluation

We evaluated Bobo in comparison with regular Yahoo! search with and without using contextual terms. Results returned from Yahoo! may vary with time. This, however, will not change the general trends revealed by our empirical study. From these trends we conclude that, Bobo is a simple yet effective paradigm for query intent disambiguation without altering the original query and with maximized utilization of domain knowledge.

5.1 Experiment Setting and Methodology

Parameter setting. To emphasize the Bobo idea, unless otherwise specified, we used default options in the experiments that implement conventional approaches, e.g., TF-IDF for term weighting and Cosine coefficient for similarity computation. By default, number of seeds was set to 10 with each seed having at least 10 terms. The number of layers was set such that round II results were re-ranked in decreasing order of similarity. Cleaning seeds was set to yes. Purifying seeds, elf seed and weighting seeds were set to no.

Dataset. Finding information about people is one of the most common search activities. Around 30% of web queries include person names (Artiles et al., 2005). Person names, however, are highly ambiguous, e.g., only 90,000 different names are shared by 100 million people according to the U.S. Census Bureau (Guha and Garg, 2004).

To test the disambiguation effectiveness of Bobo, we constructed 60 ambiguous name queries and 180 test cases from the Wikipedia disambiguation pages.[3]

In Wikipedia, articles about two or more different topics could have the same natural page title. Disambiguation pages are then used to solve the conflicts. From the various categories, we used the human name category, containing disambiguation pages for multiple people of the same name. For each name, the disambiguation page lists all the different people together with their brief introductions. For example, an Alan Jackson is introduced as "born 1958, American country music singer and songwriter".

[3] en.wikipedia.org/wiki/Category:Disambiguation_pages.

Person names were chosen from the most common English first and last names for the year 2000 published on Wikipedia. The first 10 male and first 10 female given names were combined with the first 10 most common last names to make a list of 200 possible names. From this list, names were chosen based on the following criteria. For each name, there are at least 2 distinct people with the same name, each having at least 3 relevant pages in the returned 30 results.

In total 60 names were chosen as ambiguous queries. For each query, the actual information need was predetermined in a random manner. Then, for this predetermined person, 3 contextual terms were selected from her brief introduction, or her Wikipedia page in case the introduction was too short. For example, for the above Alan Jackson example, "music", "singer", or "songwriter" can be selected as contextual terms. Contextual terms were used one at a time, thus there are 3 test cases for each ambiguous query.

The identification of relevance of search results was done manually. For each query, let R_{30} be the set of relevant pages w.r.t. the information need contained in the 30 retrieved results. R_{30} can be considered containing the most important relevant pages for the original query.

Comparison partners and evaluation measures. To compare with Bobo, two types of regular search methods were used. The *Yahoo!* method uses the original query and performs the simplest Yahoo! web search, returning the same set of results as Bobo but without re-ranking.

To demonstrate the relevance improvement of Bobo over the *Yahoo!* method, we used a couple of standard ranking-aware evaluation measures, which were 11-point precision-recall graph, precision at k graph, Mean Average Precision (MAP) and R-precision.

The *Yahoo!-refined* method is the straightforward query refinement approach we previously discussed. It refines the original query by adding some contextual terms. The refined query alters the original query, leading to unfavorable ranking of results and failing to include many important relevant pages, i.e., R_{30} pages, in the top results.

To demonstrate this point, we used the recall at k evaluation measure, which measures the frac-

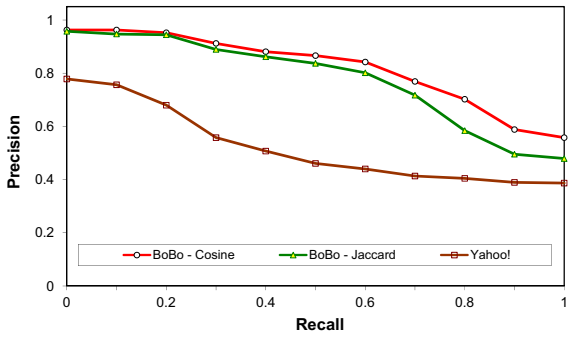

Figure 3: Bobo vs. Yahoo! on Averaged 11-point Precision-Recall.

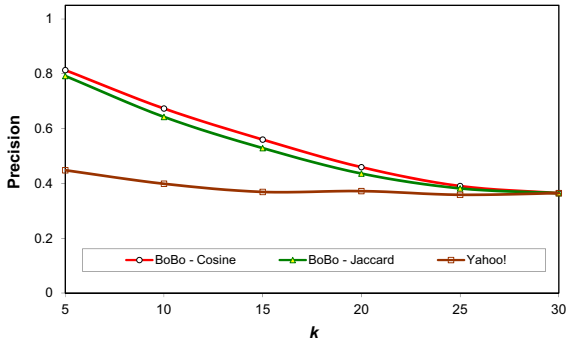

Figure 4: Bobo vs. Yahoo! on Averaged Precision at k.

tion of relevant pages (here, ones in R_{30}) contained in the top k results.

In the entire empirical study, the *Yahoo!* results were averaged over 60 queries, whereas all other results were averaged over 180 test cases.

5.2 Evaluation Results

In Figures 3, 4 and 5, Bobo results using both Cosine similarity and Jaccard coefficient are shown. The two performed similarly, with the former (default) slightly better.

Bobo vs. *Yahoo!*. The 11-point precision-recall graphs and precision at k graphs are presented in Figure 3 and Figure 4 respectively.

Web search users would typically browse a few top-ranked results. From Figure 4 we can see that for k =15, 10 and 5, the precision improvement of Bobo over *Yahoo!* is roughly 20% – 40%.

In addition, the MAP and R-precision values for Bobo are 0.812 and 0.740 respectively, whereas they are 0.479 and 0.405 for *Yahoo!* respectively. The improvement of Bobo over *Yahoo!* is about 33% for both measures.

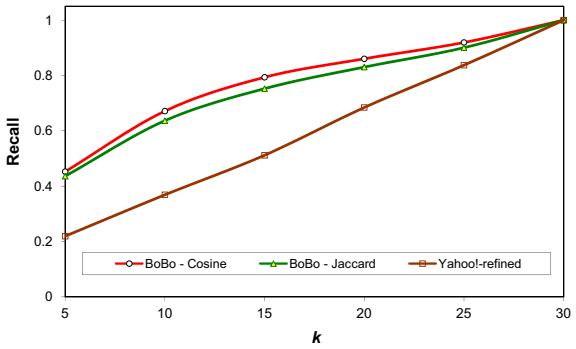

Figure 5: Bobo vs. Yahoo!-refined on Averaged Recall at k.

Bobo vs. *Yahoo!-refined*. The recall at k graphs are presented in Figure 5. From the figure we can see that for $k = 15$, $k = 10$ and $k = 5$, the recall (of important R_{30} pages) improvement of Bobo over *Yahoo!* is roughly 30%.

The results demonstrated that, although the straightforward query refinement approach can effectively improve relevance, it fails to rank those important relevant pages high, as it alters the original query and changes the query themes. Bobo, on the contrary, overcomes this problem by using the contextual terms "in the backstage", effectively improving relevance while keeping the original query intact.

Due to the page limit, here we omit other series of experiments that evaluated the flexibility of Bobo in choosing effective contextual terms and how the varied user preferences affect its performance. A user study was also conducted to test the usability and performance of Bobo.

6 Conclusions

As the web increases in size at an increasing rate, ambiguity becomes ubiquitous. In this paper, we introduced a novel Bobo approach to achieve simple yet effective search intent disambiguation without altering the original query and with maximized domain knowledge utilization.

Although we introduce Bobo in the context of web search, the idea can be applied to the settings of traditional archival information retrieval or multimedia information retrieval.

Abstract

We present GENSEM, a tool for generating input semantic representations for two sentence generators based on the same reversible Tree Adjoining Grammar. We then show how GENSEM can be used to produced large and controlled benchmarks and test the relative performance of these generators.

1 Introduction

Although computational grammars are mostly used for parsing, they can also be used to generate sentences. This has been done, for instance, to *detect overgeneration by the grammar* (Gardent and Kow, 2007). Sentences that are generated but are ungrammatical indicate flaws in the grammar. This has also been done to *test a parser* (Nederhof, 1996; Purdom, 1972). Using the sentences generated from the grammar ensures that the sentences given to the parser are in the language it defines. Hence a parse failure necessarily indicates a flaw in the parser's design as opposed to a lack of coverage by the grammar.

Here we investigate a third option, namely, the *focused benchmarking of sentence realisers* based on reversible grammars, i.e. on grammars that can be used both to produce sentences from a semantic representation and semantic representations from a sentence.

More specifically, we present a linguistically-controlled grammar traversal algorithm for Tree Adjoining Grammar (TAG) which, when applied to a reversible TAG, permits producing arbitrarily many of the semantic representations associated by this TAG with the sentences it generates. We then show that the semantic representations thus produced can be used to compare the relative performance of two sentence generators based on this grammar.

Although the present paper concentrates on Tree Adjoining Grammar realisers, it is worth pointing out that the semantic representations produced could potentially be used to evaluate any surface realiser whose input is a flat semantic formula.

Section 2 discusses related work and motivates the approach. Section 3 presents GENSEM, the DCG-based grammar traversal algorithm we developed. We show, in particular, that the use of a DCG permits controlling grammar traversal in such a way as to systematically generate sets of semantic representations covering certain computationally or linguistically interesting cases. Finally, Section 4 reports on the benchmarking of two surface realisers with respect to a GENSEM-produced benchmark.

2 Motivations

Previous work on benchmark construction for testing the performance of surface realisers falls into two camps depending on whether or not the realiser uses a reversible grammar, that is, a grammar that can be used for both parsing and generation.

To test a surface realiser based on a large reversible Head-Driven Phrase Structure Grammar (HPSG), Carroll et al. (1999) use a small test set of two hand-constructed and 40 parsing-derived cases to test the impact of intersective modifiers[1] on generation performance. More recently, Carroll and Oepen (2005) present a perfor-

[1] As first noted by Brew (1992) and Kay (1996), given a set of n modifiers all modifying the same structure, all possible intermediate structures will be constructed, i.e., 2^{n+1}.

Coling 2008: Poster Volume, pages 338–346,
Beijing, August 2010

mance evaluation which uses as a benchmark the set of semantic representations produced by parsing 130 sentences from the Penn Treebank and manually selecting the correct semantic representations. Finally, White (2004) profiles a CCG[2]-based sentence realiser using two domain-focused reversible CCGs to produce two test suites of 549 and 276 ⟨ semantic formula, target sentence ⟩ pairs, respectively.

For realisers that are not based on a reversible grammar, there are approaches which derive large sets of realiser input from the Penn Treebank (PTB). For example, Langkilde-Geary (2002) proposes to translate the PTB annotations into a format accepted by her sentence generator Halogen. The output of this generator can then be automatically compared with the PTB sentence from which the corresponding input was derived. Similarly, Callaway (2003) builds an evaluation benchmark by transforming PTB trees into a format suitable for the KPML realiser he uses.

In all of the above cases, the data is derived from real world sentences, thereby exemplifying "real world complexity". If the corpus is large enough (as in the case of the PTB), the data can furthermore be expected to cover a broad range of syntactic phenomena. Moreover, the data, being derived from real world sentences, is not biased towards system-specific capabilities. Nonetheless, there are also limits to these approaches.

First, they fail to support graduated performance testing on constructs such as intersective modifiers or lexical ambiguity, which are known to be problematic for surface realisation.

Second, the construction of the benchmark is in both cases time consuming. In the reversible approach, for each input sentence, the correct interpretation must be manually selected from among the semantic formulae produced by the parser. As a side effect, the constructed benchmarks remain relatively small (825 in the case of White (2004); 130 in Carroll and Oepen (2005)). In the case of a benchmark derived by transformation from a syntactically annotated corpus, the implementation of the converter is both time-intensive and corpus-bound. For instance, Callaway (2003) reports that the implementation of such a processor for the SURGE realiser was the most time-consuming part of the evaluation with the resulting component containing 4000 lines of code and 900 rules.

As we shall show in the following sections, the GENSEM approach to benchmark construction aims to address both of these shortcomings. By using a DCG to implement grammar traversal, it permits both a full automation of the benchmark creation and some control over the type and the distribution of the benchmark items.

3 GenSem

As mentioned above, GENSEM is a grammar traversal algorithm for TAG. We first present the specific TAG used for traversal, namely SEMXTAG (Alahverdzhieva, 2008) (section 3.1). We then show how to automatically derive a DCG that describes the derivation trees of this grammar (section 3.2). Finally, we show how this DCG encoding permits generating formulae while enabling control over the set of semantic representations to be produced (section 3.3).

3.1 SemXTAG

The SEMXTAG grammar used by GENSEM and by the two surface realisers is a Feature-Based Lexicalised Tree Adjoining Grammar augmented with a unification-based semantics as described by Gardent and Kallmeyer (2003). We briefly introduce each of these components and describe the grammar coverage.

FTAG. A Feature-based TAG (Vijay-Shanker and Joshi, 1988) consists of a set of (auxiliary or initial) elementary trees and of two tree-composition operations: substitution and adjunction. Initial trees are trees whose leaves are labelled with substitution nodes (marked with a downarrow) or terminal categories. Auxiliary trees are distinguished by a foot node (marked with a star) whose category must be the same as that of the root node. Substitution inserts a tree onto a substitution node of some other tree while adjunction inserts an auxiliary tree into a tree. In an FTAG, the tree nodes are furthermore decorated with two feature structures (called **top** and

[2]Combinatory Categorial Grammar

bottom) which are unified during derivation as follows. On substitution, the top of the substitution node is unified with the top of the root node of the tree being substituted in. On adjunction, the top of the root of the auxiliary tree is unified with the top of the node where adjunction takes place; and the bottom features of the foot node are unified with the bottom features of this node. At the end of a derivation, the top and bottom of all nodes in the derived tree are unified. Finally, each sentence derivation in an FTAG is associated with both a **derived tree** representing the phrase structure of the sentence and a **derivation tree** recording how the corresponding elementary trees were combined to form the derived tree.

FTAG with semantics. To associate semantic representations with natural language expressions, the FTAG is modified as proposed by Gardent and Kallmeyer (2003).

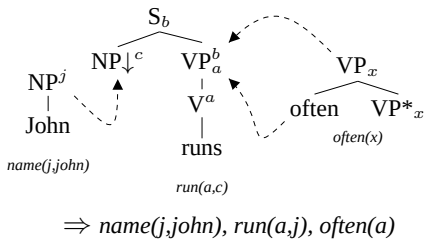

Figure 1: Flat semantics for "John often runs"

Each elementary tree is associated with a flat semantic representation. For instance, in Figure 1,[3] the trees for *John*, *runs*, and *often* are associated with the semantics *name(j,john)*, *run(a,c)*, and *often(x)*, respectively. Importantly, the arguments of a semantic functor are represented by unification variables which occur both in the semantic representation of this functor and on some nodes of the associated syntactic tree. For instance in Figure 1, the semantic index c occurring in the semantic representation of *runs* also occurs on the subject substitution node of the associated elementary tree. The value of semantic arguments is determined by the unifications resulting from adjunction and substitution. For instance, the semantic index c in the tree for *runs* is unified during substitution with the semantic index labelling the root node of the tree for *John*. As a result, the semantics of *John often runs* is {name(j,john),run(a,j),often(a)}.

SemXTAG. SEMXTAG is an FTAG for English augmented with a unification-based compositional semantics of the type described above. Its syntactic coverage approaches that of XTAG, the FTAG developed for English by the XTAG group (The XTAG Research Group, 2001). Like this grammar, it contains around 1300 elementary trees and covers auxiliaries, copula, raising and small clause constructions, topicalization, relative clauses, infinitives, gerunds, passives, adjuncts, ditransitives and datives, ergatives, it-clefts, wh-clefts, PRO constructions, noun-noun modification, extraposition, sentential adjuncts, imperatives and resultatives.

3.2 Converting SemXTAG to a DCG

We would like to be able to traverse SEMXTAG in order to generate semantic representations that are licensed by it. In the DCG formalism, a grammar is represented as a set of Prolog definite clauses, and Prolog's query mechanism provides built-in grammar traversal. We take advantage of this by deriving a DCG from SEMXTAG and then using Prolog queries to generate semantic representations that are associated with sentences in the language described by it.

Another advantage of the DCG formalism is that arbitrary Prolog goals can be inserted into a rule, to constrain when the rule applies or to bind variables occurring in it. We use this to ground derivations with lexical items, which are represented using Prolog assertions. We also use it to control Prolog's grammar traversal in such a way as to generate sets of semantic formulae covering certain computationally interesting cases (see section 3.3).

Our algorithm for converting SEMXTAG to a DCG is inspired by Schmitz and Le Roux (2008), who derive from an FTAG a feature-based regular tree grammar (RTG) whose language is the derivation trees of the FTAG. Indeed, in our implementation, we derive a DCG from such an RTG, thereby taking advantage of a SEMXTAG-

[3] C^x/C_x abbreviate a node with category C and a top/bottom feature structure including the feature-value pair { **index :** x}.

to-RTG converter previously implemented by Sylvain Schmitz.

TAG to RTG. In the conversion to RTG[4], each elementary tree in SEMXTAG is converted to a rule that models the contribution of the tree to a TAG derivation. A TAG derivation involves the selection of an initial tree, which has some nodes requiring substitution and some permitting adjunction. Let us think of the potential adjunction sites as requiring, rather than permitting, adjunction, but such that the requirement can be satisfied by 'null' adjunction. Inserting another tree into this initial tree satisfies one of the substitution or adjunction requirements, but introduces some new requirements into the resulting tree, in the form of its own substitution nodes and adjunction sites.

Thus, intuitively, the RTG representation of a SEMXTAG elementary tree is a rule that rewrites the satisfied requirement as a local tree whose root is a unique identifier of the tree and whose leaves are the introduced requirements. A requirement of a substitution or adjunction of a tree of root category X is written as X_S or X_A, respectively. Here, for example, is the translation to RTG of the TAG tree (minus semantics) for *runs* in Figure 1, using the word anchoring the tree as its identifier (the superscripts abbreviate feature structures: b/t refers to the bottom/top feature structure and the upper case letters to the semantic index value, so $[idx : X]$ is abbreviated to X):

$$S_S^{[t:T]} \rightarrow runs(S_A^{[t:T,b:B]}\ NP_S^{[t:C]}\ VP_A^{[t:B,b:A]}\ V_A^{[t:A]})$$

The semantics of the SEMXTAG tree are carried over as-is to the corresponding RTG rule. Further, the feature structures labelling the nodes of SEMXTAG trees are carried over to the RTG rules so as to correctly interact with substitution and adjunction (see Schmitz and Le Roux (2008) for more details on this part of the conversion process).

To account for the optionality of adjunction, there are additional rules allowing any adjunction requirement to be rewritten as the symbol ϵ, a terminal symbol of the RTG.

The terminal symbols of the RTG are thus the tree identifiers and the symbol ϵ, and its non-terminals are X_S and X_A for each terminal or non-terminal X of SEMXTAG.

RTG to DCG. Since the right-hand side of each RTG rule is a local tree – that is, a tree of depth no more than one – we can flatten each of them into a list consisting of the root node followed by the leaves without losing any structural information. This is the insight underlying the RTG-to-DCG conversion step. Each RTG rule is converted to a DCG rule that is essentially identical except for this flattening of the right-hand side. Here is the translation to DCG of the RTG rule above[5]:

```
rule(s,init,Top,Bot,Sem;S;N;VP;V)
  -->  [runs],
       {lexicon(runs,n0V,[run])},
       rule(s,aux,Top,[B],S),
       rule(np,init,[C],_,N),
       rule(vp,aux,[B],[A],VP),
       rule(v,aux,[A],_,V),
       {Sem =.. [run,A,C]}.
```

We represent non-terminals of the DCG using the `rule` predicate, whose five (non-hidden)[6] arguments, in order, are the category, the subscript (`init` for subscript S, `aux` for subscript A), the *top* and *bottom* feature values, and the semantics. Feature structures are represented using Prolog lists with a fixed argument position for each attribute in the grammar (in this example, only the index attribute). The semantics associated with the left-hand-side symbol (here, `Sem;S;N;VP;V`, with the semicolon representing semantic conjunction) are composed of the semantics associated with this rule and those associated with each of the right-hand-side symbols.

The language of the resulting DCG is neither the language of the RTG nor the language of SEMXTAG, and indeed the language of the DCG does not interest us but rather its derivation trees.

[4]For a more precise description of the FTAG to RTG conversion see Schmitz and Le Roux (2008).

[5]In practice, the lexicon is factored out, so there is no rule specifically for *runs*, but one for intransitive verbs (n0V) in general. Each rule hooks into the lexicon, so that a given invocation of a rule is grounded by a particular lexical item.

[6]The $-->$ notation is syntactic sugar for the usual Prolog $:-$ definite clause notation with two hidden arguments on each predicate. The hidden arguments jointly represent the list of terminals dominated by the symbol.

These are correlated one-to-one with the trees in the language described by the RTG, i.e. with the derivation trees of SEMXTAG, and the latter can be trivially reconstructed from the DCG derivations. From a SEMXTAG derivation tree, one can compose the semantic representation of the associated sentence, and in fact this semantic composition occurs as a side effect of a Prolog query against the DCG, allowing semantic representations licensed by SEMXTAG to be returned as query results.

We define a Prolog predicate for querying against the DCG, as follows. Its one input argument, `Cat`, is the label of the root node of the derivation tree (typically `s`), and its one output argument, `Sem`, is the semantic representation associated with that tree[7].

```
genSem(Cat,Sem) :-
    rule(Cat,init,_,_,Sem,_,[]).
```

3.3 Control parameters

In order to give the users some control over the sorts of semantic representations that they get back from a query against the DCG, we augment the DCG in such a way as to allow control over the TAG family[8] of the root tree in the derivation tree, over the number and type of adjunctions in the derivation, and over the depth of substitutions. To implement control over the family is quite simple: we need merely to index the DCG rules by family and modify the GENSEM call accordingly. For instance, the above DCG rule becomes :

```
rule(s,init,Top,Bot,n0V,Sem;S;NP;VP;V)
  -->  [runs],
       {lexicon(runs,n0V,[run])},
       ...
```

We implement restrictions on adjunctions by adding an additional argument to the grammar symbols, namely a vector of non-negative integers representing the number of non-null adjunctions of each type that are in the derivation subtree dominated by the symbol. By 'type' of adjunction, we mean the category of the adjunction site. In DCG terms, a non-null adjunction of a category `X` is represented as the expansion of an `x/aux` symbol other than as ϵ. So, for example, a DCG symbol associated with the vector `[1,0,0,0,0]`, where the five dimensions of the vector correspond to the `n`, `np`, `v`, `vp`, and `s` categories, respectively, dominates a subtree containing exactly one `n/aux` symbol expanded by a non-epsilon rule, and no other `aux` symbol expanded by a non-epsilon rule. We link the vector associated with the root of the derivation to the query predicate.

We define a special predicate to handle the divvying up of a mother node's vector among the daughters, taking advantage of the fact that the DCG formalism permits the insertion of arbitrary Prolog goals into a rule.

Finally, we add an additional argument to the DCG rule and to the GENSEM's call to control the traversal depth with respect to the number of substitutions applied. The overall depth of each derivation is therefore constrained both by the user defined adjunctions and substitution depth constraints.

Our query predicate now has four input arguments and one output argument:

```
genSem(Cat,Fam,[N,NP,V,VP,S],Dth,Sem):-
    rule(Cat,init,_,_,Fam,
         [N,NP,V,VP,S],Dth,Sem,_,[]).
```

4 Using GENSEM for benchmarking

We now show how GENSEM can be put to work for comparing two TAG-based surface realisers, namely GENI (Gardent and Kow, 2007) and RTGEN (Perez-Beltrachini, 2009). These two realisers follow globally similar algorithms but differ in several respects. We show how GENSEM can be used to produce benchmarks that are tailored to test hypotheses about how these differences might impact performance. We then use this GENSEM-generated benchmark to compare the performance of the two realisers.

4.1 GenI and RTGen

Both GENI and RTGEN use the SEMXTAG grammar described in section 3.1. Moreover, both realisers follow an algorithm pipelining three main phases. First, **lexical selection** selects from the

[7] The 6th and 7th arguments of the rule call are the hidden arguments needed by the DCG.

[8] TAG families group together trees which belong together, in particular, the trees associated with various realisation of a specific subcategorisation type. Thus, here the notion of TAG family is equivalent to that of subcategorisation type.

grammar those elementary trees whose semantics subsumes part of the input semantics. Second, the **tree combining** phase systematically tries to combine trees using substitution and adjunction. Third, the **retrieval phase** extracts the yields of the complete derived trees, thereby producing the generated sentence(s).

There are also differences however. We now spell these out and indicate how they might impact the relative performance of the two surface realisers.

Derived vs. derivation trees. While GENI constructs derived trees, RTGEN uses the RTG encoding of SEMXTAG sketched in the previous section to construct derivation trees. These are then unraveled into derived trees at the final retrieval stage. As noted by Koller and Striegnitz (2002), these trees are simpler than TAG elementary trees, which can favourably impact performance.

Interleaving of feature constraint solving and syntactic analysis. GENI integrates in the tree combining phase a filtering step in which the initial search space is pruned by eliminating from it all combinations of TAG elementary trees that cover the input semantics but cannot possibly lead to a valid derived tree. This filtering eliminates all combinations of trees such that either the category of a substitution node cannot be cancelled out by that of the root node of a different tree, or a root node fails to have a matching substitution site. Importantly, filtering ignores feature information and tree combining takes place after filtering. RTGEN, on the other hand, directly combines derivation trees decorated with full feature structure information.

Handling of intersective modifiers. GENI and RTGEN differ in their strategies for handling modification.

Adapting Carroll and Oepen's (2005) proposal to TAG, GENI adopts a two-step tree-combining process such that in the first step, only substitution applies, while in the second, only adjunction is used. Although the number of intermediate structures generated is still 2^n for n modifiers, this strategy has the effect of blocking these 2^n structures from multiplying out with other structures in the chart.

RTGEN, on the other hand, uses a standard Earley algorithm that includes sharing and packing. Sharing allows intermediate structures common to several derivations to be represented once only while packing groups together partial derivation trees with identical semantic coverage and similar combinatorics (same number and type of substitution and adjunction requirements), keeping only one representative of such groups in the chart. In this way, intermediate structures covering the same set of intersective modifiers in a different order are only represented once and the negative impact of intersective modifiers is lessened.

4.2 Two GENSEM benchmarks

We use GENSEM to construct two benchmarks designed to test the impact of the differences between the two realisers and, more specifically, to compare the relative performance of both realisers (i) on cases involving intersective modifiers and (ii) on cases of varying overall complexity.

The MODIFIERS benchmark focuses on intersective modifiers and contains semantic formulae corresponding to sentences involving an increasing number of modifiers. Recall that GENSEM calls are of the form *gensem(Cat,Family,[N,NP,V,VP,S],Dth,Sem)* where *N,NP,V,VP,S* indicates the number of required adjunctions in *N, NP, V, VP* and *S*, respectively, while *Family* constrains the subcategorisation type of the root tree in the derivations produced by GENSEM. To produce formulae involving the lexical selection of intersective modifiers, we set the following constraints. *Cat* is set to s and *Family* is set to either n0V (intransitive verbs) or n0Vn1 (transitive verbs). Furthermore, N and VP vary from 0 to 4 thereby requiring the adjunction of 0 to 4 N and/or VP modifiers. All other adjunction counters are set to null. To avoid producing formulae with identical derivation trees but distinct lemmas, we use a restricted lexicon containing one lemma of each syntactic type, e.g. one transitive verb, one intransitive verb, etc. Given these settings, GENSEM produces 1 789 formulae whose adjunction requirements vary from 1 to 6. For instance, the semantic formula

{*sleep(b,c),man(c),a(c),blue(c),sleep(i,c),carefully(b)*} (*A sleeping blue man sleeps carefully*) extracted from the MODIFIERS benchmark contains two NP adjunctions and one VP adjunction.

The MODIFIERS benchmark is tailored to focus on cases involving a varying number of intersective modifiers. To support a comparison of the realisers on this dimension, it displays little or no variation w.r.t. other dimensions, such as verb type and non-modifying adjunctions.

To measure the performance of the two realisers on cases of varying overall complexity, we construct a second benchmark (COMPLEXITY) displaying such variety. The GENSEM parameters for the construction of this suite are the following. The verb type (*Family*) is one of 28 possible verb types[9]. The number and type of required adjunctions vary from 0 to 4 for N adjunctions, 0 to 1 for NP, 0 to 4 for VP and 0 to 1 for S. The resulting benchmark contains 890 semantic formulae covering an extensive set of verb types and of adjunction requirements.

4.3 Results

Using the two GENSEM-generated benchmarks, we now compare GENI and RTGEN. We plot the average number of chart items against both the number of intersective modifiers present in the input (Figure 3) and the size of the Initial Search Space (ISS), i.e., the number of combinations of elementary TAG trees covering the input semantics to be explored after the **lexical selection** step (Figure 2). In our case, the ISS gives a more meaningful idea about the complexity than considering only the number of input literals. In an FTAG, the number of elementary trees selected by a given literal may vary considerably depending on the number and the size of the tree families selected by this literal. For instance, a literal selecting the n0Vn2n1 class will select many more trees than a literal selecting the n0V family because there are many more ways of realising the three arguments of a ditransitive verb than the single subject argument of an intransitive one. Chart items include all elementary trees selected by the lexical selection step as well as the intermediate and final structures produced by the tree combining phase. In RTGEN, we distinguish between the number of structures built before unpacking (packed chart) and the number of structures obtained after unpacking (unpacked chart).

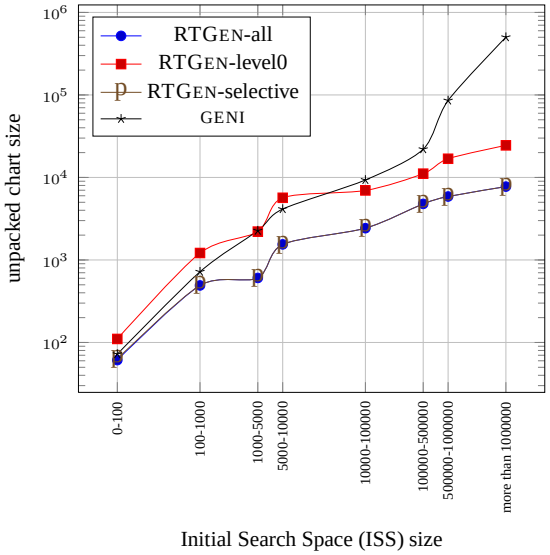

Figure 2: Performance of realisation approaches on the COMPLEXITY benchmark, average unpacked chart size as a function of the ISS complexity.

Both realisers are implemetned in different programming languages, GENI is implemented in Haskell whereas RTGEN in Prolog. As for the time results comparison, preliminary experiments show that GENI is faster is simple input cases. On the other hand, in the case of more complex cases, the point of producing much less intermediate results pays off compared to the overhead of the chart/agenda operations.

[9]The 28 verb types are En1V,n0BEn1,n0lVN1Pn2,n0V,n0Va1,n0VAN1,n0VAN1Pn2, n0VDAN1,n0VDAN1Pn2,n0VDN1,n0VDN1Pn2,n0Vn1, n0VN1,n0Vn1Pn2,n0VN1Pn2,n0Vn2n1,n0Vpl,n0Vpln1, n0Vpn1,n0VPn1,n0Vs1,REn1VA2,REn1VPn2,Rn0Vn1A2, Rn0Vn1Pn2,s0V,s0Vn1,s0Vton1. The notational convention for verb types is from XTAG and reads as follows. Subscripts indicate the thematic role of the verb argument. n indicates a nominal, Pn a PP and s a sentential argument. pl is a verbal particle. Upper case letters describe the syntactic functor type: V is a verb, E an ergative, R a resultative and BE the copula. Sequences of upper case letters such as VAN in n0VAN1 indicate a multiword functor with syntactic categories V, A, and N. For instance, n0Vn1 indicates a verb taking two nominal arguments (e.g., *like*) and n0VAN1 a verb locution such as *to cry bloody murder*.

Overall efficiency. The plot in Figure 2 shows the results obtained by running both realisers on the COMPLEXITY benchmark. Recall (cf. section 4.2) that the COMPLEXITY benchmark contains input with varying verb arity and a varying number of required adjunctions. Hence it provides cases of increasing complexity in terms of ISS to be explored. Furthermore, test cases in the benchmark trigger sentence realisation involving certain TAG families, which have a certain number of trees. Those trees within a family often have identical combinatorics but different features. Consequently, the COMPLEXITY benchmark also provides an appropriate testbed for testing the impact of feature structure information on the two approaches to tree combination.

The graphs show that as complexity increases, the performance delta between GENI and RTGEN increases. We conjecture that as complexity grows, the filtering used by GENI does not suffice to reduce the search space to a manageable size. Conversely, the overhead introduced by RTGEN's all-in-one, tree-combining Earley with packing strategy seems compensated throughout by the construction of a derivation rather than a derived tree and pays off increasingly as complexity increases.

Modifiers. Figure 3 plots the results obtained by running the realisers on the MODIFIERS benchmark. Here again, RTGEN outperforms GENI and the delta between the two realisers grows with the number of intersective modifiers to be handled. A closer look at the data shows that the global constraints set by GENSEM on the number of required adjunctions covers an important range of variation in the data complexity. For instance, there are cases where 4 modifiers modify the same NP (or VP) and cases where the modifiers are distributed over two NPs. Similarly, literals introduced into the formula by a GENSEM adjunction requirement vary in terms of the number of auxiliary trees whose selection they trigger. The steep curve in GENI's plot suggests that although the delayed adjunction mechanism helps in avoiding the proliferation of intermediate incomplete modifiers' structures, the lexical ambiguity of modifiers still poses a problem. In contrast, RTGEN's

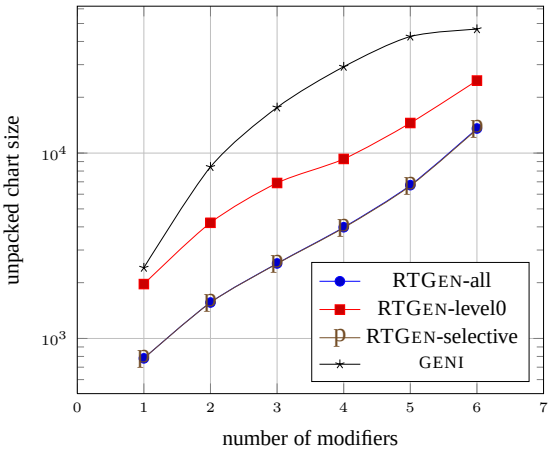

Figure 3: Performance of realisation approaches on the MODIFIERS benchmark, average unpacked chart size as a function of the number of modifiers.

packing uniformly applies to word order variations and to the cases of lexical ambiguity raised by intersective modifiers because the items have the same combinatoric potential and the same semantics.

5 Conclusion

Surface realisers are complex systems that need to handle diverse input and require complex computation. Testing raises among other things the issue of coverage – how can the potential input space be covered? – and of test data creation – should this data be hand tailored, created randomly, or derived from real world text?

In this paper, we presented an approach which permits automating the creation of test input for surface realisers whose input is a flat semantic formula. The approach differs from other existing evaluation schemes in two ways. First, it permits producing arbitrarily many inputs. Second, it supports the construction of grammar-controlled, linguistically focused benchmarks.

We are currently working on further extending GENSEM with more powerful (recursive) control restrictions on the grammar traversal; on combining GENSEM with tools for detecting grammar overgeneration; and on producing a benchmark that could be made available to the community for testing surface realisers whose input is either a dependency tree or a flat semantic formula.

Verbs are where all the action lies: Experiences of Shallow Parsing of a Morphologically Rich Language

Harshada Gune **Mugdha Bapat** **Mitesh M. Khapra** **Pushpak Bhattacharyya**
Department of Computer Science and Engineering,
Indian Institute of Technology Bombay
{harshadag,mbapat,miteshk,pb}@cse.iitb.ac.in

Abstract

Verb suffixes and verb complexes of morphologically rich languages carry a lot of information. We show that this information if harnessed for the task of shallow parsing can lead to dramatic improvements in accuracy for a morphologically rich language- Marathi[1]. The crux of the approach is to use a powerful morphological analyzer backed by a high coverage lexicon to generate rich features for a CRF based sequence classifier. Accuracy figures of 94% for Part of Speech Tagging and 97% for Chunking using a modestly sized corpus (20K words) vindicate our claim that for morphologically rich languages linguistic insight can obviate the need for large amount of annotated corpora.

1 Introduction

Shallow parsing which involves Part-of-Speech (POS) tagging and Chunking is a fundamental task of Natural Language Processing (NLP). It is natural to view each of these sub-tasks as a sequence labeling task of assigning POS/chunk labels to a given word sequence. For languages like English where annotated corpora are available in abundance these tasks can be performed with very high accuracy using data-driven machine learning techniques. Languages of the world show different levels of readiness with respect to such annotated resources and hence not all languages may provide a conducive platform for machine learning techniques.

In this scenario, morphologically rich languages from the Indian subcontinent present a very interesting case. While these languages do not enjoy the resource abundance of English, their linguistic richness can be used to offset this resource deficit. Specifically, in such languages, the suffixes carry a lot of information about the category of a word which can be harnessed for shallow parsing. This is especially true in the case of verbs where suffixes like णे {ne}, णारे {naare} [2] clearly indicate the category of the word. Further, the structure of verb groups in such languages is relatively rigid and can be used to reduce the ambiguity between main verbs and auxiliary verbs.

In the current work, we aim to reduce the data requirement of machine learning techniques by appropriate feature engineering based on the characteristics of the language. Specifically, we target Marathi- a morphologically rich language- and show that a powerful morphological analyzer backed by a high coverage lexicon and a simple but accurate Verb Group Identifier (VGI) can go a long way in improving the accuracy of a state of the art sequence classifier. Further, we show that harnessing such features is the only way by which one can hope to build a high-accuracy classifier for such languages, and that simply throwing in a large amount of annotated corpora does not serve the purpose. Hence it makes more sense to invest time and money in developing good morphological analyzers for such languages than investing in annotation. Accuracy figures of 94% for Part of

[1] Marathi is the official language of Maharashtra, a state in Western India. The language has close to 20 million speakers in the world.

[2] These are the suffixes which derive infinitive and gerund verb forms respectively.

Coling 2008: Poster Volume, pages 347–355,
Beijing, August 2010

Speech Tagging and 97% for Chunking using a modestly sized corpus (20K words) vindicate our claim that for morphologically rich languages linguistic knowledge plays a very important role in shallow parsing of these languages.

2 Related Work

Many POS taggers have been built for English employing machine learning techniques ranging from Decision Trees (Black et al., 1992) to Graphical Models (Brants, 2000; Brill, 1995; Ratnaparkhi, 1996; Lafferty et al., 2001). Even hybrid taggers such as CLAWS (Garside and Smith, 1997) which combine stochastic and rule based approaches have been developed. However, most of these techniques do not focus on harnessing the morphology; instead they rely on the abundance of data which is not a very suitable proposition for some of the resource deprived languages of the Indian sub-continent.

Morphological processing based taggers using a combination of hand-crafted rules and annotated corpora have been tried for Turkish (Oflazer and Kuruöz, 1994), Arabic (Tlili-Guiassa, 2006), Hungarian (Megyesi, 1999) and Modern Greek (Giorgos et al., 1999). The work on Hindi POS tagging (Singh et al., 2006) comes closest to our approach which showed that using a detailed linguistic analysis of morphosyntactic phenomena, followed by leveraging suffix information and accurate verb group identification can help to build a high-accuracy (93-94%) part of speech tagger for Hindi. However, to the best of our knowledge, there is no POS tagger and Chunker available for Marathi and ours is the first attempt at building one.

3 Motivating Examples

To explain the importance of suffix information for shallow parsing we present two motivating examples. First, consider the following Marathi sentence,

हा रस्ता दोन गावांना जोडणारा आहे.
*haa rasta don gavaannaa **jodaNaaraa_VM** aahe.*
*this road two villages **connecting** is*
*this is the road **connecting_VM** two villages.*

The word जोडणारा {jodaNaaraa} (connecting) in the above sentence is a verb and can be categorized as such by simply looking at the suffix णारा {Naaraa} as this suffix does not appear with any other POS category. When suffix information is used as a feature a statistical POS tagger is able to identify the correct POS tag of जोडणारा {jodaNaaraa} even when it does not appear in the training data. Hence, using suffix information ensures that a classifier is able to learn meaningful patterns even in the absence of large training data. Next, we consider two examples for chunking.

- **VGNN (Gerund Verb Chunk)**
  माणसाने उडण्याचा प्रयत्न केला.
  *maaNasaane **uDaNyaachaa_B-VGNN**[3]*
  prayatna kelaa.
  *man **fly** try do*
  *man tried **flying_B-VGNN**.*

- **VGINF (Infinitival Verb Chunk)**
  त्याने चालायला सुरुवात केली.
  *tyaane **chaalaayalaa_B-VGNF** suruvaata kelii.*
  *he **walk** start did*
  *he started **to walk_B-VGINF**.*

Here, we are dealing with the case of two specific verb chunks, *viz.*, VGNN (gerund verb chunk) and VGINF (infinitival verb chunk). A chunk having a gerund always gets annotated as VGNN and a chunk having an infinitival verb always gets annotated as VGINF. Thus, the correct identification of these verb chunks boils down to the correct identification of gerunds and infinitival verb forms in the sentence which in turn depend on the careful analysis of suffix information. For example, in Marathi, the attachment of the verbal suffix "ण्याचा" {Nyaachaa} to a verb root always results in a gerund. Similarly, the attachment of the verbal suffix "यला" {yalaa} to a verb root always results in an infinitival verb form. The use of such suffix information as features can thus lead to better generalization for handling unseen words and thereby reduce the need for additional training data. For instance, in the first sentence, even when the word "उडण्याचा" {uDaNyaachaa} does not appear in

[3]Note that for all our experiments we used BI scheme for chunking as opposed to the BIO scheme

the training data, a classifier which uses suffix information is able to label it correctly based on its experience of previous words having suffix "ण्याचा" {Nyaachaa} whereas a classifier which does not use suffix information fails to classify it correctly.

4 Morphological Structure of Marathi

Marathi nouns inflect for number and case. They may undergo derivation on the attachment of postpositions. In the oblique case, first a stem is obtained from the root by applying the rules of inflection. Then a postposition is attached to the stem. Postpositions (including case markers and the derivational suffixes) play a very important role in Marathi morphology due to the complex morphotactics.

Marathi adjectives can be classified into two categories: ones that do not inflect and others that inflect for gender, number and case where such an inflection agrees with the gender and number of the noun modified by them.

The verbs inflect for gender, number and person of the subject and the direct object in a sentence. They also inflect for tense and aspect of the action as well as mood of the speaker in an illocutionary act. They may even undergo derivation to derive the nouns, adjectives or postpositions. Verbal morphology in Marathi is based on *Aakhyaata* theory for inflection and *Krudanta* theory for derivation which are two types of verb suffixes (Damale, 1970).

Aakhyaata Theory: *Aakhyaata* refers to tense, aspect and mood. Aakhyaata form is realized through an aakhyaata suffix which is a closing suffix attached to verb root. For example, बसला {basalaa} (*sat*) comes from *basa* + *laa*. There are 8 types of aakhyaatas named after the phonemic shape of the aakhyaata suffix. Associated with every aakhyaata are various aakhyaata-arthas which indicate the features: tense, aspect and mood. An aakhyaata may or may not agree with gender.

Krudanta Theory: Krudanta suffixes are attached to the end of verbs to form non-infinitive verb forms. For example, धावायला (धाव + आयला) {dhaavaayalaa} (to run). There are 8 types of krudantas defined in Marathi.

5 Design of Marathi Shallow Parser

Figure 1 and 2 show the overall architectures of Marathi POS tagger and chunker. The proposed system contains 3 important components. First, a morphological analyzer which provides ambiguity schemes and suffix information for generating a rich set of features. Ambiguity Scheme refers to the list of possible POS categories a word can take. This can add valuable information to a sequence classifier by restricting the set of possible POS categories for a word. For example, the word जात {jaat} meaning caste or go(caste-noun, go- VM/VAUX) can appear as a noun or a main verb or an auxiliary verb. Hence it falls in the ambiguity scheme <NN-VM-VAUX>. This information is stored in a lexicon. These features are then fed to a CRF based engine which couples them with other elementary features (previous/next words and bigram tags) for training a sequence labeler. Finally, in the case of POS tagger, we use a Verb Group Identifier (VGI) which acts as an error correcting module for correcting the output of the CRF based sequence labeler. Each of these components is described in detail in the following sub-sections.

5.1 Morphological Analyzer

The formation of polymorphemic words leads to complexities which need to be handled during the analysis process. For example, consider the steps involved in the formation of the word देवासमोरच्याने {devasamorchyane} (the one in front of the God + ERGATIVE).

$$
\begin{aligned}
\text{devaasamora} &= (\text{deva} \rightarrow \text{devaa}) \\
&\quad + \text{samora} \\
\text{devaasamorachaa} &= (\text{devaasamora} \rightarrow \text{devaasamora}) \\
&\quad + \text{chaa} \\
\text{devaasamorachyaane} &= (\text{devaasamorachaa} \rightarrow \text{devaasamorachyaa}) \\
&\quad + \text{ne}
\end{aligned}
$$

In theory, the process can continue recursively for the attachment of any number of suffixes. However, in practice, we have observed that a word in Marathi contains at most 4 suffixes.

FSMs prove to be elegant and computationally efficient tools for analyzing polymorphemic

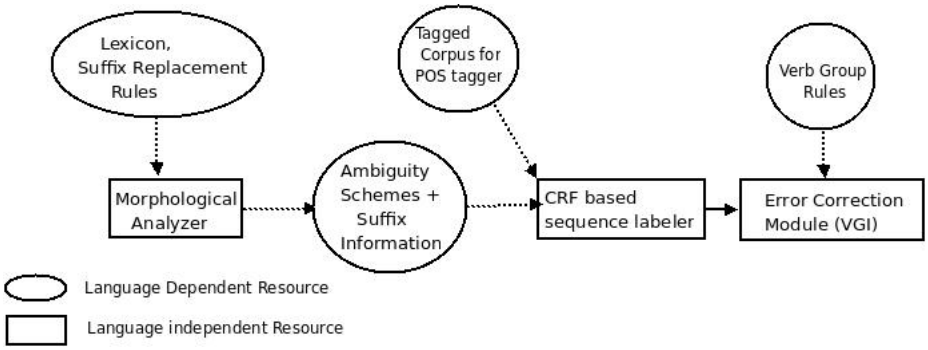

Figure 1: Architecture of POS Tagger

words. However, the recursive process of word formation in Marathi involves inflection at the time of attachment of every new suffix. The FSM needs to be modified to handle this. However, during the *i-th* recursion only *(i-1)-th* morpheme changes its form which can be handled by suitably modifying the FSM. The formation of word देवासमोरच्याने {devaasamorachyaane} can be viewed as:

devaasamora	=	(deva → devaa)
		+ samora
devaasamorachaa	=	(deva → devaa)
		+ (samora → samora)
		+ chaa
devaasamorachyaane	=	(deva → devaa)
		+ (samora → samora)
		+ (chaa → chyaa)
		+ ne

In general,
Polymorphemic word = $(inflected\_morpheme_1)$ + $(inflected\_morpheme_2)$ + ...

Now, we can create an FSM which is aware of these inflected forms of morphemes in addition to the actual morphemes to handle the above recursive process of word formation. These inflected forms are generated using the paradigm-based[4] system written in Java and then fed to the FSM implemented using SFST[5].

[4]A paradigm identifies the uninflected form of words which share similar inflectional patterns.

[5]http://www.ims.uni-stuttgart.de/projekte/gramotron/SOFTWARE/SFST.html

Our lexicon contains 16448 nouns categorized into 76 paradigms, 8516 adjectives classified as inflecting and non-inflecting adjectives, 1160 verbs classified into 22 classes. It contains 142 postpositions, 80 aakhyaata and 8 krudanta suffixes.

5.2 CRF

Conditional Random Fields (Lafferty et al., 2001) are undirected graphical models used for labeling sequential data. Under this model, the conditional probability distribution of a tag given the observed word sequence is given by,

$$P(Y|X;\lambda) = \frac{1}{Z(X)} \cdot e^{\sum_{t=1}^{T}\sum_{k=1}^{K}\lambda_k f_k(Y_{t-1},Y_t,X,t)} \quad (1)$$

where,

$$X = source\ word$$
$$Y = target\ word$$
$$T = length\ of\ sentence$$
$$K = number\ of\ features$$
$$\lambda_k = feature\ weight$$
$$Z(X) = normalization\ constant$$

We used CRF++[6], an open source implementation of CRF, for training and further decoding the tag sequence. We used the following features for training the sequence labeler (here, w_i is the *i-th* word, t_i is the *i-th* pos tag and c_i is the *i-th* chunk tag).

[6]http://crfpp.sourceforge.net/

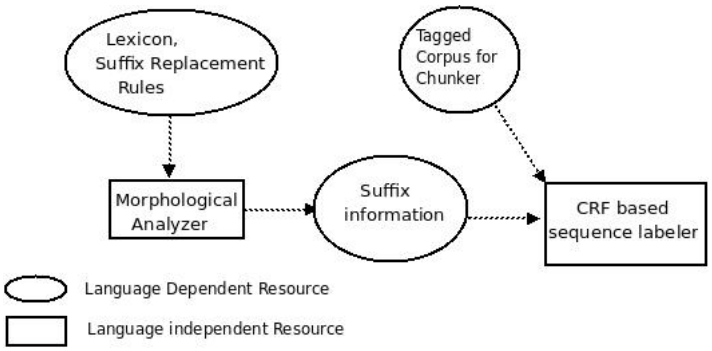

Figure 2: Architecture of Chunker

Features used for POS tagger training
Consider position of interest = i

- $t_i\ t_{i-1}$ and w_j such that $i-3 < j < i+3$
- $t_i\ t_{i-1}$ and suffix information of w_i
- $t_i\ t_{i-1}$ and ambiguity scheme of w_i

Here, the first features are ***weak features*** which depend only on the previous/next words and bigram tags. The next two are ***rich morphological features*** which make use of the output of the morphological analyzer.

Features used for Chunker training
Consider position of interest = i

- $c_i\ c_{i-1}$ and t_j, w_j such that $i-3 < j < i+3$
- $c_i\ c_{i-1}$ and suffix information of w_i

where c_i, $c_{i-1} \in \{B, I\}$. Here again, the first set of features are ***weak features*** and the second set of features are ***rich morphological features***.

5.3 Verb Group Identification (VGI)

In Marathi, certain auxiliaries like असते {asate} (be), आहे {aahe} (is) *etc.*. can also act as main verbs in certain contexts. This ambiguity between VM (main verbs) and VAUX (auxiliary verbs) can lead to a large number of errors in POS tagging if not handled correctly. However, the relatively rigid structure of Marathi VG coupled with distinct suffix-affinity of auxiliary verbs allows us to capture this ambiguity well using the following simple regular expression:

MainVerbRoot (KrudantaSuffix AuxVerbRoot)* AakhyaataSuffix

The above regular expression imposes some restriction on the occurrence of certain auxiliary verbs after specific *krudanta* suffixes. This restriction is captured with the help of a rule file containing *krudanta suffix-auxiliary verb* pairs. A sample entry from this file is

ऊन , काढ *[oon, kaaDh]*

which suggests that the auxiliary verb काढ {kaaDh} can appear after the suffix ऊन {oon}. We created a rule file containing around 350 such valid *krudanta suffix-auxiliary* verb pairs.

An important point which needs to be highlighted here is that a simple left to right scan ignoring suffix information and marking the first verb constituent as main verb and every other constituent as auxiliary verb does not work for Marathi. For example, consider the following verb sequence,

त्याला उचलून आणावे लागले.
tyaalaa uchaluun aaNaave laagale
He carry bring need
It was needed to carry and bring him.

Here, a simple left to right scan of the verb sequence ignoring the suffix information would imply that उचलून is a VM whereas आणावे and लागले are VAUX. However, this is not the case and can be identified correctly by considering the suffix affinity of auxiliary verbs. Specifically, in this case, the verb root आण cannot take the role of an auxiliary verb when it appears after the *krudanta* suffix ऊन. This suggests that the verb

आणावे does not belong to the same verb group as उचलून and hence is not a VAUX. This shows suffix and regular expression help in disambiguating VM-VAUX which is a challenge in all POS taggers.

6 Experimental Setup

We used documents from the TOURISM and NEWS domain for all our experiments [7]. These documents were hand annotated by two Marathi lexicographers. The total size of the corpus was kept large (106273 POS tagged words and 63033 chunks) to study the impact of the size of training data versus the amount of linguistic information used. The statistics about each POS tag and chunk tag are summarized in Table 1 and Table 2.

POS Tag	Frequency in Corpus	POS Tag	Frequency in Corpus

Table 2: Chunk Tags in Training Data

7 Results

We report results in four different settings:
Weak Features (WF): Here we use the basic CRF classifier with elementary word features (*i.e.*, words appearing in a context window of 3) and bigram tag features and POS tags in case of chunker.
Weak Morphological Features (Weak-MF): In addition to the elementary features we use substrings of length 1 to 7 appearing at the end of the word as feature. The idea here is that such substrings taken from the end of the word can provide a good approximation of the actual suffix of the word. Such substrings thus provide a statistical approximation of the suffixes in the absence of a full fledged morphological analyzer. This should not be confused with weak features which mean tags and word.
Rich Morphological Features (Rich-MF): In addition to the elementary features we use the ambiguity schemes and suffix information provided by the morphological analyzer.
Reach Morphological Features + Verb Group Identification (Rich-MF+VGI): This setting is applicable only for POS tagging where we apply an error correcting VGI module to correct the output of the feature rich CRF tagger.

In each case we first divided the data into four folds (75% for training and 25% for testing). Next, we varied the training data in increments of 10K and calculated the accuracy of each of the above models. The x-axis represents the size of the training data and the y-axis represents the precision of the tagger/chunker. Figure 3 plots the average precision of the POS tagger across all categories using WF, Weak-MF, Rich-MF and Rich-MF_VGI for varying sizes of the training data. Figure 6 plots the average precision of the chunker across all categories using WF, Weak-MF and Rich-MF. Next, to show that the impact of morphological analysis is felt more for verbs than other POS categories we plot the accuracies of verb pos tags (Figure 4) and verb chunk tags (Figure 7) using WF, Weak-MF, Rich-MF and Rich-MF_VGI for varying sizes of the training data.

8 Discussions

We made the following interesting observations from the above graphs and tables.
1. Importance of linguistic knowledge: Figure 3 shows that using a large amount of annotated corpus (91k), the best accuracy one can hope

[7] The data can be found at www.cfilt.iitb.ac.in/

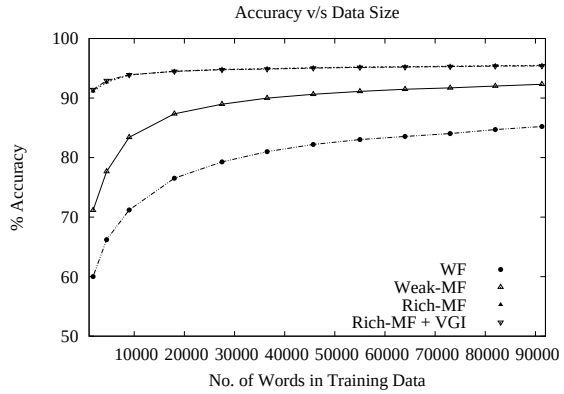

Figure 3: Average Accuracy of all POS Tags
(Note: The graphs for Rich-MF and Rich-MF+VGI coincide)

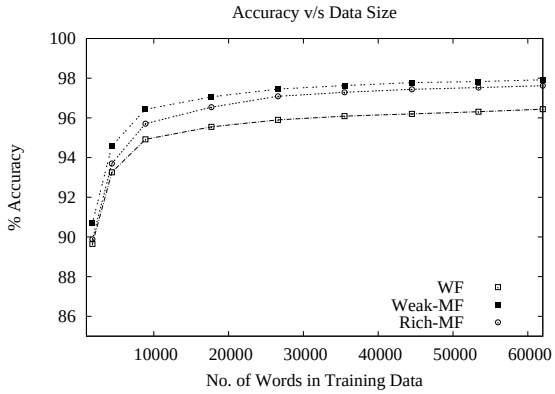

Figure 6: Average Accuracy of all Chunk Tags

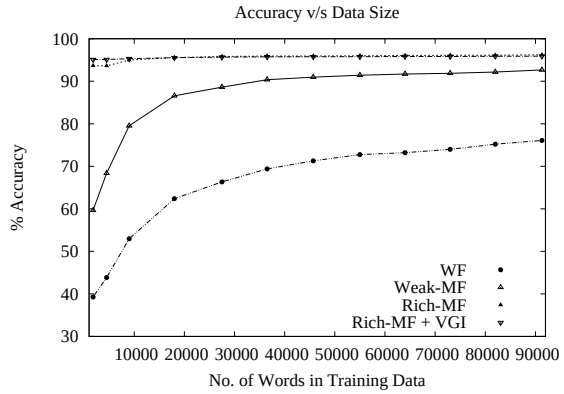

Figure 4: Average Accuracy of Verb POS Tags
(Note: The graphs for Rich-MF and Rich-MF+VGI almost coincide)

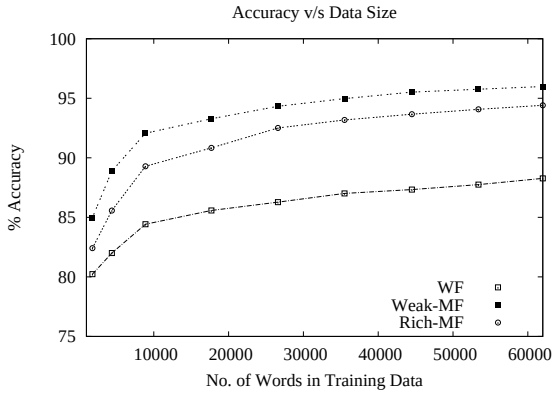

Figure 7: Average Accuracy of Verb Chunks

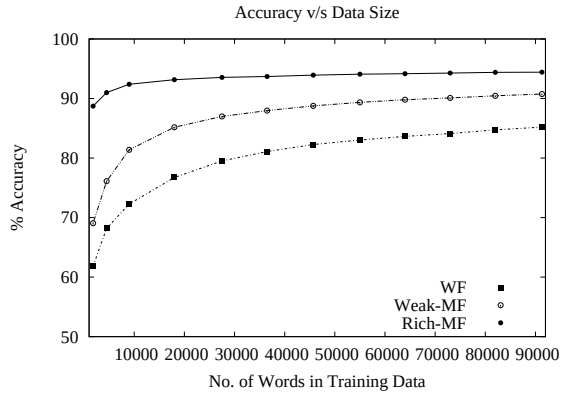

Figure 5: Average Accuracy of Non Verb POS Tags

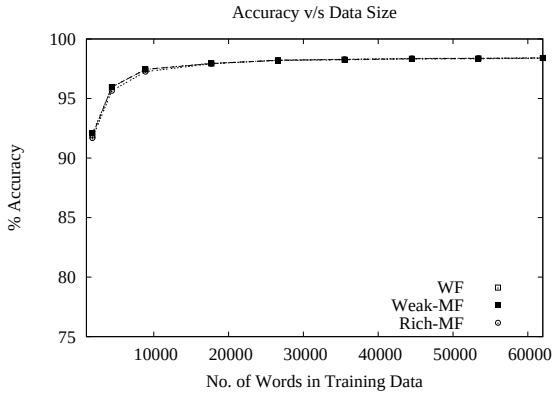

Figure 8: Average Accuracy of Non Verb Chunks
(Note: All the graphs coincide.)

for is around 85% if morphological information is not harnessed *i.e.*, if only weak features are used. Adding more data will definitely not be of much use as the curve is already close to saturation. On the other hand, if morphological information is completely harnessed using a rich morphological analyzer then an accuracy as high as 94% can be obtained by using data as small as 20k words. Figure 6 tells a similar story. In the absence of morphological features a large amount of annotated corpus (62k words) is needed to reach an accuracy of 96%, whereas if suffix information is used then the same accuracy can be reached using a much smaller training corpus (20k words). This clearly shows that while dealing with morphologically rich languages, time and effort should be invested in building powerful morphological analyzer.

2. Weak morphological features vs rich morphological analyzer: Figure 3 shows that in the case of POS tagging using just weak morphological features gives much better results than the baseline (i.e. using only weak features). However, it does not do as well as the rich features especially when the training size is small, thereby suggesting that an approximation of the morphological suffixes may not work for a language having rich and diverse morphology. On the other hand, in the case of chunking, the weak morphological features do marginally better than the rich morphological features suggesting that for a relatively easier task (chunking as compared to POS tagging) even a simple approximation of the actual suffixes may deliver the goods.

3. Specific case of verbs: Figure 4 shows that in case of POS tagging using suffixes as features results in a significant increase in accuracy of verbs. Specifically accuracy increases from 62% to 95% using a very small amount of annotated corpus (20K words). Comparing this with figure 5 we see that while using morphological information definitely helps other POS categories, the impact is not as high as that felt for verbs. Figures 7 and 8 for chunking show a similar pattern *i.e.*, the accuracy of verb chunks is affected more by morphology as compared to other chunk tags. These figures support our claim that "verbs is where all the action lies" and they indeed need special treatment in terms of morphological analysis.

	VM	VAUX
VM	17078	347
VAUX	257	6025

Table 3: Confusion matrix for VM-VAUX using Rich-MF

4. Effect of VGI: Figures 3 and 4 show that the VGI module does not lead to any improvement in the overall accuracy. A detailed analysis showed that this is mainly because there was not much VM-VAUX ambiguity left after applying CRF model containing rich morphological features. To further illustrate our point we present the confusion matrix (see Table 3) for verb tags for a POS tagger using Rich-MF. Table 3 shows that there were only 347 VM tags which got wrongly tagged as VAUX and 257 VAUX tags which got wrongly tagged as VM. Thus the rich morphological features were able to take care of most VM-VAUX ambiguities in the data. However we feel that if the data contains several VM-VAUX ambiguities such as the one illustrated in the example in Section 5.3 then the VGI module would come in play and help to boost the performance by resolving such ambiguities.

9 Conclusion

We presented here our work on shallow parsing of a morphologically rich language- Marathi. Our results show that while dealing with such languages one cannot ignore the importance of harnessing morphological features. This is especially true for verbs where improvements upto 50% in accuracy can be obtained by adroit handling of suffixes and accurate verb group identification. An important conclusion that can be drawn from our work is that while dealing with morphologically rich languages it makes sense to invest time and money in developing powerful morphological analyzers than placing all the bets on annotating data.

A Semantic Network Approach to Measuring Relatedness

Brian Harrington
Oxford University Computing Laboratory
brian.harrington@comlab.ox.ac.uk

Abstract

Humans are very good at judging the strength of relationships between two terms, a task which, if it can be automated, would be useful in a range of applications. Systems attempting to solve this problem automatically have traditionally either used relative positioning in lexical resources such as WordNet, or distributional relationships in large corpora. This paper proposes a new approach, whereby relationships are derived from natural language text by using existing NLP tools, then integrated into a large scale semantic network. Spreading activation is then used on this network in order to judge the strengths of all relationships connecting the terms. In comparisons with human measurements, this approach was able to obtain results on par with the best purpose built systems, using only a relatively small corpus extracted from the web. This is particularly impressive, as the network creation system is a general tool for information collection and integration, and is not specifically designed for tasks of this type.

1 Introduction

The ability to determine semantic relatedness between terms is useful for a variety of NLP applications, including word sense disambiguation, information extraction and retrieval, and text summarisation (Budanitsky and Hirst, 2006). However, there is an important distinction to be made between semantic *relatedness* and semantic *similarity*. As (Resnik, 1999) notes, "Semantic similarity represents a special case of semantic relatedness: for example, cars and gasoline would seem to be more closely related than, say, cars and bicycles, but the latter pair are certainly more similar". (Budanitsky and Hirst, 2006) further note that "Computational applications typically require relatedness rather than just similarity; for example, money and river are cues to the in-context meaning of bank that are just as good as trust company".

Systems for automatically determining the degree of semantic relatedness between two terms have traditionally either used a measurement based on the distance between the terms within WordNet (Banerjee and Pedersen, 2003; Hughes and Ramage, 2007), or used co-occurrence statistics from a large corpus (Mohammad and Hirst, 2006; Padó and Lapata, 2007). Recent systems have, however, shown improved results using extremely large corpora (Agirre et al., 2009), and existing large-scale resources such as Wikipedia (Strube and Ponzetto, 2006).

In this paper, we propose a new approach to determining semantic relatedness, in which a semantic network is automatically created from a relatively small corpus using existing NLP tools and a network creation system called ASKNet (Harrington and Clark, 2007), and then spreading activation is used to determine the strength of the connections within that network. This process is more analogous to the way the task is performed by humans. Information is collected from fragments and assimilated into a large semantic knowledge structure which is not purposely built for a single task, but is constructed as a general resource containing a wide variety of information. Relationships represented within this

Coling 2008: Poster Volume, pages 356–364,
Beijing, August 2010

structure can then be used to determine the total strength of the relations between any two terms.

2 Existing Approaches

2.1 Resource Based Methods

A popular method for automatically judging semantic distance between terms is through WordNet (Fellbaum, 1998), using the lengths of paths between words in the taxonomy as a measure of distance. While WordNet-based approaches have obtained promising results for measuring semantic similarity (Jiang and Conrath, 1997; Banerjee and Pedersen, 2003), the results for the more general notion of semantic relatedness have been less promising (Hughes and Ramage, 2007).

One disadvantage of using WordNet for evaluating semantic relatedness is its hierarchical taxonomic structure. This results in terms such as *car* and *bicycle* being close in the network, but terms such as *car* and *gasoline* being far apart. Another difficulty arises from the non-scalability of WordNet. While the quality of the network is high, the manual nature of its construction means that arbitrary word pairs may not occur in the network. Hence in this paper we pursue an approach in which the resource for measuring semantic relatedness is created automatically, based on naturally occurring text.

A similar project, not using WordNet is WikiRelate (Strube and Ponzetto, 2006), which uses the existing link structure of Wikipedia as its base network, and uses similar path based measurements to those found in WordNet approaches to compute semantic relatedness. This project has seen improved results over most WordNet base approaches, largely due to the nature of Wikipedia, where articles tend to link to other articles which are related, rather than just ones which are similar.

2.2 Distributional Methods

An alternative method for judging semantic distance is using word co-occurrence statistics derived from a very large corpus (McDonald and Brew, 2004; Padó and Lapata, 2007) or from the web using search engine results (Turney, 2001).

In a recent paper, Agirre et al. (2009) parsed 4 billion documents (1.6 Terawords) crawled from the web, and then used a search function to extract syntactic relations and context windows surrounding key words. These were then used as features for vector space, in a similar manner to work done in (Padó and Lapata, 2007), using the British National Corpus (BNC). This system has produced excellent results, indicating that the quality of the results for these types of approaches is related to the size and coverage of their corpus. This does however present problems moving forward, as 1.6 Terawords is obviously an extremely large corpus, and it is likely that there would be a diminishing return on investment for increasingly large corpora. In the same paper, another method was shown which used the pagerank algorihm, run over a network formed from WordNet and the WordNet gloss tags in order to produce equally impressive results.

3 A Semantic Network Approach

The resource we use is a semantic network, automatically created by the large scale network creation program, ASKNet. The relations between nodes in the network are based on the relations returned by a parser and semantic analyser, which are typically the arguments of predicates found in the text. Hence terms in the network are related by the chain of syntactic/semantic relations which connect the terms in documents, making the network ideal for measuring the general notion of semantic relatedness.

Distinct occurrences of terms and entities are combined into a single node using a novel form of spreading activation (Collins and Loftus, 1975). This combining of distinct mentions produces a cohesive connected network, allowing terms and entities to be related across sentences and even larger units such as documents. Once the network is built, spreading activation is used to determine semantic

relatedness between terms. For example, to determine how related *car* and *gasoline* are, activation is given to one of the nodes, say *car*, and the network is "fired" to allow the activation to spread to the rest of the network. The amount of activation received by *gasoline* is then a measure of the strength of the semantic relation between the two terms.

We use three datasets derived from human judgements of semantic relatedness to test our technique. Since the datasets contain general terms which may not appear in an existing corpus, we create our own corpus by harvesting text from the web via Google. This approach has the advantage of requiring little human intervention and being extensible to new datasets. Our results using the semantic network derived from the web-based corpus are comparable to the best performing existing methods tested on the same datasets.

4 Creating the Semantic Networks

ASKNet creates the semantic networks using existing NLP tools to extract syntactic and semantic information from text. This information is then combined using a modified version of the update algorithm used by Harrington and Clark (2007) to create an integrated large-scale network. By mapping together concepts and objects that relate to the same real-world entities, the system is able to transform the output of various NLP tools into a single network, producing semantic resources which are more than the sum of their parts. Combining information from multiple sources results in a representation which would not have been possible to obtain from analysing the original sources separately.

The NLP tools used by ASKNet are the C&C parser (Clark and Curran, 2007) and the semantic analysis program Boxer (Bos et al., 2004), which operates on the CCG derivations output by the parser to produce a first-order representation. The named entity recognizer of Curran and Clark (2003) is also used to recognize the standard set of MUC entities, including `person`, `location` and `organisation`.

As an example of the usefulness of information integration, consider the *monk-asylum* example, taken from the RG dataset (described in Section 5.1). It is possible that even a large corpus could contain sentences linking *monk* with *church*, and linking *church* with *asylum*, but no direct links between *monk* and *asylum*. However, with an integrated semantic network, activation can travel across multiple links, and through multiple paths, and will show a relationship, albeit probably not a very strong one, between *monk* and *asylum*, which corresponds nicely with our intuition.

Figure 1, which gives an example network built from DUC documents describing the Elian Gonzalez custody battle, gives an indication of the kind of network that ASKNet builds. This figure does not give the full network, which is too large to show in a single figure, but shows the "core" of the network, where the core is determined using the technique described in (Harrington and Clark, 2009). The black boxes represent named entities mentioned in the text, which may have been mentioned a number of times across documents, and possibly using different names (e.g. Fidel Castro vs. President Castro). The diamonds are named directed edges, which represent relationships between entities.

A manual evaluation using human judges has been performed to measure the accuracy of ASKNet networks. On a collection of DUC documents, the "cores" of the resulting networks were judged to be 80% accurate on average, where accuracy was measured for the merged entity nodes in the networks and the relations between those entities (Harrington and Clark, 2009). The motivation for fully automatic creation is that very large networks, containing millions of edges, can be created in a matter of hours.

Automatically creating networks does result in lower precision than manual creation, but this is offset by the scalability and speed of creation. The experiments described in this paper are a good test of the automatic creation methodology.

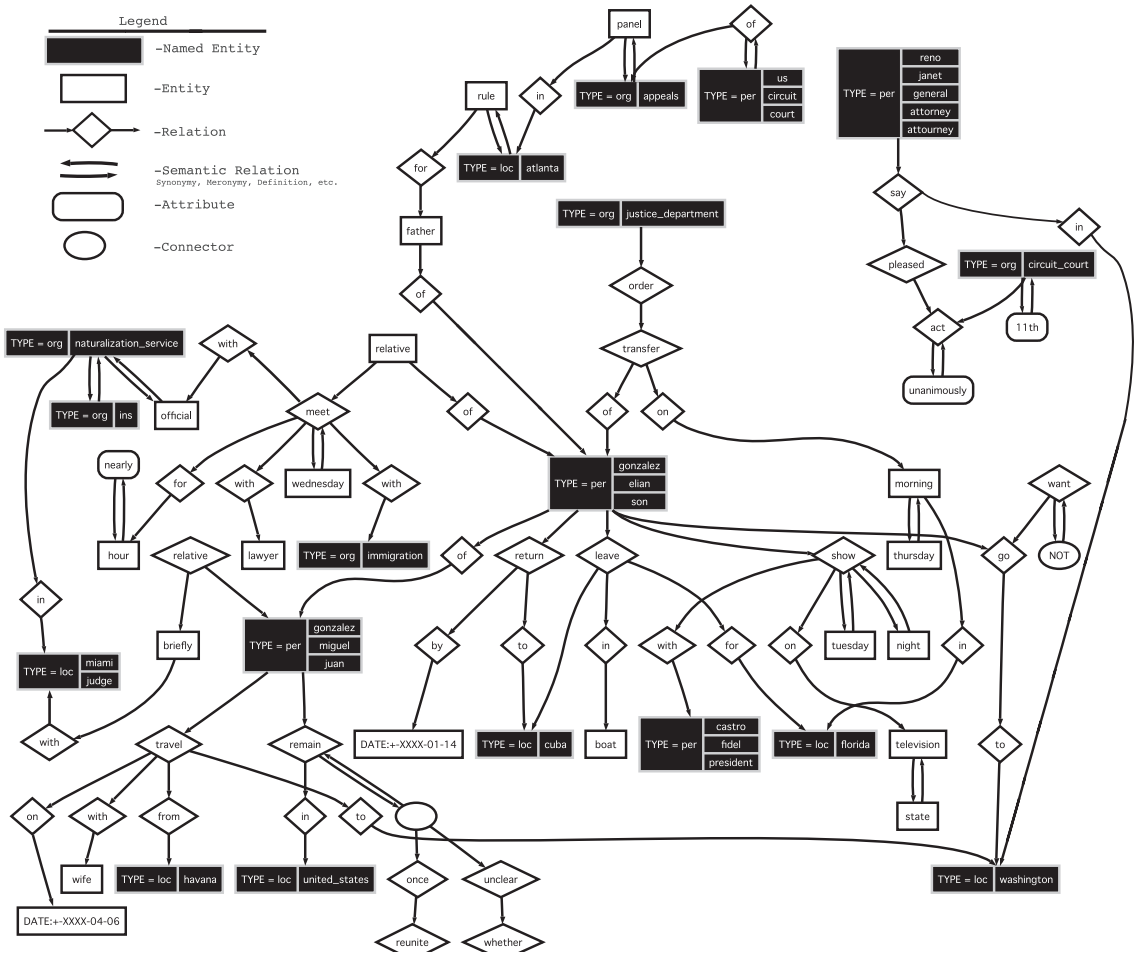

Figure 1: Example network core derived from DUC documents describing a news story from 2000.

The update algorithm

In order to merge information from multiple sources into a single cohesive resource, ASKNet uses a spreading activation based update algorithm (Harrington and Clark, 2007). As the system encounters new information, it attempts to map named entities in the new sentences it encounters to those already in its network. Each new sentence is turned into an *update fragment*; a fragment of the network representing the information contained in the sentence. Initial mapping scores, based on lexical similarity and named entity type, are made between the update fragment's named entities and those in the main network. The job of the update algorithm is to improve upon those initial scorings using the semantic information contained within the network.

The update algorithm iterates over each named entity node in the update fragment. This *base* node is provided with activation, which is allowed to spread throughout the fragment. All named entities which receive activation in this process, then transfer their activation to their *target* named entity nodes (nodes in the main network with which they have a current mapping score greater than zero). The amount transferred is based on the strength of the mapping score. The activation is then allowed to circulate through the main network until it reaches a stable state. At this point, the base node's mappings are updated based on which of its target nodes received activation. The more activation a target node receives, the more its mapping score with the

base node will increase.

The intuition behind the update algorithm is that we can use relatedness of nodes in the update fragment to determine appropriate mappings in the main network. So if our base node has the label "Crosby", and is related to named entity nodes referring to "Canada", "Vancouver" and "2010", those nodes will pass their activation onto their main network targets, and hopefully onto the node representing the ice hockey player Sidney Crosby. We would then increase the mapping score between our base node and this target, while at the same time decreasing the mapping score between out base node and the singer Bing Crosby, who (hopefully) would have received little or no activation. The update algorithm is also self-reinforcing, as in the successive stages, the improved scores will focus the activation further. In our example, in successive iterations, more of the activation coming to the "Crosby" node will be sent to the appropriate target node, and therefore there will be less spurious activation in the network to create noise.

For the purposes of these experiments, we extended the update algorithm to map together general object nodes, rather than focusing solely on named entities. This was necessary due to the nature of the task. Simply merging named entities would not be sufficient, as many of the words in datasets would not likely be associated strongly with any particular named entities. Extending the algorithm in this way resulted in a much higher frequency of mapping, and a much more connected final network. Because of this, we found that several of the parameters had to be changed from those used in Harrington and Clark (2009). Our initial activation input was set to double that used in Harrington and Clark's experiments (100 instead of 50), to compensate for the activation lost over the higher number of links. We also found that the number of iterations required to reach a stable state had increased to more than 4 times the previous number. This was to be expected due to the increased number of links passing activation. We also had to remove the named entity type calculation from the initial mapping score, thus leaving the initial scoring to be simply the ratio of labels in the two nodes which overlapped. These changes were all done after manual observation of test networks built from searches not relating to any dataset, and were not changed once the experiments had begun.

4.1 Measuring semantic relatedness

Once a large-scale network has been constructed from a corpus of documents, spreading activation can be used to efficiently obtain a distance score between any two nodes in the network, which will represent the semantic relatedness of the pair. Each node in the network has a current amount of activation and a threshold (similar to classical ideas from the neural network literature). If a node's activation exceeds its threshold, it will fire, sending activation to all of its neighbours, which may cause them to fire, and so on. The amount of activation sent between nodes decreases with distance, so that the effect of the original firing is localized. The localized nature of the algorithm is important because it means that semantic relatedness scores can be calculated efficiently even for pairs of nodes in very large networks.

To obtain a score between nodes `x` and `y`, first a set amount of activation is placed in node `x`; then the network is fired until it stabilises, and the total amount of activation received by node `y` is stored as `act(x,y)`. This process is repeated starting with node `y` to obtain `act(y,x)`. The sum of these two values, which we call `dist(x,y)`, is used as the measure of semantic relatedness between `x` and `y`.[1]

`dist(x,y)` is a measure of the total strength of connection between nodes `x` and `y`, relative to the other nodes in their region. This takes into account not just direct paths, but also indirect paths, if the links along those paths are of sufficient strength. Since the

[1]The average could be used also but this has no effect on the ranking statistics used in the later experiments.

networks potentially contain a wide variety of relations between terms, the calculation of `dist(x,y)` has access to a wide variety of information linking the two terms. If we consider the *(car, gasoline)* example mentioned earlier, the intuition behind our approach is that these two terms are likely to be closely related in a semantic network built from text, either fairly directly because they appear in the same sentence or document, or indirectly because they are related to the same entities.

5 Experiments

The purpose of the experiments was to develop an entirely automated approach for replicating human judgements of semantic relatedness of words. We used three existing datasets of human judgements: the Hodgson, Rubenstein & Goodenough (RG) and Wordsimilarity-353 (WS-353) datasets. For each dataset we created a corpus using results returned by Google when queried for each word independently (Described in Section 5.2). We then built a semantic network from that corpus and used the spreading activation technique described in the previous section to measure semantic relatedness between the word pairs in the dataset.

The parser and semantic analysis tool used to create the networks were developed on newspaper data (a CCG version of the Penn Treebank (Steedman and Hockenmaier, 2007; Clark and Curran, 2007)), but our impression from informally inspecting the parser output was that the accuracy on the web data was reasonable. The experimental results show that the resulting networks were of high enough quality to closely replicate human judgements.

5.1 The datasets

Many studies have shown a marked priming effect for semantically related words. In his single-word lexical priming study, (Hodgson, 1991) showed that the presentation of a *prime word* such as *election* directly facilitates processing of a target word such as *vote*. Hodgson showed an increase in both response speed and accuracy when the prime and target are semantically related. 143 word pairs were tested across 6 different lexical relations: antonymy (e.g., *enemy*, *friend*); conceptual association (e.g., *bed*, *sleep*); category coordination (e.g., *train*, *truck*); phrasal association (e.g., *private*, *property*); superordination/subordination (e.g., *travel*, *drive*); and synonymy (e.g., *value*, *worth*). It was shown that equivalent priming effects (i.e., reduced processing time) were present across all relation types, thus indicating that priming was a result of the terms' semantic relatedness, not merely their similarity or other simpler relation type.

The Hodgson dataset consists of the 143 word pairs divided by lexical category. There were no scores given as all pairs were shown to have relatively similar priming effects. No examples of unrelated pairs are given in the dataset. We therefore used the unrelated pairs created by McDonald and Brew (2004).

The task in this experiment was to obtain scores for all pairs, and to do an ANOVA test to determine if there is a significant difference between the scores for related and unrelated pairs.

The WS-353 dataset (Finkelstein et al., 2002) contains human rankings of the semantic distance between pairs of terms. Although the name may imply that the scores are based on similarity, human judges were asked to score 353 pairs of words for their *relatedness* on a scale of 1 to 10, and so the dataset is ideal for our purposes. For example, the pair *(money, bank)* is in the dataset and receives a high relatedness score of 8.50, even though the terms are not lexically similar.

The dataset contains regular nouns and named entities, as well as at least one term which does not appear in WordNet (*Maradona*). In this experiment, we calculated scores for all word pairs, and then used rank correlation to compare the similarity of our generated scores to those obtained from human judgements.

The RG dataset (Rubenstein and Goodenough, 1965) is very similar to the WS-353,

though with only 65 word pairs, except that the human judges were asked to judge the pairs based on synonymy, rather than overall relatedness. Thus, for example, the pair *(monk,asylum)*, receives a significantly lower score than the pair *(crane,implement)*.

5.2 Data collection, preparation and processing

In order to create a corpus from which to build the semantic networks, we first extracted each individual word from the pairings, resulting in a list of 440 words for the WS-353 collection, 48 words for the RG (some words were used in multiple pairings), and 282 words for the Hodgson collection. For each of the words in this list, we then performed a query using Google, and downloaded the first 5 page results for that query. The choice of 5 as the number of documents to download for each word was based on a combination of informal intuition about the precision and recall of search engines, as well as the practical issue of obtaining a corpus that could be processed in reasonable space and time.

Each of the downloaded web pages was then cleaned by a set of Perl scripts which removed all HTML markup. Statistics for the resulting corpora are given in Table 1.

Three rules were added to the retrieval process to deal with problems encountered in formatting of web-pages:

1. Pages from which no text could be retrieved were ignored and replaced with the next result.
2. HTML lists preceded by a colon were recombined into sentences.
3. For Wikipedia disambiguation pages (pages which consist of a list of links to articles relating to the various possible senses of a word), all of the listed links were followed and the resulting pages added to the corpus.

Each of these heuristics was performed automatically and without human intervention.

The largest of the networks, created for the WS-353 dataset, took slightly over 24 hours to complete, including time for parsing and semantic analysis.

corpus	sentences	words
Hodgson	814,779	3,745,870
RG	150,165	573,148
WS-353	1,042,128	5,027,947

Table 1: Summary statistics for the corpora generated for the experiments.

6 Results

6.1 Hodgson priming dataset

After processing the Hodgson corpus to build a semantic network with approximately 500,000 nodes and 1,300,000 edges, the appropriate node pairs were fired to obtain the distance measure as previously described. Those measurements were then recorded as measurements of semantic relatedness between two terms. If a term was used as a label in two or more nodes, all nodes were tried, and the highest scoring pairs were used.

As the Hodgson dataset did not provide examples of unrelated pairs against which we could compare, unrelated pairs were generated as described in (McDonald and Brew, 2004). This is not an ideal method, as several pairs that were identified as unrelated did have some relatively obvious relationship (e.g. *tree – house*, *poker – heart*). However we chose to retain the methodology for consistency with previous literature as it was also used in (Padó and Lapata, 2007).

Scores were obtained from the network for the word pairs, and for each target an average score was calculated for all primes in its category. Example scores are given in Table 2.

Two-way analysis of variance (ANOVA) was carried out on the network scores with the the relatedness status of the pair being the independent variable. A reliable effect was observed for the network scores with the primes for related words being significantly larger than those for unrelated words. The results are given in Table 3.

The use of ANOVA shows that there is a

Word pair	Related	Network Score
empty - full	Yes	10.13
coffee - mug	Yes	5.86
horse - goat	Yes	0.96
dog - leash	Yes	4.70
friend - antonym	No	0.53
vote - conceptual	No	1.37
property - phrasal	No	2.47
drive - super/sub	No	1.86

Table 2: Example scores obtained from the network for related and unrelated word pairs from the Hodgson dataset

difference in the scores of the related and unrelated word pairs that cannot be accounted for by random variance. However, in order to compare the strength of the experimental effects between two experiments, additional statistics must be used. Eta-squared (η^2) is a measure of the strength of an experimental effect. A high η^2 indicates that the independent variable accounts for more of the variability, and thus indicates a stronger experimental effect. In our experiments, we found an η^2 of 0.411, which means that approximately 41% of the overall variance can be explained by the relatedness scores.

For comparison, we provide the ANOVA results for experiments by (McDonald and Brew, 2004) and (Padó and Lapata, 2007) on the same dataset. Both of these experiments obtained scores using vector based models populated with data from the BNC.

We also include the results obtained from performing the same ANOVA tests on Pointwise Mutual Information scores collected over our corpus. These results were intended to provide a baseline when using the web-based corpus. To calculate the PMI scores for this experiment, we computed scores for the number of times the two words appeared in the same paragraph or document, and the total number of occurrences of words in the corpus. The PMI scores were calculated by simply dividing the number of times the words co-occurred within a paragraph, by the product of the number of occurrences of each word within a document.

	F	MSE	p	η^2
McDonald & Brew	71.73	0.004	< 0.001	
Padó & Lapata	182.46	0.93	< 0.01	0.332
PMI	42.53	3.79	< 0.001	0.263
Network	50.71	3.28	< 0.0001	0.411

Table 3: ANOVA results of scores generated from the Hodgson dataset compared to those reported for existing systems. (F = F-test statistic, MSE = Mean squared error, p = P-value, η^2 = Effect size)

6.2 ws-353 and rg datasets

The methodology used to obtain scores for the WS-353 and RG collections was identical to that used for the Hodgson data, except that scores were only obtained for those pairs listed in the data set. Because both collections provided direct scores, there was no need to retrieve network scores for unrelated pairings.

	WS-353	RG
WikiRelate!	0.48	0.86
Hughes-Ramage	0.55	0.84
Agirre Et Al	0.66	0.89
PMI	0.41	0.80
Network	0.62	0.86

Table 4: Rank correlation scores for the semantic network and PMI-based approaches, calculated on the WS-353 and RG collections, shown against scores for existing systems.

For consistency with previous literature, the scores obtained by the semantic network were compared with those from the collections using Spearman's rank correlation. The correlation results are given in Table 4. For comparison, we have included the results of the same correlation on scores from three top scoring systems using the approaches described above. We also include the scores obtained by using a simple PMI calculation as in the previous experiment.

The scores obtained by our system were not an improvement on those obtained by existing systems. However, our scores were on par with the best performing systems, which were purpose built for this application, and at least in the case of the system by Agirre et al. used a corpus several orders of magnitude larger.

7 Conclusion

In this paper we have shown that a semantic network approach to determining semantic relatedness of terms can achieve performance on par with the best purpose built systems. This is interesting for two reasons. Firstly, the approach we have taken in this paper is much more analogous to the way humans perform similar tasks. Secondly, the system used was not purpose built for this application. It is instead a general tool for information collection and integration, and this result indicates that it will likely be useful for a wide variety of language processing applications.

Conundrums in Unsupervised Keyphrase Extraction: Making Sense of the State-of-the-Art

Kazi Saidul Hasan and **Vincent Ng**
Human Language Technology Research Institute
University of Texas at Dallas
{saidul,vince}@hlt.utdallas.edu

Abstract

State-of-the-art approaches for unsupervised keyphrase extraction are typically evaluated on a single dataset with a single parameter setting. Consequently, it is unclear how effective these approaches are on a new dataset from a different domain, and how sensitive they are to changes in parameter settings. To gain a better understanding of state-of-the-art unsupervised keyphrase extraction algorithms, we conduct a systematic evaluation and analysis of these algorithms on a variety of standard evaluation datasets.

1 Introduction

The keyphrases for a given document refer to a group of phrases that *represent* the document. Although we often come across texts from different domains such as scientific papers, news articles and blogs, which are labeled with keyphrases by the authors, a large portion of the Web content remains untagged. While keyphrases are excellent means for providing a concise summary of a document, recent research results have suggested that the task of automatically identifying keyphrases from a document is by no means trivial. Researchers have explored both supervised and unsupervised techniques to address the problem of automatic keyphrase extraction. Supervised methods typically recast this problem as a binary classification task, where a model is trained on annotated data to determine whether a given phrase is a keyphrase or not (e.g., Frank et al. (1999), Turney (2000; 2003), Hulth (2003), Medelyan et al. (2009)). A disadvantage of supervised approaches is that they require a lot of training data and yet show bias towards the domain on which they are trained, undermining their ability to generalize well to new domains. Unsupervised approaches could be a viable alternative in this regard.

The unsupervised approaches for keyphrase extraction proposed so far have involved a number of techniques, including language modeling (e.g., Tomokiyo and Hurst (2003)), graph-based ranking (e.g., Zha (2002), Mihalcea and Tarau (2004), Wan et al. (2007), Wan and Xiao (2008), Liu et al. (2009a)), and clustering (e.g., Matsuo and Ishizuka (2004), Liu et al. (2009b)). While these methods have been shown to work well on a particular domain of text such as short paper abstracts and news articles, their effectiveness and portability across different domains have remained an unexplored issue. Worse still, each of them is based on a set of assumptions, which may only hold for the dataset on which they are evaluated.

Consequently, *we have little understanding of how effective the state-of the-art systems would be on a completely new dataset from a different domain*. A few questions arise naturally. How would these systems perform on a different dataset with their original configuration? What could be the underlying reasons in case they perform poorly? Is there any system that can generalize fairly well across various domains?

We seek to gain a better understanding of the state of the art in unsupervised keyphrase extraction by examining the aforementioned questions. More specifically, we compare five unsupervised keyphrase extraction algorithms on four corpora with varying domains and statistical characteristics. These algorithms represent the ma-

Coling 2008: Poster Volume, pages 365–373,
Beijing, August 2010

jor directions in this research area, including Tf-Idf and four recently proposed systems, namely, TextRank (Mihalcea and Tarau, 2004), SingleRank (Wan and Xiao, 2008), ExpandRank (Wan and Xiao, 2008), and a clustering-based approach (Liu et al., 2009b). Since none of these systems (except TextRank) are publicly available, we reimplement all of them and make them freely available for research purposes.[1] To our knowledge, this is the *first* attempt to compare the performance of state-of-the-art unsupervised keyphrase extraction systems on multiple datasets.

2 Corpora

Our four evaluation corpora belong to different domains with varying document properties. Table 1 provides an overview of each corpus.

The **DUC-2001** dataset (Over, 2001), which is a collection of 308 news articles, is annotated by Wan and Xiao (2008). We report results on all 308 articles in our evaluation.

The **Inspec** dataset is a collection of 2,000 abstracts from journal papers including the paper title. Each document has two sets of keyphrases assigned by the indexers: the *controlled keyphrases*, which are keyphrases that appear in the *Inspec* thesaurus; and the *uncontrolled keyphrases*, which do not necessarily appear in the thesaurus. This is a relatively popular dataset for automatic keyphrase extraction, as it was first used by Hulth (2003) and later by Mihalcea and Tarau (2004) and Liu et al. (2009b). In our evaluation, we use the set of 500 abstracts designated by these previous approaches as the test set and its set of uncontrolled keyphrases. Note that the average document length for this dataset is the smallest among all our datasets.

The **NUS Keyphrase Corpus** (Nguyen and Kan, 2007) includes 211 scientific conference papers with lengths between 4 to 12 pages. Each paper has one or more sets of keyphrases assigned by its authors and other annotators. We use all the 211 papers in our evaluation. Since the number of annotators can be different for different documents and the annotators are not specified along with the annotations, we decide to take the union of all the gold standard keyphrases from all the sets to construct one single set of annotation for each paper. As Table 1 shows, each NUS paper, both in terms of the average number of tokens (8291) and candidate phrases (2027) per paper, is more than five times larger than any document from any other corpus. Hence, the number of candidate keyphrases that can be extracted is potentially large, making this corpus the most challenging of the four.

Finally, the **ICSI meeting corpus** (Janin et al., 2003), which is annotated by Liu et al. (2009a), includes 161 meeting transcriptions. Following Liu et al., we remove topic segments marked as 'chitchat' and 'digit' from the dataset and use all the remaining segments for evaluation. Each transcript contains three sets of keyphrases produced by the same three human annotators. Since it is possible to associate each set of keyphrases with its annotator, we evaluate each system on this dataset three times, once for each annotator, and report the average score. Unlike the other three datasets, the gold standard keys for the ICSI corpus are mostly unigrams.

3 Unsupervised Keyphrase Extractors

A generic unsupervised keyphrase extraction system typically operates in three steps (Section 3.1), which will help understand the unsupervised systems explained in Section 3.2.

3.1 Generic Keyphrase Extractor

Step 1: Candidate lexical unit selection The first step is to filter out unnecessary word tokens from the input document and generate a list of potential keywords using heuristics. Commonly used heuristics include (1) using a stop word list to remove non-keywords (e.g., Liu et al. (2009b)) and (2) allowing words with certain part-of-speech tags (e.g., nouns, adjectives, verbs) to be considered candidate keywords (Mihalcea and Tarau (2004), Liu et al. (2009a), Wan and Xiao (2008)). In all of our experiments, we follow Wan and Xiao (2008) and select as candidates words with the following Penn Treebank tags: NN, NNS, NNP, NNPS, and JJ, which are obtained using the Stanford POS tagger (Toutanova and Manning, 2000).

[1] See `http://www.hlt.utdallas.edu/~saidul/code.html` for details.

	Corpora			
	DUC-2001	*Inspec*	NUS	ICSI
Type	News articles	Paper abstracts	Full papers	Meeting transcripts
# Documents	308	500	211	161
# Tokens/Document	876	134	8291	1611
# Candidate words/Document	312	57	3271	453
# Candidate phrases/Document	207	34	2027	296
# Tokens/Candidate phrase	1.5	1.7	1.6	1.5
# Gold keyphrases	2484	4913	2327	582
# Gold keyphrases/Document	8.1	9.8	11.0	3.6
U/B/T/O distribution (%)	17/61/18/4	13/53/25/9	27/50/16/7	68/29/2/1
# Tokens/Gold keyphrase	2.1	2.3	2.1	1.3

Table 1: Corpus statistics for the four datasets used in this paper. A candidate word/phrase, typically a sequence of one or more adjectives and nouns, is extracted from the document initially and considered a potential keyphrase. The U/B/T/O distribution indicates how the gold standard keys are distributed among unigrams, bigrams, trigrams, and other higher order n-grams.

Step 2: Lexical unit ranking Once the candidate list is generated, the next task is to rank these lexical units. To accomplish this, it is necessary to build a representation of the input text for the ranking algorithm. Depending on the underlying approach, each candidate word is represented by its syntactic and/or semantic relationship with other candidate words. The relationship can be defined using co-occurrence statistics, external resources (e.g., neighborhood documents, Wikipedia), or other syntactic clues.

Step 3: Keyphrase formation In the final step, the ranked list of candidate words is used to form keyphrases. A candidate phrase, typically a sequence of nouns and adjectives, is selected as a keyphrase if (1) it includes one or more of the top-ranked candidate words (Mihalcea and Tarau (2004), Liu et al. (2009b)), or (2) the sum of the ranking scores of its constituent words makes it a top scoring phrase (Wan and Xiao, 2008).

3.2 The Five Keyphrase Extractors

As mentioned above, we re-implement five unsupervised approaches for keyphrase extraction. Below we provide a brief overview of each system.

3.2.1 Tf-Idf

Tf-Idf assigns a score to each term t in a document d based on t's frequency in d (term frequency) and how many other documents include t (inverse document frequency) and is defined as:

$$\text{tfidf}_t = \text{tf}_t \times log(D/D_t) \quad (1)$$

where D is the total number of documents and D_t is the number of documents containing t.

Given a document, we first compute the Tf-Idf score of each candidate word (see Step 1 of the generic algorithm). Then, we extract all the longest n-grams consisting of candidate words and score each n-gram by summing the Tf-Idf scores of its constituent unigrams. Finally, we output the top N n-grams as keyphrases.

3.2.2 TextRank

In the TextRank algorithm (Mihalcea and Tarau, 2004), a text is represented by a graph. Each vertex corresponds to a word type. A weight, w_{ij}, is assigned to the edge connecting the two vertices, v_i and v_j, and its value is the number of times the corresponding word types co-occur within a window of W words in the associated text. The goal is to (1) compute the score of each vertex, which reflects its *importance*, and then (2) use the word types that correspond to the highest-scored vertices to form keyphrases for the text. The score for v_i, $S(v_i)$, is initialized with a default value and is computed in an iterative manner until convergence using this recursive formula:

$$S(v_i) = (1-d) + d \times \sum_{v_j \epsilon Adj(v_i)} \frac{w_{ji}}{\sum_{v_k \epsilon Adj(v_j)} w_{jk}} S(v_j) \quad (2)$$

where $Adj(v_i)$ denotes v_i's neighbors and d is the damping factor set to 0.85 (Brin and Page, 1998). Intuitively, a vertex will receive a high score if it has many high-scored neighbors. As noted before, after convergence, the T% top-scored vertices are

selected as keywords. Adjacent keywords are then collapsed and output as a keyphrase.

According to Mihalcea and Tarau (2004), TextRank's best score on the *Inspec* dataset is achieved when only nouns and adjectives are used to create a uniformly weighted graph for the text under consideration, where an edge connects two word types only if they co-occur within a window of two words. Hence, our implementation of TextRank follows this configuration.

3.2.3 SingleRank

SingleRank (Wan and Xiao, 2008) is essentially a TextRank approach with three major differences. First, while each edge in a TextRank graph (in Mihalcea and Tarau's implementation) has the same weight, each edge in a SingleRank graph has a weight equal to the number of times the two corresponding word types co-occur. Second, while in TextRank only the word types that correspond to the top-ranked vertices can be used to form keyphrases, in SingleRank, we do not filter out any low-scored vertices. Rather, we (1) score each candidate keyphrase, which can be any longest-matching sequence of nouns and adjectives in the text under consideration, by summing the scores of its constituent word types obtained from the SingleRank graph, and (2) output the N highest-scored candidates as the keyphrases for the text. Finally, SingleRank employs a window size of 10 rather than 2.

3.2.4 ExpandRank

ExpandRank (Wan and Xiao, 2008) is a TextRank extension that exploits neighborhood knowledge for keyphrase extraction. For a given document d, the approach first finds its k nearest neighboring documents from the accompanying document collection using a similarity measure (e.g., cosine similarity). Then, the graph for d is built using the co-occurrence statistics of the candidate words collected from the document itself and its k nearest neighbors.

Specifically, each document is represented by a term vector where each vector dimension corresponds to a word type present in the document and its value is the Tf-Idf score of that word type for that document. For a given document d_0, its k nearest neighbors are identified, and together they form a larger document set of k+1 documents, $D = \{d_0, d_1, d_2, ..., d_k\}$. Given this document set, a graph is constructed, where each vertex corresponds to a candidate word type in D, and each edge connects two vertices v_i and v_j if the corresponding word types co-occur within a window of W words in the document set. The weight of an edge, $w(v_i, v_j)$, is computed as follows:

$$w(v_i, v_j) = \sum_{d_k \epsilon D} sim(d_0, d_k) \times freq_{d_k}(v_i, v_j) \quad (3)$$

where $sim(d_0, d_k)$ is the cosine similarity between d_0 and d_k, and $freq_{d_k}(v_i, v_j)$ is the co-occurrence frequency of v_i and v_j in document d_k. Once the graph is constructed, the rest of the procedure is identical to SingleRank.

3.2.5 Clustering-based Approach

Liu et al. (2009b) propose to cluster candidate words based on their semantic relationship to ensure that the extracted keyphrases *cover* the entire document. The objective is to have each cluster represent a unique aspect of the document and take a representative word from each cluster so that the document is covered from all aspects.

More specifically, their algorithm (henceforth referred to as KeyCluster) first filters out the stop words from a given document and treats the remaining unigrams as candidate words. Second, for each candidate, its relatedness with another candidate is computed by (1) counting how many times they co-occur within a window of size W in the document and (2) using Wikipedia-based statistics. Third, candidate words are clustered based on their relatedness with other candidates. Three clustering algorithms are used of which spectral clustering yields the best score. Once the clusters are formed, one representative word, called an exemplar term, is picked from each cluster. Finally, KeyCluster extracts from the document all the longest n-grams starting with zero or more adjectives and ending with one or more nouns, and if such an n-gram includes one or more exemplar words, it is selected as a keyphrase. As a post-processing step, a frequent word list generated from Wikipedia is used to filter out the frequent unigrams that are selected as keyphrases.

4 Evaluation

4.1 Experimental Setup

TextRank and SingleRank setup Following Mihalcea and Tarau (2004) and Wan and Xiao (2008), we set the co-occurrence window size for TextRank and SingleRank to 2 and 10, respectively, as these parameter values have yielded the best results for their evaluation datasets.

ExpandRank setup Following Wan and Xiao (2008), we find the 5 nearest neighbors for each document from the remaining documents in the same corpus. The other parameters are set in the same way as in SingleRank.

KeyCluster setup As argued by Liu et al. (2009b), Wikipedia-based relatedness is computationally expensive to compute. As a result, we follow them by computing the *co-occurrence-based* relatedness instead, using a window of size 10. Then, we cluster the candidate words using spectral clustering, and use the frequent word list that they generously provided us to post-process the resulting keyphrases by filtering out those that are frequent unigrams.

4.2 Results and Discussion

In an attempt to gain a better insight into the five unsupervised systems, we report their performance in terms of precision-recall curves for each of the four datasets (see Figure 1). This contrasts with essentially all previous work, where the performance of a keyphrase extraction system is reported in terms of an F-score obtained via a particular parameter setting on a particular dataset. We generate the curves for each system as follows. For Tf-Idf, SingleRank, and ExpandRank, we vary the number of keyphrases, N, predicted by each system. For TextRank, instead of varying the number of predicted keyphrases, we vary T, the percentage of top-scored vertices (i.e., unigrams) that are selected as keywords at the end of the ranking step. The reason is that TextRank only imposes a ranking on the unigrams but not on the keyphrases generated from the high-ranked unigrams. For KeyCluster, we vary the number of clusters produced by spectral clustering rather than the number of predicted keyphrases, again because KeyCluster does not impose a ranking on the resulting keyphrases. In addition, to give an estimate of how each system performs in terms of F-score, we also plot curves corresponding to different F-scores in these graphs.

Tf-Idf Consistent with our intuition, the precision of Tf-Idf drops as recall increases. Although it is the simplest of the five approaches, Tf-Idf is the best performing system on all but the *Inspec* dataset, where TextRank and KeyCluster beat Tf-Idf on just a few cases. It clearly outperforms all other systems for NUS and ICSI.

TextRank The TextRank curves show a different progression than Tf-Idf: precision does not drop as much when recall increases. For instance, in case of DUC and ICSI, precision is not sensitive to changes in recall. Perhaps somewhat surprisingly, its precision increases with recall for *Inspec*, allowing it to even reach a point (towards the end of the curve) where it beats Tf-Idf. While additional experiments are needed to determine the reason for this somewhat counter-intuitive result, we speculate that this may be attributed to the fact that the TextRank curves are generated by progressively increasing T (i.e., the percentage of top-ranked vertices/unigrams that are used to generate keyphrases) rather than the number of predicted keyphrases, as mentioned before. Increasing T does not necessarily imply an increase in the number of predicted keyphrases, however. To see the reason, consider an example in which we want TextRank to extract the keyphrase "advanced machine learning" for a given document. Assume that TextRank ranks the unigrams "advanced", "learning", and "machine" first, second, and third, respectively in its ranking step. When $T = \frac{2}{n}$, where n denotes the total number of candidate unigrams, only the two highest-ranked unigrams (i.e., "advanced" and "learning") can be used to form keyphrases. This implies that "advanced" and "learning" will each be predicted as a keyphrase, but "advanced machine learning" will not. However, when $T = \frac{3}{n}$, all three unigrams can be used to form a keyphrase, and since TextRank collapses unigrams adjacent to each other in the text to form a keyphrase, it will correctly predict "advanced machine learning" as a keyphrase. Note that as we increase T from $\frac{2}{n}$ to $\frac{3}{n}$, recall increases, and so does precision, since

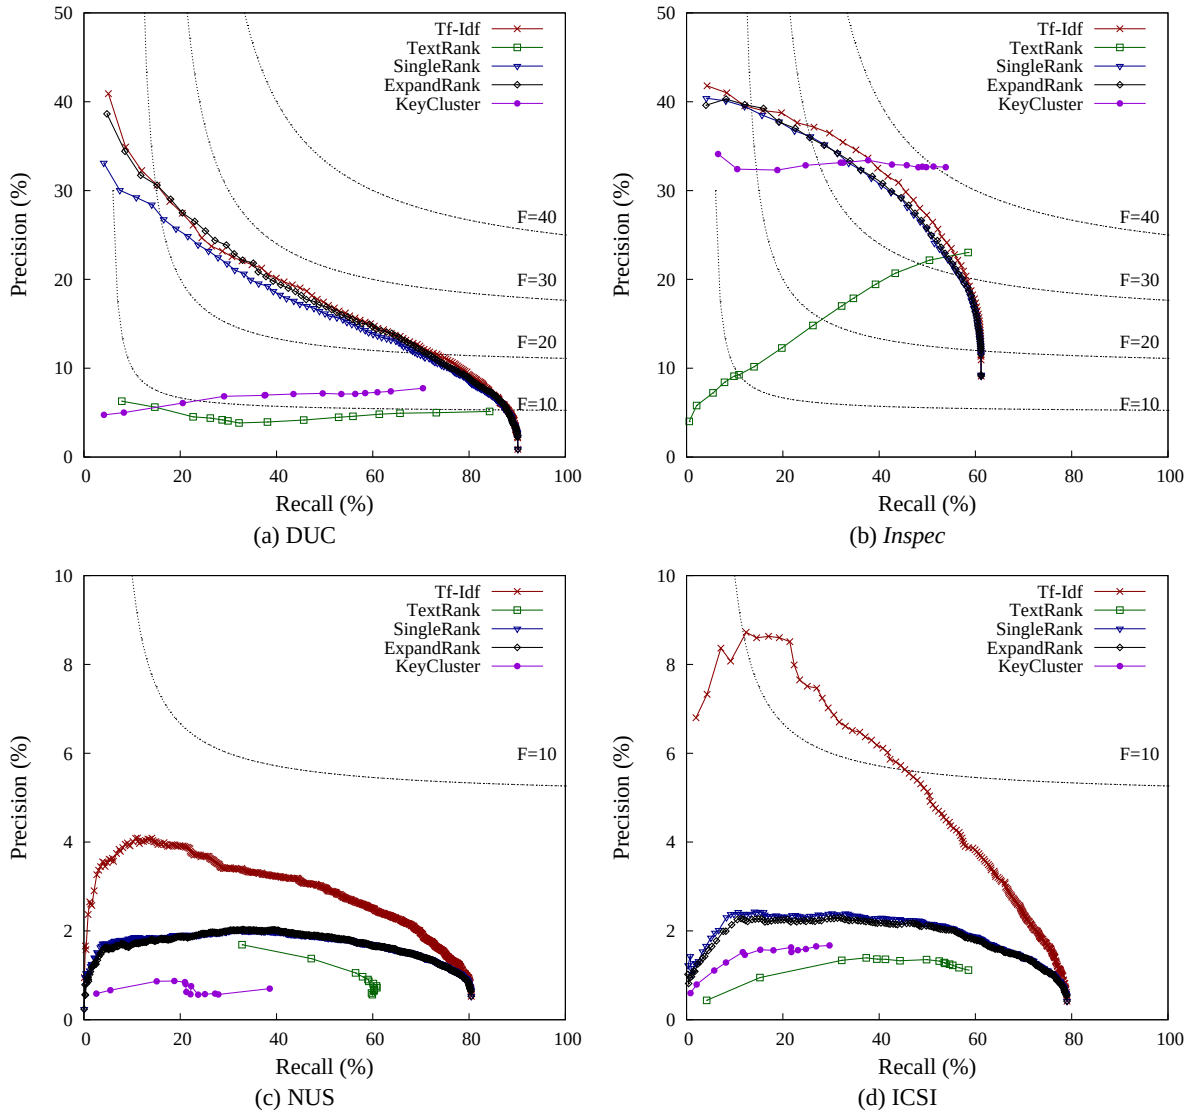

Figure 1: Precision-recall curves for all four datasets

"advanced" and "learning" are now combined to form one keyphrase (and hence the number of predicted keyphrases decreases). In other words, it is possible to see a simultaneous rise in precision and recall in a TextRank curve. A natural question is: why does is happen only for *Inspec* but not the other datasets? The reason could be attributed to the fact that *Inspec* is composed of abstracts: since the number of keyphrases that can be generated from these short documents is relatively small, precision may not drop as severely as with the other datasets even when all of the unigrams are used to form keyphrases.

On average, TextRank performs much worse compared to Tf-Idf. The curves also prove TextRank's sensitivity to T on *Inspec*, but not on the other datasets. This certainly gives more insight into TextRank since it was evaluated on *Inspec* only for T=33% by Mihalcea and Tarau (2004).

SingleRank SingleRank, which is supposed to be a simple variant of TextRank, surprisingly exhibits very different performance. First, it shows a more intuitive nature: precision drops as recall increases. Second, SingleRank outperforms TextRank by big margins on all the datasets. Later, we will examine which of the differences between them is responsible for the differing performance.

	DUC		*Inspec*		NUS		ICSI	
	Parameter	F	Parameter	F	Parameter	F	Parameter	F
Tf-Idf	N = 14	27.0	N = 14	36.3	N = 60	6.6	N = 9	12.1
TextRank	T = 100%	9.7	T = 100%	33.0	T = 5%	3.2	T = 25%	2.7
SingleRank	N = 16	25.6	N = 15	35.3	N = 190	3.8	N = 50	4.4
ExpandRank	N = 13	26.9	N = 15	35.3	N = 177	3.8	N = 51	4.3
KeyCluster	$m = 0.9n$	14.0	$m = 0.9n$	40.6	$m = 0.25n$	1.7	$m = 0.9n$	3.2

Table 2: Best parameter settings. N is the number of predicted keyphrases, T is the percentage of vertices selected as keywords in TextRank, m is the number of clusters in KeyCluster, expressed in terms of n, the fraction of candidate words.

ExpandRank Consistent with Wan and Xiao (2008), ExpandRank beats SingleRank on DUC when a small number of phrases are predicted, but their difference diminishes as more phrases are predicted. On the other hand, their performance is indistinguishable from each other on the other three datasets. A natural question is: why does ExpandRank improve over SingleRank only for DUC but not for the other datasets? To answer this question, we look at the DUC articles and find that in many cases, the 5-nearest neighbors of a document are on the same topic involving the same entities as the document itself, presumably because many of these news articles are simply updated versions of an evolving event. Consequently, the graph built from the neighboring documents is helpful for predicting the keyphrases of the given document. Such topic-wise similarity among the nearest documents does not exist in the other datasets, however.

KeyCluster As in TextRank, KeyCluster does not always yield a drop in precision as recall improves. This, again, may be attributed to the fact that the KeyCluster curves are generated by varying the number of clusters rather than the number of predicted keyphrases, as well as the way keyphrases are formed from the exemplars. Another reason is that the frequent Wikipedia unigrams are excluded during post-processing, making KeyCluster more resistant to precision drops. Overall, KeyCluster performs slightly better than TextRank on DUC and ICSI, yields the worst performance on NUS, and scores the best on *Inspec* when the number of clusters is high. These results seem to suggest that KeyCluster works better if more clusters are used.

Best parameter settings Table 2 shows for each system the parameter values yielding the best F-score on each dataset. Two points deserve mention. First, in comparison to SingleRank and ExpandRank, Tf-Idf outputs fewer keyphrases to achieve its best F-score on most datasets. Second, the systems output more keyphrases on NUS than on other datasets to achieve their best F-scores (e.g., 60 for Tf-Idf, 190 for SingleRank, and 177 for ExpandRank). This can be attributed in part to the fact that the F-scores on NUS are low for all the systems and exhibit only slight changes as we output more phrases.

Our re-implementations Do our duplicated systems yield scores that match the original scores? Table 3 sheds light on this question.

First, consider KeyCluster, where our score lags behind the original score by approximately 5%. An examination of Liu et al.'s (2009b) results reveals a subtle caveat in keyphrase extraction evaluations. In *Inspec*, not all gold-standard keyphrases appear in their associated document, and as a result, none of the five systems we consider in this paper can achieve a recall of 100. While Mihalcea and Tarau (2004) and our reimplementations use *all* of these gold-standard keyphrases in our evaluation, Hulth (2003) and Liu et al. address this issue by using as gold-standard keyphrases only those that appear in the corresponding document when computing recall.[2] This explains why our KeyCluster score (38.9) is lower than the original score (43.6). If we follow Liu et al.'s way of computing recall, our reimplementation score goes up to 42.4, which lags behind their score by only 1.2.

Next, consider TextRank, where our score lags behind Mihalcea and Tarau's original score by more than 25 points. We verified our implementation against a publicly available implementation

[2] As a result, Liu et al. and Mihalcea and Tarau's scores are not directly comparable, but Liu et al. did not point this out while comparing scores in their paper.

	Dataset	F-score	
		Original	Ours
Tf-Idf	DUC	25.4	25.7
TextRank	*Inspec*	36.2	10.0
SingleRank	DUC	27.2	24.9
ExpandRank	DUC	31.7	26.4
KeyCluster	*Inspec*	43.6	38.9

Table 3: Original vs. re-implementation scores

of TextRank[3], and are confident that our implementation is correct. It is also worth mentioning that using our re-implementation of SingleRank, we are able to match the best scores reported by Mihalcea and Tarau (2004) on *Inspec*.

We score 2 and 5 points less than Wan and Xiao's (2008) implementations of SingleRank and ExpandRank, respectively. We speculate that document pre-processing (e.g., stemming) has contributed to the discrepancy, but additional experiments are needed to determine the reason.

SingleRank vs. TextRank Figure 1 shows that SingleRank behaves very differently from TextRank. As mentioned in Section 3.2.3, the two algorithms differ in three major aspects. To determine which aspect is chiefly responsible for the large difference in their performance, we conduct three "ablation" experiments. Each experiment modifies exactly one of these aspects in SingleRank so that it behaves like TextRank, effectively ensuring that the two algorithms differ only in the remaining two aspects. More specifically, in the three experiments, we (1) change SingleRank's window size to 2, (2) build an unweighted graph for SingleRank, and (3) incorporate TextRank's way of forming keyphrases into SingleRank, respectively. Figure 2 shows the resultant curves along with the SingleRank and TextRank curves on *Inspec* taken from Figure 1b. As we can see, the way of forming phrases, rather than the window size or the weight assignment method, has the largest impact on the scores. In fact, after incorporating TextRank's way of forming phrases, SingleRank exhibits a remarkable drop in performance, yielding a curve that resembles the TextRank curve. Also note that SingleRank achieves better recall values than TextRank. To see the reason, recall that TextRank requires that every word of a gold keyphrase must appear among the top-ranked unigrams. This is a fairly strict criterion, especially in comparison to SingleRank, which does not require all unigrams of a gold keyphrase to be present in the top-ranked list. We observe similar trends for the other datasets.

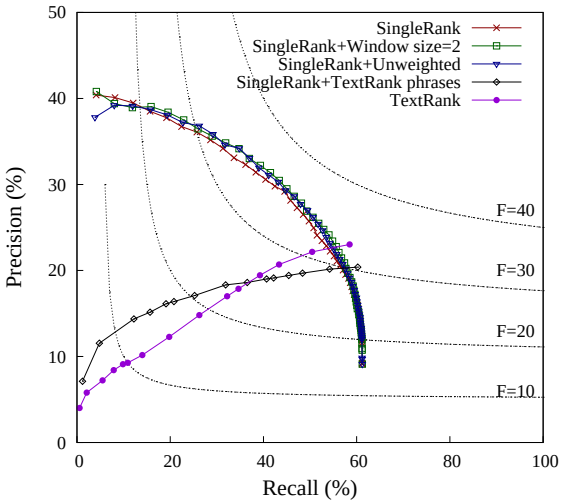

Figure 2: Ablation results for SingleRank on *Inspec*

5 Conclusions

We have conducted a systematic evaluation of five state-of-the-art unsupervised keyphrase extraction algorithms on datasets from four different domains. Several conclusions can be drawn from our experimental results. First, to fully understand the strengths and weaknesses of a keyphrase extractor, it is essential to evaluate it on multiple datasets. In particular, evaluating it on a single dataset has proven inadequate, as good performance can sometimes be achieved due to certain statistical characteristics of a dataset. Second, as demonstrated by our experiments with TextRank and SingleRank, post-processing steps such as the way of forming keyphrases can have a large impact on the performance of a keyphrase extractor. Hence, it may be worthwhile to investigate alternative methods for extracting candidate keyphrases (e.g., Kumar and Srinathan (2008), You et al. (2009)). Finally, despite the large amount of recent work on unsupervised keyphrase extractor, our results indicated that Tf-Idf remains a strong baseline, offering very robust performance across different datasets.

Acknowledgments

We thank the three anonymous reviewers for their comments. Many thanks to Anette Hulth and Yang Liu for providing us with the *Inspec* and ICSI datasets; Rada Mihalcea, Paco Nathan, and Xiaojun Wan for helping us understand their algorithms/implementations; and Peng Li for providing us with the frequent word list that he and his co-authors used in their paper. This work was supported in part by NSF Grant IIS-0812261.

Integrating N-best SMT Outputs into a TM System

Abstract

In this paper, we propose a novel framework to enrich Translation Memory (TM) systems with Statistical Machine Translation (SMT) outputs using ranking. In order to offer the human translators multiple choices, instead of only using the top SMT output and top TM hit, we merge the N-best output from the SMT system and the k-best hits with highest fuzzy match scores from the TM system. The merged list is then ranked according to the prospective post-editing effort and provided to the translators to aid their work. Experiments show that our ranked output achieve 0.8747 precision at top 1 and 0.8134 precision at top 5. Our framework facilitates a tight integration between SMT and TM, where full advantage is taken of TM while high quality SMT output is availed of to improve the productivity of human translators.

1 Introduction

Translation Memories (TM) are databases that store translated segments. They are often used to assist translators and post-editors in a Computer Assisted Translation (CAT) environment by returning the most similar translated segments. Professional post-editors and translators have long been relying on TMs to avoid duplication of work in translation.

With the rapid development in statistical machine translation (SMT), MT systems are beginning to generate acceptable translations, especially in domains where abundant parallel corpora exist. It is thus natural to ask if these translations can be utilized in some way to enhance TMs.

However advances in MT are being adopted only slowly and sometimes somewhat reluctantly in professional localization and post-editing environments because of 1) the usefulness of the TM, 2) the investment and effort the company has put into TMs, and 3) the lack of robust SMT confidence estimation measures which are as reliable as fuzzy match scores (cf. Section 4.1.2) used in TMs. Currently the localization industry relies on TM fuzzy match scores to obtain both a good approximation of post-editing effort and an estimation of the overall translation cost.

In a forthcoming paper, we propose a translation recommendation model to better integrate MT outputs into a TM system. Using a binary classifier, we only recommend an MT output to the TM-user when the classifier is highly confident that it is better than the TM output. In this framework, post-editors continue to work with the TM while benefiting from (better) SMT outputs; the assets in TMs are not wasted and TM fuzzy match scores can still be used to estimate (the upper bound of) post-editing labor.

In the previous work, the binary predictor works on the 1-best output of the MT and TM systems, presenting either the one or the other to the post-editor. In this paper, we develop the idea further by moving from binary prediction to ranking. We use a ranking model to merge the k-best lists of the two systems, and produce a ranked merged

Coling 2008: Poster Volume, pages 374–382,
Beijing, August 2010

list for post-editing. As the list is an enriched version of the TM's k-best list, the TM related assets are better preserved and the cost estimation is still valid as an upper bound.

More specifically, we recast SMT-TM integration as a ranking problem, where we apply the Ranking SVM technique to produce a ranked list of translations combining the k-best lists of both the MT and the TM systems. We use features independent of the MT and TM systems for ranking, so that outputs from MT and TM can have the same set of features. Ideally the translations should be ranked by their associated post-editing efforts, but given the very limited amounts of human annotated data, we use an automatic MT evaluation metric, TER (Snover et al., 2006), which is specifically designed to simulate post-editing effort to train and test our ranking model.

The rest of the paper is organized as follows: we first briefly introduce related research in Section 2, and review Ranking SVMs in Section 3. The formulation of the problem and experiments with the ranking models are presented in Sections 4 and 5. We analyze the post-editing effort approximated by the TER metric in Section 6. Section 7 concludes and points out avenues for future research.

2 Related Work

There has been some work to help TM users to apply MT outputs more smoothly. One strand is to improve the MT confidence measures to better predict post-editing effort in order to obtain a quality estimation that has the potential to replace the fuzzy match score in the TM. To the best of our knowledge, the first paper in this area is (Specia et al., 2009a), which uses regression on both the automatic scores and scores assigned by post-editors. The method is improved in (Specia et al., 2009b), which applies Inductive Confidence Machines and a larger set of features to model post-editors' judgment of the translation quality between 'good' and 'bad', or among three levels of post-editing effort.

Another strand is to integrate high confidence MT outputs into the TM, so that the 'good' TM entries will remain untouched. In our forthcoming paper, we recommend SMT outputs to a TM user when a binary classifier predicts that SMT outputs are more suitable for post-editing for a particular sentence.

The research presented here continues the line of research in the second strand. The difference is that we do not limit ourselves to the 1-best output but try to produce a k-best output in a ranking model. The ranking scheme also enables us to show all TM hits to the user, and thus further protects the TM assets.

There has also been work to improve SMT using the knowledge from the TM. In (Simard and Isabelle, 2009), the SMT system can produce a better translation when there is an exact or close match in the corresponding TM. They use regression Support Vector Machines to model the quality of the TM segments. This is also related to our work in spirit, but our work is in the opposite direction, i.e. using SMT to enrich TM.

Moreover, our ranking model is related to reranking (Shen et al., 2004) in SMT as well. However, our method does not focus on producing better 1-best translation output for an SMT system, but on improving the overall quality of the k-best list that TM systems present to post-editors. Some features in our work are also different in nature to those used in MT reranking. For instance we cannot use N-best posterior scores as they do not make sense for the TM outputs.

3 The Support Vector Machines

3.1 The SVM Classifier

Classical SVMs (Cortes and Vapnik, 1995) are binary classifiers that classify an input instance based on decision rules which minimize the regularized error function in (Eq. 1):

$$\begin{array}{ll} \min\limits_{w,b,\xi} & \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum\limits_{i=1}^{l}\xi_i \\ \text{subject to:} & y_i(\mathbf{w}^T\mathbf{x}_i + b) \geqslant 1 - \xi_i \\ & \xi_i \geqslant 0 \end{array} \quad (1)$$

where $(\mathbf{x}_i, y_i) \in R^n \times \{1, -1\}$ are l training instances. $\mathbf{w}$ is the weight vector, ξ is the relaxation variable and $C > 0$ is the penalty parameter.

3.2 Ranking SVM for SMT-TM Integration

The SVM classification algorithm is extended to the ranking case in (Joachims, 2002). For a cer-

tain group of instances, the Ranking SVM aims at producing a ranking r that has the maximum Kendall's τ coefficient with the the gold standard ranking r^*.

Kendall's τ measures the relevance of two rankings: $\tau(r_a, r_b) = \frac{P-Q}{P+Q}$, where P and Q are the amount of concordant and discordant pairs in r_a and r_b. In practice, this is done by building constraints to minimize the discordant pairs Q. Following the basic idea, we show how Ranking SVM can be applied to MT-TM integration as follows.

Assume that for each source sentence s, we have a set of outputs from MT, $\mathbf{M}$ and a set of outputs from TM, $\mathbf{T}$. If we have a ranking $r(s)$ over translation outputs $\mathbf{M} \bigcup \mathbf{T}$ where for each translation output $d \in \mathbf{M} \bigcup \mathbf{T}$, $(d_i, d_j) \in r(s)$ iff $d_i <_{r(s)} d_j$, we can rewrite the ranking constraints as optimization constraints in an SVM, as in Eq. (2).

$$\begin{array}{l} \min\limits_{w,b,\xi} \frac{1}{2}\mathbf{w}^T\mathbf{w} + C\sum\xi \\ \text{subject to:} \\ \forall(d_i,d_j) \in r(s_1) : \mathbf{w}(\Phi(s_1,d_i) - \Phi(s_1,d_j)) \geqslant 1 - \xi_{i,j,1} \\ ... \\ \forall(d_i,d_j) \in r(s_n) : \mathbf{w}(\Phi(s_n,d_i) - \Phi(s_n,d_j)) \geqslant 1 - \xi_{i,j,n} \\ \xi_{i,j,k} \geqslant 0 \end{array} \quad (2)$$

where $\Phi(s_n, d_i)$ is a feature vector of translation output d_i given source sentence s_n. The Ranking SVM minimizes the discordant number of rankings with the gold standard according to Kendall's τ.

When the instances are not linearly separable, we use a mapping function ϕ to map the features $\mathbf{x}_i$ ($\Phi(s_n, d_i)$ in the case of ranking) to high dimensional space, and solve the SVM with a kernel function K in where $K(\mathbf{x}_i, \mathbf{x}_j) = \phi(\mathbf{x}_i)^T\phi(\mathbf{x}_j)$.

We perform our experiments with the Radial Basis Function (RBF) kernel, as in Eq. (3).

$$K(\mathbf{x}_i, \mathbf{x}_j) = exp(-\gamma||\mathbf{x}_i - \mathbf{x}_j||^2), \gamma > 0 \quad (3)$$

4 The Ranking-based Integration Model

In this section we present the Ranking-based SMT-TM integration model in detail. We first introduce the k-best lists in MT (called N-best list) and TM systems (called m-best list in this section) and then move on to the problem formulation and the feature set.

4.1 K-Best Lists in SMT and TM

4.1.1 The SMT N-best List

The N-best list of the SMT system is generated during decoding according to the internal feature scores. The features include language and translation model probabilities, reordering model scores and a word penalty.

4.1.2 The TM M-Best List and the Fuzzy Match Score

The m-best list of the TM system is generated in descending fuzzy match score. The fuzzy match score (Sikes, 2007) uses the similarity of the source sentences to predict a level to which a translation is reusable or editable.

The calculation of fuzzy match scores is one of the core technologies in TM systems and varies among different vendors. We compute fuzzy match cost as the minimum Edit Distance (Levenshtein, 1966) between the source and TM entry, normalized by the length of the source as in Eq. (4), as most of the current implementations are based on edit distance while allowing some additional flexible matching.

$$FuzzyMatch(t) = \min_e \frac{EditDistance(s,e)}{Len(s)} \quad (4)$$

where s is the source side of the TM hit t, and e is the source side of an entry in the TM.

4.2 Problem Formulation

Ranking lists is a well-researched problem in the information retrieval community, and Ranking SVMs (Joachims, 2002), which optimizes on the ranking correlation τ have already been applied successfully in machine translation evaluation (Ye et al., 2007). We apply the same method here to rerank a merged list of MT and TM outputs.

Formally given an MT-produced N-best list $\mathbf{M} = \{m_1, m_2, ..., m_n\}$, a TM-produced m-best list $\mathbf{T} = \{t_1, t_2, ..., t_m\}$ for a input sentence s, we define the gold standard using the TER metric (Snover et al., 2006): for each $d \in \mathbf{M} \bigcup \mathbf{T}$, $(d_i, d_j) \in r(s)$ iff $TER(d_i) < TER(d_j)$. We train and test a Ranking SVM using cross validation on a data set created according to this criterion. Ideally the gold standard would be created by human annotators. We choose to use TER

as large-scale annotation is not yet available for this task. Furthermore, TER has a high correlation with the HTER score (Snover et al., 2006), which is the TER score using the post-edited MT output as a reference, and is used as an estimation of post-editing effort.

4.3 The Feature Set

When building features for the Ranking SVM, we are limited to features that are independent of the MT and TM system. We experiment with system-independent fluency and fidelity features below, which capture translation fluency and adequacy, respectively.

4.3.1 Fluency Features

Source-side Language Model Scores. We compute the LM probability and perplexity of the input source sentence on a language model trained on the source-side training data of the SMT system, which is also the TM database. The inputs that have lower perplexity on this language model are more similar to the data set on which the SMT system is built.

Target-side Language Model Scores. We compute the LM probability and perplexity as a measure of the fluency of the translation.

4.3.2 Fidelity Features

The Pseudo-Source Fuzzy Match Score. We translate the output back to obtain a pseudo source sentence. We compute the fuzzy match score between the original source sentence and this pseudo-source. If the MT/TM performs well enough, these two sentences should be the same or very similar. Therefore the fuzzy match score here gives an estimation of the confidence level of the output.

The IBM Model 1 Score. We compute the IBM Model 1 score in both directions to measure the correspondence between the source and target, as it serves as a rough estimation of how good a translation it is on the word level.

5 Experiments

5.1 Experimental Settings

5.1.1 Data

Our raw data set is an English–French translation memory with technical translation from a multi-national IT security company, consisting of 51K sentence pairs. We randomly select 43K to train an SMT system and translate the English side of the remaining 8K sentence pairs, which is used to run cross validation. Note that the 8K sentence pairs are from the same TM, so that we are able to create a gold standard by ranking the TER scores of the MT and TM outputs.

Duplicated sentences are removed from the data set, as those will lead to an exact match in the TM system and will not be translated by translators. The average sentence length of the training set is 13.5 words and the size of the training set is comparable to the (larger) translation memories used in the industry.

5.1.2 SMT and TM systems

We use a standard log-linear PB-SMT model (Och and Ney, 2002): GIZA++ implementation of IBM word alignment model 4, the phrase-extraction heuristics described in (Koehn et al., 2003), minimum-error-rate training (Och, 2003), a 5-gram language model with Kneser-Ney smoothing trained with SRILM (Stolcke, 2002) on the English side of the training data, and Moses (Koehn et al., 2007) to decode. We train a system in the opposite direction using the same data to produce the pseudo-source sentences.

We merge distinct 5-best lists from MT and TM systems to produce a new ranking. To create the distinct list for the SMT system, we search over a 100-best list and keep the top-5 distinct outputs. Our data set consists of mainly short sentences, leading to many duplications in the N-best output of the SMT decoder. In such cases, top-5 distinct outputs are good representations of the SMT's output.

5.2 Training, Tuning and Testing the Ranking SVM

We run training and prediction of the Ranking SVM in 4-fold cross validation. We use the

SVM*light*[1] toolkit to perform training and testing.

When using the Ranking SVM with the RBF kernel, we have two free parameters to tune on: the cost parameter C in Eq. (1) and the radius parameter γ in Eq. (3). We optimize C and γ using a brute-force grid search before running cross-validation and maximize precision at top-5, with an inner 3-fold cross validation on the (outer) Fold-1 training set. We search within the range $[2^{-6}, 2^{9}]$, the step size is 2 on the exponent.

5.3 The Gold Standard

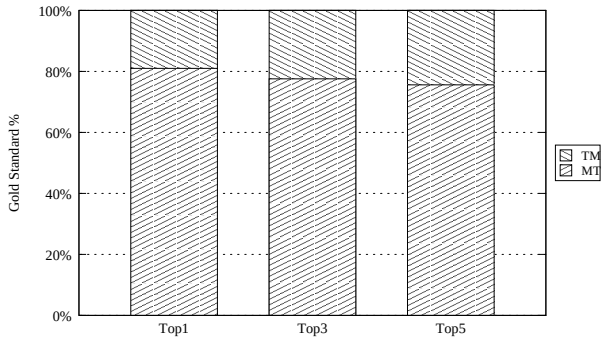

Figure 1: MT and TM's percentage in gold standard

Figure 1 shows the composition of translations in the gold standard. Each source sentence is associated with a list of translations from two sources, i.e. MT output and TM matches. This list of translations is ranked from best to worst according TER scores. The figure shows that over 80% of the translations are from the MT system if we only consider the top-1 translation. As the number of top translations we consider increases, more TM matches can be seen. On the one hand, this does show a large gap in quality between MT output and TM matches; on the other hand, however, it also reveals that we will have to ensure two objectives in ranking: the first is to rank the 80% MT translations higher and the second is to keep the 20% 'good' TM hits in the Top-5. We design our evaluation metrics accordingly.

5.4 Evaluation Metrics

The aim of this research is to provide post-editors with translations that in many cases are easier to edit than the original TM output. As we formulate this as a ranking problem, it is natural to measure the quality of the ranking output by the number of better translations that are ranked high. Sometimes the top TM output is the easiest to edit; in such a case we need to ensure that this translation has a high rank, otherwise the system performance will degrade.

Based on this observation, we introduce the idea of *relevant* translations, and our evaluation metrics: PREC@k and HIT@k.

Relevant Translations. We borrow the idea of *relevence* from the IR community to define the idea of translations worth ranking high. For a source sentence s which has a top TM hit t, we define an MT/TM output m as relevant, if $TER(m) \leq TER(t)$. According to the definition, relevant translations should need no more post-edits than the original top hit from the TM system. Clearly the top TM hit is always relevant.

PREC@k. We calculate the precision (PREC@k) of the ranking for evaluation. Assuming that there are n relevant translations in the top k list for a source sentence s, we have PREC@k= n/k for s. We test PREC@k, for $k = 1...10$, in order to evaluate the overall quality of the ranking.

HIT@k. We also estimate the probability of having one of the relevant translations in the top k, denoted as HIT@k. For a source sentence s, HIT@k equals to 1 if there is at least one relevant translation in top k, and 0 otherwise. This measures the quality of the best translation in top k, which is the translation the post-editor will find and work on if she reads till the kth place in the list. HIT@k equals to 1.0 at the end of the list.

We report the mean PREC@k and HIT@k for all s with the 0.95 confidence interval.

5.5 Experimental Results

In Table 1 we report PREC@k and HIT@k for $k = 1..10$. The ranking receives 0.8747 PREC@1, which means that most of the top ranked translations have at least the same quality as the top TM output. We notice that precision remains above 0.8 till $k = 5$, leading us to conclude that most of the *relevant* translations are ranked in the top-5 positions in the list.

[1] `http://svmlight.joachims.org/`

Table 1: PREC@k and HIT@k of Ranking

	PREC %	HIT %
k=1	87.47±1.60	87.47±1.60
k=2	85.42±1.07	93.36±0.53
k=3	84.13±0.94	95.74±0.61
k=4	82.79±0.57	97.08±0.26
k=5	81.34±0.51	98.04±0.23
k=6	79.26±0.59	99.41±0.25
k=7	74.99±0.53	99.66±0.29
k=8	70.87±0.59	99.84±0.10
k=9	67.23±0.48	99.94±0.08
k=10	64.00±0.46	100.0±0.00

Using the HIT@k scores we can further confirm this argument. The HIT@k score grows steadily from 0.8747 to 0.9941 for $k = 1...6$, so most often there will be at least one *relevant* translation in top-6 for the post-editor to work with. After that room for improvement becomes very small.

In sum, both of the PREC@k scores and the HIT@k scores show that the ranking model effectively integrates the two translation sources (MT and TM) into one merged k-best list, and ranks the *relevant* translations higher.

Table 2: PREC@k - MT and TM Systems

	MT %	TM %
k=1	85.87±1.32	100.0±0.00
k=2	82.52±1.60	73.58±1.04
k=3	80.05±1.11	62.45±1.14
k=4	77.92±0.95	56.11±1.11
k=5	76.22±0.87	51.78±0.78

To measure whether the ranking model is effective compared to pure MT or TM outputs, we report the PREC@k of those outputs in Table 2. The k-best output used in this table is ranked by the MT or TM system, without being ranked by our model. We see the ranked outputs consistently outperform the MT outputs for all $k = 1...5$ w.r.t. precision at a significant level, indicating that our system preserves some high quality hits from the TM.

The TM outputs alone are generally of much lower quality than the MT and Ranked outputs, as is shown by the precision scores for $k = 2...5$. But TM translations obtain 1.0 PREC@1 according to the definition of the PREC calculation. Note that it does not mean that those outputs will need less post-editing (cf. Section 6.1), but rather indicates that each one of these outputs meet the lowest acceptable criterion to be *relevant*.

6 Analysis of Post-Editing Effort

A natural question follows the PREC and HIT numbers: after reading the ranked k-best list, will the post-editors edit less than they would have to if they did not have access to the list? This question would be best answered by human post-editors in a large-scale experimental setting. As we have not yet conducted a manual post-editing experiment, we try to measure the post-editing effort implied by our model with the edit statistics captured by the TER metric, sorted into four types: *Insertion*, *Substitution*, *Deletion* and *Shift*. We report the average number of edits incurred along with the 0.95 confidence interval.

6.1 Top-1 Edit Statistics

We report the results on the 1-best output of TM, MT and our ranking system in Table 3.

In the single best results, it is easy to see that the 1-best output from the MT system requires the least post-editing effort. This is not surprising given the distribution of the gold standard in Section 5.3, where most MT outputs are of better quality than the TM hits.

Moreover, since TM translations are generally of much lower quality as is indicated by the numbers in Table 3 (e.g. 2x as many substitutions and 3x as many deletions compared to MT), unjustly including very few of them in the ranking output will increase loss in the edit statistics. This explains why the ranking model has better ranking precision in Tables 1 and 2, but seems to incur more edit efforts. However, in practice post-editors can neglect an obvious 'bad' translation very quickly.

6.2 Top-k Edit Statistics

We report edit statistics of the Top-3 and Top-5 outputs in Tables 4 and 5, respectively. For each system we report two sets of statistics: the Best-statistics calculated on the best output (according

Table 3: Edit Statistics on Ranked MT and TM Outputs - Single Best

	Insertion	Substitution	Deletion	Shift
TM-Top1	0.7554 ± 0.0376	4.2461 ± 0.0960	2.9173 ± 0.1027	1.1275 ± 0.0509
MT-Top1	0.9959 ± 0.0385	2.2793 ± 0.0628	0.8940 ± 0.0353	1.2821 ± 0.0575
Rank-Top1	1.0674 ± 0.0414	2.6990 ± 0.0699	1.1246 ± 0.0412	1.2800 ± 0.0570

to TER score) in the list, and the Mean- statistics calculated on the whole Top-k list.

The Mean- numbers allow us to have a general overview of the ranking quality, but it is strongly influenced by the poor TM hits that can easily be neglected in practice. To control the impact of those TM hits, we rely on the Best- numbers to estimate the edits performed on the translations that are more likely to be used by post-editors.

In Table 4, the ranking output's edit statistics is closer to the MT output than the Top-1 case in Table 3. Table 5 continues this tendency, in which the Best-in-Top5 Ranking output requires marginally less *Substitution* and *Deletion* operations and significantly less *Insertion* and *Shift* operations (starred) than its MT counterpart. This shows that when more of the list is explored, the advantage of the ranking model – utilizing multiple translation sources – begins to compensate for the possible large number of edits required by poor TM hits and finally leads to reduced post-editing effort.

There are several explanations to why the relative performance of the ranking model improves when k increases, as compared to other models. The most obvious explanation is that a single poor translation is less likely to hurt edit statistics on a k-best list with large k, if most of the translations in the k-best list are of good quality. We see from Tables 1 and 2 that the ranking output is of better quality than the MT and TM outputs w.r.t. precision. For a larger k, the small number of incorrectly ranked translations are less likely to be chosen as the Best- translation and hold back the Best- numbers.

A further reason is related to our ranking model which optimizes on Kendall's τ score. Accordingly the output might not be optimal when we evaluate the Top-1 output, but will behave better when we evaluate on the list. This is also in accordance with our aim, which is to enrich the TM with MT outputs and help the post-editor, instead of choosing the translation for the post-editor.

6.3 Comparing the MT, TM and Ranking Outputs

One of the interesting findings from Tables 3 and 4 is that according to the TER edit statistics, the MT outputs generally need a smaller number of edits than the TM and Ranking outputs. This certainly confirms the necessity to integrate MT into today's TM systems.

However, this fact should not lead to the conclusion that TMs should be replaced by MT completely. First of all, all of our experiments exclude exact TM matches, as those translations will simply be reused and not translated. While this is a realistic setting in the translation industry, it removes all sentences for which the TM works best from our evaluations.

Furthermore, Table 5 shows that the Best-in-Top5 Ranking output performs better than the MT outputs, hence there are TM outputs that lead to smaller number of edits. As k increases, the ranking model is able to better utilize these outputs.

Finally, in this task we concentrate on ranking useful translations higher, but we are not interested in how useless translations are ranked. Ranking SVM optimizes on the ranking of the whole list, which is slightly different from what we actually require. One option is to use other optimization techniques that can make use of this property to get better Top-k edit statistics for a smaller k. Another option is obviously to perform regression directly on the number of edits instead of modeling on the ranking. We plan to explore these ideas in future work.

7 Conclusions and Future Work

In this paper we present a novel ranking-based model to integrate SMT into a TM system, in order to facilitate the work of post-editors. In such

Rank-Mean-Top5	1.1173 ± 0.0181	2.8777 ± 0.0312	1.1585 ± 0.0200	1.3675 ± 0.0260

a model, the user of the TM will be presented with an augmented k-best list, consisting of translations from both the TM and the MT systems, and ranked according to ascending prospective post-editing effort.

From the post-editors' point of view, the TM remains intact. And unlike in the binary translation recommendation, where only one translation recommendation is provided, the ranking model offers k-best post-editing candidates, enabling the user to use more resources when translating. As we do not actually throw away any translation produced from the TM, the assets represented by the TM are preserved and the related estimation of the upper bound cost is still valid.

We extract system independent features from the MT and TM outputs and use Ranking SVMs to train the ranking model, which outperforms both the TM's and MT's k-best list w.r.t. precision at k, for all ks.

We also analyze the edit statistics of the integrated k-best output using the TER edit statistics. Our ranking model results in slightly increased number of edits compared to the MT output (apparently held back by a small number of poor TM outputs that are ranked high) for a smaller k, but requires less edits than both the MT and the TM output for a larger k.

This work can be extended in a number of ways. Most importantly, We plan to conduct a user study to validate the effectiveness of the method and to gather HTER scores to train a better ranking model. Furthermore, we will try to experiment with learning models that can further reduce the number of edit operations on the top ranked translations. We also plan to improve the adaptability of this method and apply it beyond a specific domain and language pair.

Learning Phrase Boundaries for Hierarchical Phrase-based Translation

Zhongjun HE Yao MENG Hao YU
Fujitsu R&D Center CO., LTD.
{hezhongjun, mengyao, yu}@cn.fujitsu.com

Abstract

Hierarchical phrase-based models provide a powerful mechanism to capture non-local phrase reorderings for statistical machine translation (SMT). However, many phrase reorderings are arbitrary because the models are weak on determining phrase boundaries for pattern-matching. This paper presents a novel approach to learn phrase boundaries directly from word-aligned corpus without using any syntactical information. We use phrase boundaries, which indicate the beginning/ending of phrase reordering, as soft constraints for decoding. Experimental results and analysis show that the approach yields significant improvements over the baseline on large-scale Chinese-to-English translation.

1 Introduction

The hierarchial phrase-based (HPB) model (Chiang, 2005) outperformed previous phrase-based models (Koehn et al., 2003; Och and Ney, 2004) by utilizing hierarchical phrases consisting of both words and variables. Thus the HPB model has generalization ability: a translation rule learned from a phrase pair can be used for other phrase pairs with the same pattern, e.g. reordering information of a short span can be applied for a large span during decoding. Therefore, the model captures both short and long distance phrase reorderings.

However, one shortcoming of the HPB model is that it is difficult to determine phrase boundaries for pattern-matching. Therefore, during decoding, a rule may be applied for all possible source phrases with the same pattern. However, incorrect pattern-matching will cause wrong translation.

Consider the following rule that is used to translate the Chinese sentence in Figure 1 into English:

$$X \rightarrow \langle X_L \text{ de } X_R, X_R \text{ in } X_L \rangle \qquad (1)$$

The rule translates the Chinese word "de" into English word "in", and swaps the left sub-phrase covered by X_L and the right sub-phrase covered by X_R on the target side. However, X_L may pattern-match 5 spans on the left side of "de" and X_R may pattern-match 3 spans on the right side. Therefore, the rule produces 15 different derivations. However, 14 of them are incorrect.

The correct derivation S_c is shown in Figure 2, while one of the wrong derivations S_i is shown in Figure 3. We observe that the basic difference between S_c and S_i is the phrase boundary matched by "X_R". In S_c, X_R matches the span $[7, 9]$ and moves it as a whole unit. While in S_i, X_R matches the span $[7, 8]$ and left the last word $[9, 9]$ be translated separately. Similarly, other incorrect derivations are caused by inadequate pattern-matching of X_L and/or X_R.

Previous research showed that phrases should be constrained to some extent for improving translation quality. Most of the existing approaches utilized syntactic information to constrain phrases to respect syntactic boundaries. Chiang (2005) introduced a constituent feature to reward phrases that match a syntactic tree but did not yield significant improvement. Marton and Resnik (2008) revised this method by distinguishing different constituent syntactic types, and defined features for each type to count whether a phrase matches or crosses the syntactic boundary. This led to a substantial improvements. Gimpel and Smith (2008) presented rich contextual features on the source side including constituent syntactical features for phrase-based translation. Cherry (2008) utilized a dependency tree as a soft constraint to detect syntactic cohesion violations for a phrase-based

system. Xiong et al. (2009) presented a syntax-driven bracketing model to predict whether two phrases are translated together or not, using syntactic features learned from training corpus. Although these approaches differ from each other, the main basic idea is the utilization of syntactic information.

In this paper, we present a novel approach to learn phrase boundaries for hierarchical phrase-based translation. A phrase boundary indicates the beginning or ending of a phrase reordering. Motivated by Ng and Low (2004) that built a classifier to predict word boundaries for word segmentation, we build a classifier to predict phrase boundaries. We classify each source word into one of the 4 boundary tags: "b" indicates the beginning of a phrase, "m" indicates a word appears in the middle of a phrase, "e" indicates the end of a phrase, "s" indicates a single-word phrase.

We use phrase boundaries as soft constraints for decoding. To do this, we incorporate our classifier as a feature into the HPB model and propose an efficient decoding algorithm.

Compared to the previous work, out approach has the following advantages:

- Our approach maintains the strength of the phrase-based models since it does not require any syntactical information. Therefore, phrases do not need to respect syntactic boundaries.
- The training instances are directly learned from a word-aligned bilingual corpus, rather than from manually annotated corpus.

- The decoder outputs phrase segmentation information as a byproduct, in addition to translation result.

We evaluate our approach on large-scale Chinese-to-English translation. Experimental results and analysis show that using phrase boundaries as soft constraints achieves significant improvements over the baseline system.

2 Previous Work

2.1 Learning Word Boundaries

In some languages, such as Chinese, words are not demarcated. Therefore, it is a preliminary task to determine word boundaries for a sentence, which is the so-called word segmentation.

Ng and Low (2004) regarded word segmentation as a classification problem. They labelled each Chinese character with one of 4 possible boundary tags: "b", "m", "e" respectively indicates the begin, the middle and the end of a word, and "s" indicates a single-character word. Their segmenter was built within a maximum entropy framework and trained on manually segmented sentences.

Learning phrase boundaries is analogous to word boundaries. The basic difference is that the unit for learning word boundaries is character while the unit for learning phrase boundaries is word. In this paper, we adopt the boundary tags presented by Ng and Low (2004) and build a classifier to predict phrase boundaries within maximum entropy framework. We train it directly on a word-aligned bilingual corpus, without any manually annotation and syntactical information.

2.2 The Hierarchical Phrase-based Model

We built a hierarchical phrase-based MT system (Chiang, 2007) based on weighted SCFG. The translation knowledge is represented by rewriting rules:

$$\mathrm{X} \rightarrow \langle \alpha, \gamma, \sim \rangle \tag{2}$$

where X is a non-terminal, α and γ are source and target strings, respectively. Both of them contain words and possibly co-indexed non-terminals. $\sim$ describes a one-to-one correspondence between non-terminals in α and γ.

Chiang (2007) used the standard log-linear framework (Och and Ney, 2002) to combine various features:

$$Pr(e|f) \propto \sum_i \lambda_i h_i(\alpha, \gamma) \tag{3}$$

where $h_i(\alpha, \gamma)$ is a feature function and λ_i is the weight of h_i. Analogous to the previous phrase-based model, Chiang defined the following features: translation probabilities $p(\gamma|\alpha)$ and $p(\alpha|\gamma)$, lexical weights $p_w(\gamma|\alpha)$ and $p_w(\alpha|\gamma)$, word penalty, rule penalty, and a target n-gram language model.

In this paper, we integrate a phrase boundary classifier as an additional feature into the log-linear model to provide soft constraint for pattern-matching during decoding. The feature weights are optimized by MERT algorithm (Och, 2003).

3 Learning Phrase Boundaries

We build a phrase boundary classifier (PBC) within a maximum entropy framework. The PBC predicts a boundary tag for each source word, considering contextual features:

$$P_{tag}(t|f_j, F_1^J) = \frac{exp(\sum_i \lambda_i h_i(t, f_j, F_1^J))}{\sum_t exp(\sum_i \lambda_i h_i(t, f_j, F_1^J)} \tag{4}$$

where, $t \in \{b, m, e, s\}$, f_j is the jth word in source sentence F_1^J, h_i is a feature function and λ_i is the weight of h_i.

To build PBC, we first present a method to recognize phrase boundaries and extract training examples from word-aligned bilingual corpus, then we define contextual feature functions.

3.1 Phrase Boundary

During decoding, intuitively, words within a phrase should be translated or moved together. Therefore, a phrase boundary should indicate reordering information. We assign one of the boundary tags (b, m, e, s) to each word in source sentences. Thus the word with tag *b*, *e* or *s* is a phrase boundary. One question is that how to assign boundary tag to a word? In this paper, we recognize the largest source span which has the monotone translation. Then we assign boundary

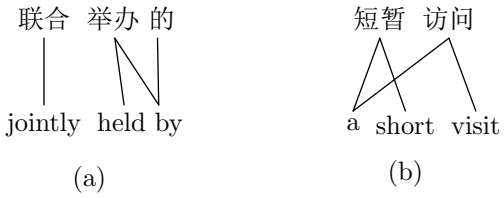

Figure 4: Illustration for monotone span (a) and PM span (b).

tags to each word in the source span, according to their position.

To do this, we first introduce some notations. Given a bilingual sentence (F_1^J, E_1^I) together with word alignment matrix A, we use $L(A_j)$ and $H(A_j)$ to represent the lowest and highest target word position which links to the source word f_j, respectively. Since the word alignment for f_j maybe "one-to-many", all the corresponding target words will appear in the span $[L(A_j), H(A_j)]$.

we define a source span $[j_1, j_2]$ $(1 \leq j_1 \leq j_2 \leq J)$ a *monotone* span, iff:

1. $\forall (j,i) \in A, j_1 \leq j \leq j_2 \leftrightarrow L(A_{j_1}) \leq i \leq H(A_{j_2})$
2. $\forall k_1, k_2 \in [j_1, j_2], k_1 \leq k_2 \rightarrow H(A_{k_1}) \leq L(A_{k_2})$

The first condition indicates that $(F_{j_1}^{j_2}, E_{L(A_{j_1})}^{H(A_{j_2})})$ is a phrase pair as described previously in phrase-based SMT models. While the second condition indicates that the lower target bound linked to a source word cannot be lower than any target word position linked to the previous source word. Therefore, a monotone span does not contain crossed links or internal reorderings.

Considering that word alignments could be very noisy and complex in real-world data, we define *pseudo-monotone* (PM) span by loosening the second condition:

$$\forall k_1, k_2 \in [j_1, j_2], k_1 \leq k_2 \rightarrow L(A_{k_1}) \leq L(A_{k_2}) \quad (5)$$

This condition allows crossed links to some extent by loosening the bound of A_{k_1} from upper to lower. Figure 4 (a) shows an example of monotone span, in which the translation is monotone. While Figure 4 (b) is not a monotone span because there is a cross link between the upper bound of "短暂" and the lower bound of "访问" on the target side. However, it is a PM span according to the definition. Note that in some cases, a source word may not be contained in any phrase pair, therefore we consider a single word span as a PM span, specificly.

An interesting feature of PM span is that if two PM spans are consecutive on both source side and their corresponding target side, the two PM spans can be combined as a larger PM span. Formally,

$$(F_{j_1}^{j}, E_{i_1}^{i}) \bigoplus (F_{j+1}^{j_2}, E_{i+1}^{i_2}) = (F_{j_1}^{j_2}, E_{i_1}^{i_2}) \quad (6)$$

where $[j_1, j]$ and $[j+1, j_2]$ are PM spans, $[i_1, i]$ and $[i+1, i_2]$ are the target spans corresponding to $[j_1, j]$ and $[j+1, j_2]$, respectively. For example, Figure 4 (a) shows a PM phrase pair that consists of two small PM pairs "联合, jointly" and "举办的, held by".

In this paper, we are interested in phrase reordering boundaries for a source sentence. We define *translation span* (TS) the largest possible PM span. A TS may consist of one or more PM spans. According to our definition, cross links may appear within PM spans but do not appear between PM spans within a TS. Therefore, TS is the largest possible span that will be translated as a unit and phrase reorderings may occur between TSs during decoding.

To obtain phrase boundary examples from word-aligned bilingual sentences, we first find all possible TSs and then assign boundary tags to each word. For a TS $[j_1, j_2]$ $(j_1 < j_2)$ that contain more than two words, we assign "b" to the first word f_{j_1} and "e" to the last word f_{j_2}, and "m" to the middle words f_j $(j_1 < j < j_2)$. For a single word span TS $[j, j]$, we assign "s" to the word f_j.

Figure 5 shows an example of labelling source words with boundary tags. The source sentence is segmented into 4 TSs. Using the phrase boundary information to guide decoding, the decoder will produce the correct derivation and translation as shown in Figure 2.

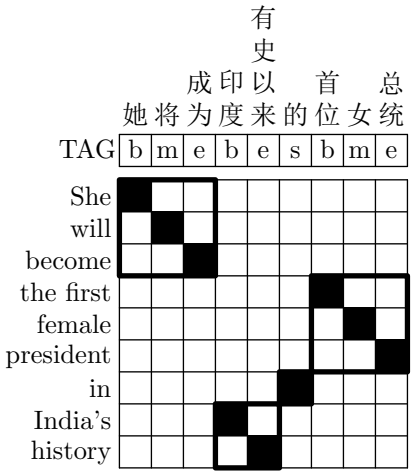

Figure 5: Illustration for labelling the source words with boundary tags. The solid boxes present word alignments. The bordered boxes are TSs.

3.2 Feature Definition

The features we used for the PS model are analogous to (Ng and Low, 2004). For a word W_0, we define the following contextual features with a window of "n":

- The word feature W_n, which denotes the left (right) n words of the current word W_0;
- The part-of-speech (POS) feature P_n, which denotes the POS tag of the word W_n.

For example, the tag of the word "成为 (become)" in Figure 5 is "e", indicating that it is the end of a phrase. If we set the context window $n = 2$, the features of the word "成为 (become)" are:

- W_{-2}=她 W_{-1}=将 W_0=成 为 W_1=印 度 W_2=有史以来
- P_{-2}=r P_{-1}=d P_0=v P_1=ns P_2=l

We collect TSs from bilingual sentences together with the contextual features and used a MaxEnt toolkit (Zhang, 2004) to train a PBC.

	她	将	成为
b	**0.78**	0.10	1.2e-5
m	6.4e-8	**0.75**	5.4e-5
e	2.1e-8	0.11	**0.87**
s	0.22	0.04	0.13

Table 1: The TPM for a source sentence. The highest probability of each word is in bold.

4 Phrase Boundary Constrained Decoding

Give a source sentence, we can assign boundary tags to each word by running the PBC. During decoding, a rule is prohibited to pattern-match across phrase boundaries. By doing this, the PBC is integrated as a hard constraint. However, this method will invalidate a large number of rules and the decoder suffers from a risk that there are not enough rules to cover the source sentence.

Alternatively, inspired by previous approaches, we integrate the phrase boundary classifier as a soft constraint by incorporating it as a feature into the HPB model:

$$h_{pbc}(F_1^J) = log(\prod_{j=1}^{J} P_{tag}(t|f_j, F_1^J)) \quad (7)$$

To perform translation, for each word f_j in a source sentence F_1^J, we first compute all tag probabilities $P_{tag}(t|f_j)$, where $t \in (b, m, e, s)$, $j \in [1, J]$, according to Equation 4. Therefore, we build a $4 \times J$ tag-word probability matrix (TPM). $TPM[i, j]$ indicates the probability of the word f_j labelled with the tag t_i. Table 1 shows the TPM for a source text "她 将 成为".

Then we select rule options from the rule table that can be used for translating the source text. Since each rule option $(\widetilde{f}, \widetilde{e}, a)$ [1] can be regarded as a bilingual sentence with word alignments, thus we find all TS in $\widetilde{f}$ and assign an *initial tag* (IT) for each source word. This procedure is analogous to label phrase boundary tags for a word-aligned bilingual sentence. For example, the following rules are used for translating the Chinese sentence in Table 1:

[1] We keep word alignments of a rule when it is extracted from bilingual sentence.

$$X \rightarrow \langle \text{她}^{b} X_1^{*},\ \text{She } X_1 \rangle \quad (8)$$

$$X_1 \rightarrow \langle \text{将}^{b}\ \text{成为}^{e},\ \text{will become} \rangle \quad (9)$$

Since both the source sides of these two rules are PM spans according to the word alignments, the IT sequences for rule (8) and (9) are "b *"[2] and "b e", respectively. According to Table 1, the initial h_{pbc} score for these two rules can be computed as follows:

$$h_{pbc}^{(7)} = log(P_{tag}(b|\text{她})) = log(TPM[1,1]) \quad (10)$$

$$\begin{aligned} h_{pbc}^{(8)} &= log(P_{tag}(b|\text{将})) + log(P_{tag}(e|\text{成为})) \\ &= log(TPM[1,2]) + log(TPM[3,3]) \end{aligned} \quad (11)$$

Note that to keep the tag sequence valid, e.g. "m" follows "b" rather than "s", the ITs maybe updated during decoding. The tag-updating should be consistent with the definition of TS as described in Section 3.1. Specifically, when the non-terminal symbol X is derived from its covered span $f(X)$, the boundary tags should be updated.

When a tag of word f_j is updated from t_{k_1} to t_{k_2}, the PBC score should also be updated according to TPM:

$$\Delta PBC = log(TPM[k_2, j]) - log(TPM[k_1, j]) \quad (12)$$

The following is a derivation of the source sentence in Table 1:

$$\begin{aligned} S &\Rightarrow \langle \text{她}^{b} X_1^{*},\ \text{She } X_1 \rangle \\ &\Rightarrow \langle \text{她}^{b}\text{将}^{b \rightarrow m}\ \text{成为}^{e},\ \text{She will become} \rangle \end{aligned}$$

When X_1 is derived, the tag of its left boundary word "将" is updated from "b" to "m". The reason is that after derivation, the combined span forms a larger PM span and the left boundary of $f(X_1)$ should be updated.

As a result, the h_{pbc} score is recomputed:

$$h_{pbc}(F_1^3) = h_{pbc}^{(7)} + h_{pbc}^{(8)} + \Delta PBC \quad (13)$$

where,

$$\Delta PBC = log(TPM[2,2]) - log(TPM[1,2]) \quad (14)$$

[2]We use "*" as a tag of the non-terminal symbol "X_1" since it has not been derived.

The decoding algorithm is efficient since the computing of the PBC score is a procedure of table-lookup.

5 Experiments

5.1 Experimental Setup

Our experiments were on Chinese-to-English translation. The training corpus (77M+81M) we used are from LDC [3]. The evaluation metric is BLEU (Papineni et al., 2002), as calculated by mteval-v11b.pl with case-insensitive matching of n-grams, where $n = 4$.

To obtain word alignments, we first ran GIZA++ (Och and Ney, 2002) in both translation directions and then refined it by "grow-diag-final" method (Koehn et al., 2003).

For the language model, we used the SRI Language Modeling Toolkit (Stolcke, 2002) to train two 4-gram models on xinhua portion of GigaWord corpus and the English side of the training corpus.

The NIST MT03 test set is used to tune the feature weights of the log-linear model by MERT (Och, 2003). We tested our system on the NIST MT06 and MT08 test sets.

5.2 Results

The results are shown in Table 2. We tested various settings of the context window. It is observed that the small values of n ($n = 1, 2$) drop the BLEU score, suggesting that perhaps there are not enough contextual information. With more contextual information is used, the BLEU scores are improved over all test sets. When $n = 3$, the most significant improvements are obtained on MT06G and MT08. The improvements over the baseline are statistically significant at $p < 0.01$ by using the significant test method described in (Koehn, 2004). While for MT06N, the optimized context window size is $n = 4$ but the improvement is not statistically significant. In most cases, with n larger than 3, we do not obtain further improvements because of the data sparseness for training

System	MT06G	MT06N	MT08
baseline	14.66	34.42	26.29
+PBC (n=1)	13.78	33.20	24.58
+PBC (n=2)	14.34	34.21	25.87
+PBC (n=3)	**15.19***	34.63	**27.25***
+PBC (n=4)	14.76	**34.73**	26.70

Table 2: Results on the test sets with different context window (n) of the phrase boundary classifier. The largest BLEU score on each test set is in bold. MT06G: MT06 GALE set. MT06N: MT06 NIST set. *: significantly better than the baseline at $p < 0.01$.

the classifier.

6 Discussion

The experimental results show that the phrase boundary constrained method improves the BLEU score over the baseline system. Furthermore, we are interested in how the PBC affects the translation results? We compared the outputs generated by the baseline and "+PBC ($n = 3$)" system and found some interesting translations. For example, the translations of a source sentence of NIST08 are as follows [4]:

- Src: 美$_1^b$ 财长$_2^m$ 抵$_3^m$ 中国$_4^m$ 访问$_5^e$ ‖ 环保$_6^b$ 与$_7^m$ 汇率$_8^e$ ‖ 是$_9^b$ 关切$_{10}^m$ 重点$_{11}^e$
- Ref: US$_1$ Treasury-Secretary$_2$ Arrives-in$_3$ China$_4$ for-a-Visit-with$_5$ Environment$_6$ and$_7$ Exchange-Rate$_8$ as$_9$ Focus$_{10,11}$
- HPB: US$_1$ Treasury$_2$ in-environmental-protection$_6$ and$_7$ visit$_5$ China$_4$ is$_9$ key$_{11}$ to-the-concern-of$_{10}$ the-exchange-rate$_8$
- +PBC: US$_1$ Treasury$_2$ arrived-in$_3$ China$_4$ for-a-visit$_5$ environmental-protection$_6$ and$_7$ exchange-rate$_8$ is$_9$ concerned-about$_{10}$ the-key$_{11}$

In the example, both "环保" and "汇率" in the source sentence are the concern of the "visit". Therefore, the source span $[6, 8]$ indicates a cohesive phrase, which should be translated as a whole unit. However, the baseline translates the spans $[6, 7]$ and $[8, 8]$ separately. It moves $[6, 7]$ before "visit China" and $[8, 8]$ after "concern". This makes an mistake on phrase reordering. We observe that the "+PBC" system produces a better translation. After incorporating the PBC as a soft constraint, the system assigns a boundary tag to each source word and segments the source sentence into three TSs. According to our definition, TSs are encouraged as pseudo-monotone translation unit during decoding. As a result, the "+PBC" system discourages some arbitrary reordering rules and produces more fluent translation.

[4]The co-indexes of the words on the source and target sentence indicate word alignments.

7 Conclusion and Future Work

This paper presented a phrase boundary constrained method for hierarchical phrase-based translation. A phrase boundary indicates begin or end of a phrase reordering. We built a phrase boundary classifier within a maximum entropy framework and learned phrase boundary examples directly from word-aligned bilingual corpus. We proposed an efficient decoding method to integrate the PBC into the decoder as a soft constraint. Experiments and analysis show that the phrase boundary constrained method achieves significant improvements over the baseline system.

The most advantage of the PBC is that it handles both syntactic and non-syntactic phrases. In the future, We would like to try different methods to determine more informative phrase boundaries, e.g. Xiong et al. (2010) proposed a method to learn translation boundaries from a hierarchical tree that decomposed from word alignments using a shift-reduce algorithm. In addition, we will try more features as described in (Chiang et al., 2008; Chiang et al., 2009), e.g. the length of the phrases that covered by non-terminals.

Abstract

In the field of multi-document summarization, the Pyramid method has become an important approach for evaluating machine-generated summaries. The method is based on the manual annotation of text spans with the same meaning in a set of human model summaries. In this paper, we present an unsupervised, probabilistic topic modeling approach for automatically identifying such semantically similar text spans. Our approach reveals some of the structure of model summaries and identifies topics that are good approximations of the Summary Content Units (SCU) used in the Pyramid method. Our results show that the topic model identifies topic-sentence associations that correspond to the contributors of SCUs, suggesting that the topic modeling approach can generate a viable set of candidate SCUs for facilitating the creation of Pyramids.

1 Introduction

In the field of multi-document summarization (MDS), the Pyramid method has become an important approach for evaluating machine-generated summaries (Nenkova and Passonneau, 2004; Passonneau et al., 2005; Nenkova et al., 2007). The method rewards automatic summaries for conveying content that has the same meaning as content represented in a set of human model summaries. This approach allows for variation in the way the content is expressed, which contrasts the Pyramid method with other evaluation methods such as ROUGE that measure word n-gram overlap (Lin and Hovy, 2003).

The Pyramid method groups content with the same meaning into Summary Content Units (SCU). Shared content needs to be identified manually by human inspection of summaries, adding yet another level of human effort (on top of creating model summaries) to the task of summary evaluation. However, Nenkova and Passonneau (2004) as well as Harnly et al. (2005) observe that semantically similar text spans written by different human summarizers are often expressed with a similar choice of words, albeit with differences e.g. in word variants, word order and paraphrasing (Section 2).

In this paper, we present an approach for automatically identifying semantically similar text spans in human model summaries on the basis of such re-occurring word patterns. We utilize a method known as probabilistic topic modeling (Steyvers and Griffiths, 2007). Topic models are claimed to derive semantic information from text in an unsupervised fashion, using only the observed word distributions (Section 3).

- We train a probabilistic topic model based on Latent Dirichlet Allocation (Blei et al., 2003) on the term-sentence matrix of human model summaries used in the Document Understanding Conference (DUC) 2007 Pyramid evaluation[1]. We analyze the resulting model to evaluate whether a topic model captures useful structures of these summaries (Section 4.1).

[1] http://duc.nist.gov

Coling 2008: Poster Volume, pages 391–399,
Beijing, August 2010

- Given the model, we compare the automatically identified topics with SCUs on the basis of their word distributions (Sections 4.2 and 4.3). We discover a clear correspondence between topics and SCUs, which suggests that many automatically identified topics are good approximations of manually annotated SCUs.

- We analyze the distribution of topics over summary sentences in Section 4.4, and compare the topic-sentence associations computed by our model with the SCU-sentence associations given by the Pyramid annotation. Our results suggest that the topic model finds many SCU-like topics, and associates a given topic with the same summary sentences in which a human annotator identifies the corresponding SCU.

Automatically identifying topics that approximate SCUs has clear practical applications: The topics can be used as a candidate set of SCUs for human annotators to speed up the process of SCU creation. Topics can also be identified in machine-generated summaries using standard statistical inference techniques (Asuncion et al., 2009).

2 Summary Content Units

In this section, we briefly introduce the Pyramid method and the properties of Summary Content Units that we intend to exploit in our approach.

A Pyramid is a model predicting the distribution of information content in summaries, as reflected in the summaries humans write (Passonneau et al., 2005; Nenkova et al., 2007). Similar information content is identified by inspection of similar sentences, and parts of these, in different human model summaries. Typically, the text spans which express the same semantic content are not longer than a clause. An SCU consists of a collection of text spans with the same meaning (contributors) and a defining label specified by the annotator.

Each SCU is weighted by the number of human model summaries it occurs in (i.e. the number of contributors). The Pyramid metric assumes that an SCU with a high number of contributors is more informative than an SCU with few contributors. An optimal summary, in terms of content selection, is obtained by maximizing the sum of SCU weights, given a maximum number of SCUs that can be included for a predefined summary length (Nenkova and Passonneau, 2004).

Two example SCUs are given in Table 1. SCU 18 has a weight of 3, since three model summaries contribute to it, SCU 21 has a weight of 2. SCU 18 aggregates contributors which share some key phrases such as "Air National Guard" and "search", but otherwise exhibit a quite heterogeneous word usage. Contributor 3 gives details on the aircraft type, and specifies a time when the first sea vessel was launched to search for the missing plane. Only contributor 1 gives information about the location of the search. In SCU 21, the first contributor contains additional information about communication with the Kennedy family, which is not expressed in the SCU label and therefore not part of the meaning of the SCU. Both contributors contain key terms such as "officials", "search" and "recovery", but vary in word order and verb usage. Passonneau et al. (2005) discuss this observation, and argue that SCUs emerge from the judgment of annotators, and are thus independent of what words are used, or how many.

However, an analysis of typical SCUs shows that contributors written by different human summarizers are often expressed with a similar choice of words or even phrases. Contributors vary in using different forms of the same words (inflectional or derivational variants), different word order, syntactic structure, and paraphrases (Harnly et al., 2005; Nenkova et al., 2007).

3 Probabilistic Topic Models

Our approach for discovering semantically similar text spans makes use of a statistical method known as topic modeling. Probabilistic topic models can derive semantic information from text automatically, on the basis of the observed word patterns (Hofmann, 1999; Blei et al., 2003; Steyvers and Griffiths, 2007). The main assumption of these models is that a latent set of variables – the topics – can be utilized to explain the observed patterns in the data. Documents are represented as mixtures of topics, and each topic is a distribution

SCU 18	The US Coast Guard with help from the Air National Guard then began a massive search-and-rescue mission, searching waters along the presumed flight path
Contributor 1:	The US Coast Guard with help from the Air National Guard then began a massive search-and-rescue mission, searching waters along the presumed flight path
Contributor 2:	A multi-agency search and rescue mission began at 3:28 a.m., with the Coast Guard and Air National Guard participating
Contributor 3:	The first search vessel was launched at about 4:30am. An Air National Guard C-130 and many Civil Air Patrol aircraft joined the search
SCU 21	Federal officials shifted the mission to search and recovery
Contributor 1:	Federal officials shifted the mission to search and recovery and communicated the Kennedy and Bessette families
Contributor 2:	federal officials ended the search for survivors and began a search-and-recovery mission

Table 1: Example SCUs from topic D0742 of DUC 2007.

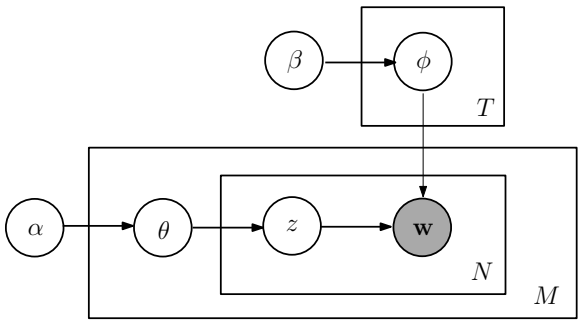

Figure 1: Graphical model representation of LDA for N words, T topics and a corpus of M documents.

over words. For example, a news article describing a meeting of the International Monetary Fund may in equal parts discuss economic and political issues. Topic models discover in a completely unsupervised fashion meaningful topics as well as intra- and inter-document statistical structure using no information except the distribution of the words themselves (Griffiths and Steyvers, 2004).

For our analysis, we use the Latent Dirichlet Allocation (LDA) model introduced by Blei et al. (2003). In this model, each document is generated by first choosing a distribution over topics $\theta^{(d)}$, parametrized by a conjugate Dirichlet prior α. Subsequently, each word of this document is generated by drawing a topic z_k from $\theta^{(d)}$, and then drawing a word w_i from topic z_k's distribution over words $\phi^{(k)}$. We follow Griffiths et al. (2004) and place a conjugate Dirichlet prior β over $\phi^{(k)}$ as well. Figure 1 shows the graphical model representation of LDA.

For T topics, the matrix $\mathbf{\Phi}$ specifies the probability $p(w|z)$ of words given topics, and $\mathbf{\Theta}$ specifies the probability $p(z|d)$ of topics given documents. $p(w|z)$ indicates which words are important in a topic, and $p(z|d)$ tells us which topics are dominant in a document. We employ Gibbs sampling (Griffiths and Steyvers, 2004) to estimate the posterior distribution over z (the assignment of word tokens to topics), given the observed words $\mathbf{w}$ of the document set. From this estimate we can approximate the distributions for the matrices $\mathbf{\Phi}$ and $\mathbf{\Theta}$.

4 Experiments

Can a topic model reveal some of the structure of human model summaries and learn topics that are approximations of manually annotated SCUs? To answer these questions, we train a topic model on the human model summaries of each of the 23 document clusters of the DUC 2007 dataset that were used in Pyramid evaluation[2]. There are 4 human model summaries available for each document cluster. On average, the summary sets contain 52.4 sentences, with a vocabulary of 260.5 terms, which occur a total of 549.7 times. The Pyramids of these summary sets consist of 68.8 SCUs on average. The number of SCUs per SCU

[2]http://www-nlpir.nist.gov/projects/duc/data.html

weight follows a Zipfian distribution, i.e. there are typically very few SCUs of weight 4, and very many SCUs of weight 1 (see also Passonneau et al. (2005)).

4.1 Topic model training

Since we are interested in modeling topics for sentences, we treat each sentence as a document[3]. We construct a matrix $\mathbf{A}$ of term-sentence co-occurrence observations for each set of human model summaries S. Each entry $\mathbf{A}_{ij}$ corresponds to the frequency of word i in sentence j, and j ranges over the union of the sentences contained in S. We preprocess terms using stemming and removing a standard list of stop words with the NLTK toolkit[4].

We run the Gibbs sampling algorithm on $\mathbf{A}$, setting the parameter T, the number of latent topics to learn, equal to the number of SCUs contained in the Pyramid of S. We use this particular value for T since we want to learn a topic model with a structure that reflects the SCUs and the distribution of SCUs of the corresponding Pyramid. For an unannotated set of summaries, determining an optimal value for T is a Bayesian model selection problem (Kass and Raftery, 1995).

The topic distribution for each sentence should be peaked toward a single or only very few topics. To ensure that the topic-specific word distributions $p(w|z)$ as well as the sentence-specific topic distributions $p(z|d)$ behave as intended, we set the Dirichlet priors $\alpha = 0.01$ and $\beta = 0.01$. This enforces a bias toward sparsity, resulting in distributions that are more peaked (Steyvers and Griffiths, 2007). A low value of β also favors more fine-grained topics (Griffiths and Steyvers, 2004). We run the Gibbs sampler for 2000 iterations, and collect a single sample from the resulting posterior distribution over topic assignments for words. From this sample we compute the conditional distributions $p(w|z)$ and $p(z|d)$.

During our experiments, we observed that the Gibbs Sampler did not always use all the topics available. Instead, some topics had a uniform distribution over words, i.e. no words were assigned to these topics during the sampling process. We assume this is due to the relatively low prior $\alpha = 0.01$ we use in our experiments. We explore the consequences of varying the LDA priors and T in Section 4.4.

This observation indicates that the topic model cannot learn as many distinct topics from a given set of summaries as there are SCUs in the Pyramid of these summaries. On average, 24.4% ($\sigma = 17.4$) of the sampled topics had a uniform word distribution, but the fraction of such topics varied. For some summary sets, it was very low (D0701, D0706 with 0%), whereas for others it was very high (D0704, D0728 with 52%). Both of the latter summary sets contain many SCUs with very similar labels and often only a single contributor, e.g. about 'Amnesty International':

- AI criticism frequently involves genocide
- AI criticism frequently involves intimidation
- AI criticism frequently involves police violence

These SCUs are derived from summary sentences that contain enumerations: "AI criticism frequently involves political prisoners, torture, intimidation, police violence, the death penalty, no alternative service for conscientious objectors, and interference with the judiciary." A topic model is based on word-document co-occurrence data, and cannot distinguish between the different grammatical objects in this case. Instead, it treats these phrases as semantically similar since they occur in the same sentence.

4.2 SCU word distributions and SCU-sentence associations

In order to evaluate the quality of the LDA topics, we compare their word distributions to the word distributions of SCUs. This allows us to analyze if the LDA topics capture similar word patterns as SCUs. We approximate the distribution over words $p(w|s_l)$ for each SCU s_l as the relative frequency of word w_i in the bag-of-words constructed from the texts of s_l's label and contributors. We denote the resulting matrix of for a set of SCUs as $\widehat{\mathbf{\Phi}}$.

[3] We will use the words document and sentence interchangeably from here on.

Figure 2: Pairwise Jensen-Shannon divergence of word distributions of LDA topics and Summary Content Units (SCUs), for 3 DUC 2007 Pyramids. Topic-SCU matches are ordered by increasing divergence along the diagonal, using a simple greedy algorithm. The examples suggest that many of the automatically identified LDA topics correspond to manually annotated SCUs.

Topic 17	SCU 31	Topic 5	SCU 32	Topic 9	SCU 25	Topic 8	SCU 36
pilot	pilot	analysi	analysi	bodi	bodi	kennedi	kennedi
kennedi	condit	control	control	diver	diver	edward	edward
condit	conduc	corkscrew	corkscrew	entomb	entomb	recoveri	recoveri
conduc	dark	descent	descent	floor	floor	son	son
dark	disorient	fall	fall	found	found	wit	wit

Table 2: Top terms of best matching LDA topics and SCUs for summary set D0742

In addition, we can compare the topic-sentence associations computed by the model to the SCU-sentence associations given by the Pyramid annotation. If the probability of a given topic is high in those sentences which contribute to a particular SCU, this would suggest that the topic model can automatically learn topics which not only have a word distribution similar to a specific SCU, but also a similar distribution over contributing sentences.

SCU contributors are typically annotated as a set of contiguous sequences of words within a single sentence. In the DUC 2007 data, there are only a few cases where a contributor spans more than one sentence. The DUCView annotation tool[5] stores the start and end character position of the phrases marked as contributors of an SCU. We can utilize this information to define which sentences an SCU is associated with. We store the associations in a matrix $\widehat{\mathbf{\Theta}}$, where $\widehat{\mathbf{\Theta}}_{ij} = 1$ if SCU i is associated with sentence j. Sentences may contain multiple SCUs, and SCUs are associated with as many sentences as their number of contributors.

[5]http://www1.cs.columbia.edu/~becky/DUC2006/2006-pyramid-guidelines.html

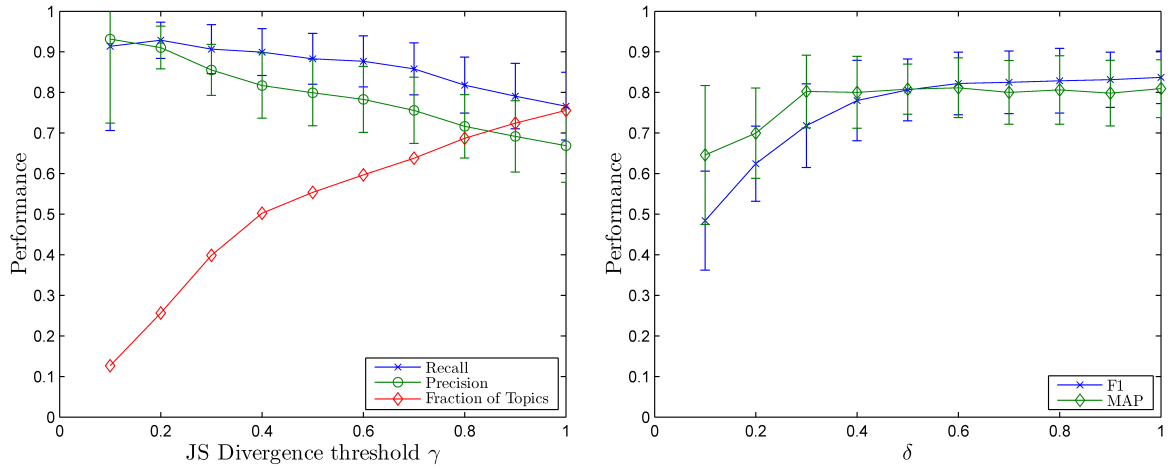
4.3 Matching SCUs and LDA topics

Before we can compare the topic-sentence associations computed by the LDA topic model with the SCU-sentence associations, we need to match SCUs to LDA topics. We consider a topic to be similar to an SCU if their word distributions are similar. We discard all LDA topics with a uniform word distribution (see Section 4.1) before the matching step.

We then compute the pair-wise Jensen-Shannon (JS) divergence between columns j of $\mathbf{\Phi}$ and k of $\widehat{\mathbf{\Phi}}$:

$$JS(\mathbf{\Phi}_j, \widehat{\mathbf{\Phi}}_k) = \left[\frac{1}{2} D_{KL}(\mathbf{\Phi}_j || M) + \frac{1}{2} D_{KL}(\widehat{\mathbf{\Phi}}_k || M)\right], \quad (1)$$

where $M = 1/2(\mathbf{\Phi}_j + \widehat{\mathbf{\Phi}}_k)$. SCUs from $\widehat{\mathbf{\Phi}}$ are matched to topics of $\mathbf{\Phi}$ on the basis of this dissimilarity using a simple greedy approach, i.e. by iteratively selecting the current most similar SCU-



(a) Precision, recall and fraction of Topic-SCU matches for different settings of γ

(b) F1 and MAP for different values of T as a fraction δ of the number of SCUs

Figure 3: (a) Precision, Recall and the fraction of LDA topics matched to SCUs for different settings of parameter γ, averaged over all summary sets with Pyramid annotations from DUC 2007. Error bars show the standard deviation. Only topic-SCU matches with $JS(\mathbf{\Phi}_j, \widehat{\mathbf{\Phi}}_k) \leq \gamma$ are considered when computing precision and recall. Both are very high, suggesting that the model identifies topics that are very similar to SCUs. (b) F_1 measure and Mean Average Precision (MAP) for different settings of the number of latent topics T as a fraction of the number of SCUs in the corresponding Pyramid ($\gamma = 0.5$).

topic pair. We reorder the rows of $\mathbf{\Theta}$ according to the computed matching.

Figure 2 shows some example SCU-topic matches for three different DUC 2007 summary sets. Each cell displays the JS divergence of the word distributions of an LDA topic (rows) compared to an SCU (columns). On the diagonal, the best matches of LDA topics and SCUs are ordered by increasing JS divergence. Multiple points with low JS divergence in a single column indicate that more than one LDA topic was very similar to this SCU. Overall, the graphs show a clear correspondence of LDA topics to the SCUs. The plots suggest that a large percentage of topics have similar distributions over words as the corresponding SCUs. Table 2 shows the most likely terms for some example topic-SCU matches. For each of these matches, the top terms are almost identical.

4.4 Evaluation

To compare the topic distributions $\mathbf{\Theta}$ with the SCU-sentence assignments $\widehat{\mathbf{\Theta}}$, we binarize $\mathbf{\Theta}$ to give $\mathbf{\Theta}'$ by setting all entries $\mathbf{\Theta}'_{ij} = 1$ if $\mathbf{\Theta}_{ij} > \epsilon$, and 0 otherwise. We set $\epsilon = 0.1$ in our experiments[6]. $\mathbf{\Theta}'_{ij}$ is therefore equal to 1 if a topic i has a high probability sentence j. We can now evaluate if a given topic occurs in the same sentences as the corresponding SCU (recall), and if it occurs in no other sentences (precision).

We compute precision and recall for each topic-SCU match with $JS(\mathbf{\Phi}_j, \widehat{\mathbf{\Phi}}_k) \leq \gamma$. Averaged over matches, these measures give us an indication of how well the LDA model approximates the set of SCUs. The parameter γ allows us to tune the performance of the model with respect to the quality and number of topic-SCU matches. Setting γ to a low value will consider only topic-SCU matches with a low JS divergence, which generally results in higher precision and recall. Increasing γ will include more topic-SCU matches, namely those with a larger JS divergence, which will therefore introduce some noise.

Figure 3(a) shows the precision and recall

[6]Since the LDA algorithm learns very peaked distributions, the actual value of this threshold does not have a large impact on the resulting binary matrix and subsequent evaluation results. We evaluated a range of settings for ϵ in $[0.001 - 0.5]$, all with similar performance. This observation is confirmed by the threshold-less Mean Average Precision results in Figure 3(b).

curves for different values of the parameter γ, averaged over all summary sets. The plots show that both the precision and recall of the discovered topic-sentence associations are quite high, suggesting that the model automatically identifies topics which are very similar to manually annotated SCUs. With increasing γ, precision and recall scores decrease: The word distributions of the topic-SCU pairs are increasingly dissimilar, and hence the sentences associated with a topic do not necessarily overlap anymore with the sentences of the paired SCU. The figure also shows the fraction of topic matches that are considered in the evaluation of precision and recall. There is a clear trade off between performance and the number of matches retrieved. However, many of the topic-SCU matches ($\approx 50\%$) have a JS divergence ≤ 0.4, suggesting that the word distributions of many LDA topics are very similar to SCU word distributions.

Since we observed that the Gibbs sampling does not always utilize the full set of topics, we repeat our experiments to evaluate how the performance of the model changes when varying the LDA priors and T. Figure 3(b) shows F_1 and Mean Average Precision (MAP)[7] results of the topic model for different values of the parameter δ, where $T = \delta * |SCU|$. For example, a value of 0.6 means that for each summary set, T was set to 60% of the number of SCUs in the corresponding Pyramid. We see that the MAP score increases quickly, and reaches a plateau for $\delta \geq 0.3$. The F_1 score increases more slowly, and levels out for $\delta \geq 0.6$. The model's performance is relatively robust with respect to δ. This observation can be helpful when training models for new summary sets without an existing Pyramid, and which therefore consider T as a parameter to be optimized.

When varying the LDA priors, we observe that for $0.01 \leq \alpha \leq 0.05$, F_1 and MAP scores are consistently high, whereas for other settings, performance decreases significantly. Similarly, $\beta \geq 0.05$ results in lower F_1 and MAP scores. The fraction of uniform topics decreases with higher α, e.g. for $\alpha = 0.1$ it is close to zero. In contrast, higher settings of β increase the fraction of uniform topics.[8]

Finally, Figure 4 shows separate precision and recall curves for SCUs of different weights, and for different settings of parameter γ. Results are again averaged over all summary sets. In 4(a), we see that the recall of topic-sentence associations is very similar for all SCUs, with SCUs of higher weight exhibiting a slightly better recall. However, as Figure 4(b) shows, the average precision of SCUs with lower weight is much higher. Intuitively, this is expectable as SCUs of higher weight tend to have a larger vocabulary due to the higher number of contributors. This results in a larger word overlap with non-relevant sentences. The fraction of topic-SCU matches retrieved for SCUs of different weight is similar for all types of SCUs (not shown here).

5 Related Work

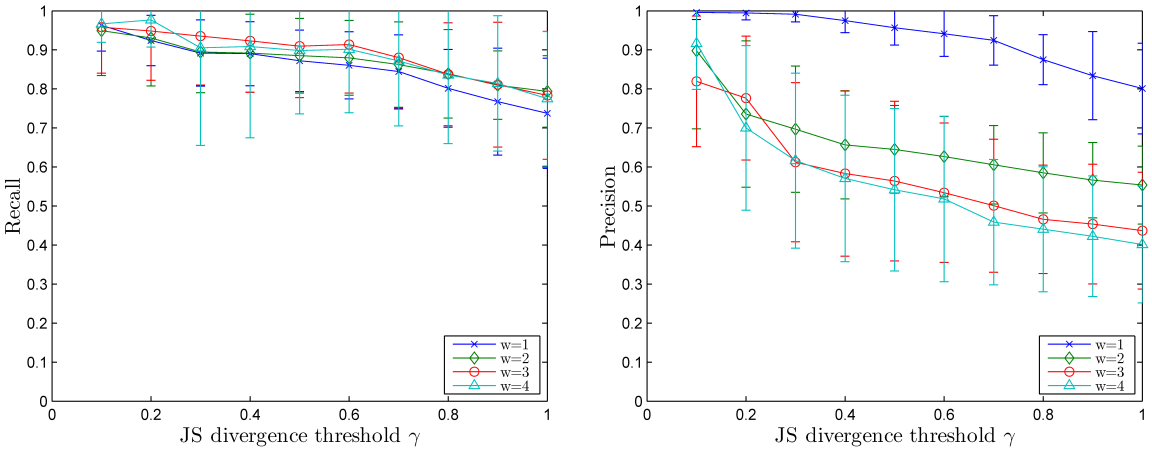
The Pyramid approach was introduced by Nenkova and Passonneau (2004) as a method for evaluating machine-generated summaries based on a set of human model summaries. The authors address a number of shortcomings of manual and automatic summary evaluation methods such as ROUGE (Lin and Hovy, 2003), and argue that the Pyramid method is reliable, diagnostic and predictive.

Passonneau and et al. (2005) give an account of the results of applying the Pyramid method during the DUC 2005 summarization evaluation, and discuss the annotation process. In subsequent work, Nenkova et al. (2007) describe in more detail the incorporation of human variation in the Pyramid method, the reliability of content annotation, and the correlation of Pyramid scores with other evaluation measures.

Harnly et al. (2005) present an approach for automatically scoring a machine summary given an existing Pyramid. Their method searches for an optimal set of candidate contributors created automatically from the machine summary and matches candidates to SCUs using a clustering approach.

[7] MAP is a rank-based measure, which avoids the need for introducing a threshold to binarize Θ (Baeza-Yates and Ribeiro-Neto, 1999). For each topic, we create a ranked list of sentences according to the transposed matrix $\mathbf{\Theta}^T$. This gives high ranks to sentences for which a particular topic has a high probability.

[8] Results are not shown due to space constraints.



(a) Recall of Topic-SCU matches for SCUs by weight

(b) Precision of Topic-SCU matches for SCUs by weight

Figure 4: (a) Recall of topic-SCU matches for SCUs of different weights, and settings of parameter γ, averaged over all summary sets. Recall is similar for SCUs of all weights. (b) Precision of the same topic-SCU matches. SCUs with a lower weight have a higher average precision. (Error bars show the standard deviation.)

The method assumes the existence of a Pyramid, whereas our approach aims to discover candidate SCUs from a set of human model summaries in an unsupervised fashion.

Recently, Louis and Nenkova (2009) presented an approach for fully automatic, model-free evaluation of machine-generated summaries. The method assumes that the distribution of words in the input and an informative summary should be similar. We think that it could be an interesting idea to combine the proposed method with our approach, in an attempt to exploit both the model-free evaluation and the shallow semantics of latent topics.

Probabilistic topic models have been successfully applied to a variety of tasks (Hofmann, 1999; Blei et al., 2003; Griffiths and Steyvers, 2004; Hall et al., 2008). In text summarization, most topic modeling approaches utilize a term-sentence co-occurrence matrix to discover topics in the set of input documents. Each sentence is typically assigned to a single topic, and a topic is a cluster of multiple sentences (Wang et al., 2009; Tang et al., 2009; Hennig, 2009).

6 Conclusions and future work

We presented a probabilistic topic modeling approach that reveals some of the structure of human model summaries. The topic model is trained on the term-sentence matrix of a set of human summaries, and discovers semantic topics in a completely unsupervised fashion. Many of the topics identified by our model for a given set of summaries show a similar distribution over words as the manually annotated Summary Content Units of the summaries' Pyramid.

We utilized the word distributions of SCUs and topics to match topics to similar SCUs, and showed that the topics identified by the model often occur in the same sentences as the contributors of the corresponding SCU. Precision and recall of these topic-sentence assignments are very high when compared to the SCU-sentence associations, indicating that many of the automatically acquired topics are good approximations of SCUs. Our results suggest that a topic model can be used to learn a candidate set of SCUs to facilitate the process of Pyramid creation.

We note that the topic model that we applied is one of the simplest latent variable models. A more complex model could integrate syntax to relax the bag-of-words assumption (Wallach, 2006), or combine the statistical model with more linguistically-grounded methods to handle linguistic features such as enumerations or negation.

Abstract

This paper proposes a novel extractive summarization method for contact center dialogues. We use a particular type of hidden Markov model (HMM) called Class Speaker HMM (CSHMM), which processes operator/caller utterance sequences of multiple domains simultaneously to model domain-specific utterance sequences and common (domain-wide) sequences at the same time. We applied the CSHMM to call summarization of transcripts in six different contact center domains and found that our method significantly outperforms competitive baselines based on the maximum coverage of important words using integer linear programming.

1 Introduction

In modern business, contact centers are becoming more and more important for improving customer satisfaction. Such contact centers typically have quality analysts who mine calls to gain insight into how to improve business productivity (Takeuchi et al., 2007; Subramaniam et al., 2009). To enable them to handle the massive number of calls, automatic summarization has been utilized and shown to successfully reduce costs (Byrd et al., 2008). However, one of the problems in current call summarization is that a domain ontology is required for understanding operator/caller utterances, which makes it difficult to port one summarization system from domain to domain.

This paper describes a novel automatic summarization method for contact center dialogues without the costly process of creating domain ontologies. More specifically, given contact center dialogues categorized into multiple domains, we create a particular type of hidden Markov model (HMM) called **Class Speaker HMM** (**CSHMM**) to model operator/caller utterance sequences. The CSHMM learns to distinguish sequences of individual domains and common sequences in all domains at the same time. This approach makes it possible to accurately distinguish utterances specific to a certain domain and thereby has the potential to generate accurate extractive summaries.

In Section 2, we review recent work on automatic summarization, including its application to contact center dialogues. In Section 3, we describe the CSHMM. In Section 4, we describe our automatic summarization method in detail. In Section 5, we describe the experiment we performed to verify our method and present the results. In Section 6, we summarize and mention future work.

2 Related Work

There is an abundance of research in automatic summarization. It has been successfully applied to single documents (Mani, 2001) as well as to multiple documents (Radev et al., 2004), and various summarization methods, such as the conventional LEAD method, machine-learning based sentence selection (Kupiec et al., 1995; Osborne, 2002), and integer linear programming (ILP) based sentence extraction (Gillick and Favre, 2009), have been proposed. Recent years have seen work on summarizing broadcast news speech (Hori and Furui, 2003), multi-party meetings (Murray et al., 2005), and contact center dialogues (Byrd et al., 2008). However, despite the large amount of previous work, little work has tackled the automatic summarization of multi-domain data.

Coling 2008: Poster Volume, pages 400–408,
Beijing, August 2010

In the past few decades, contact center dialogues have been an active research focus (Gorin et al., 1997; Chu-Carroll and Carpenter, 1999). Initially, the primary aim of such research was to transfer calls from answering agents to operators as quickly as possible in the case of problematic situations. However, real-time processing of calls requires a tremendous engineering effort, especially when customer satisfaction is at stake, which led to recent work on the offline processing of calls, such as call mining (Takeuchi et al., 2007) and call summarization (Byrd et al., 2008).

The work most related to ours is (Byrd et al., 2008), which maps operator/caller utterances to an ontology in the automotive domain by using support vector machines (SVMs) and creates a structured summary by heuristic rules that assign the mapped utterances to appropriate summary sections. Our work shares the same motivation as theirs in that we want to make it easier for quality analysts to analyze the massive number of calls. However, we tackle the problem differently in that we propose a new modeling of utterance sequences for extractive summarization that makes it unnecessary to create heuristics rules by hand and facilitates the porting of a summarization system.

HMMs have been successfully applied to automatic summarization (Barzilay and Lee, 2004). In their work, an HMM was used to model the transition of *content topics*. The Viterbi decoding (Rabiner, 1990) was performed to find content topics that should be incorporated into a summary. Their approach is similar to ours in that HMMs are utilized to model topic sequences, but they did not use data of multiple domains in creating their model. In addition, their method requires training data (original articles with their reference summaries) in order to find which content topics should be included in a summary, whereas our method requires only the raw sequences with their domain labels.

3 Class Speaker HMM

A Class Speaker HMM (CSHMM) is an extension of Speaker HMM (SHMM), which has been utilized to model two-party conversations (Meguro et al., 2009). In an SHMM, there are two states, and each state emits utterances of one of the two conversational participants. The states are connected ergodically and the emission/transition probabilities are learned from training data by using the EM-algorithm. Although Meguro et al., (2009) used SHMMs to analyze the flow of listening-oriented dialogue, we extend their idea to make it applicable to classification tasks, such as dialogue segmentation.

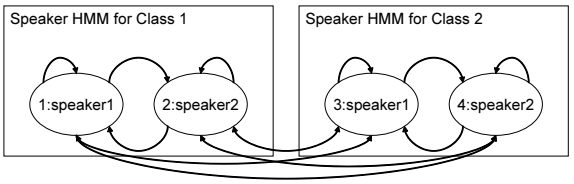

Figure 1: Topology of an ergodic CSHMM. Numbers before 'speaker1' and 'speaker2' denote state IDs.

A CSHMM is simply a concatenation of SHMMs, each of which is trained by using utterance sequences of a particular dialogue class. After such SHMMs are concatenated, the Viterbi algorithm is used to decode an input utterance sequence into class labels by estimating from which class each utterance has most likely to have been generated. Figure 1 illustrates the basic topology of a CSHMM where two SHMMs are concatenated ergodically. When the most likely state sequence for an input utterance sequence is <1,3,4,2>, we can convert these state IDs into their corresponding classes; that is, <1,2,2,1>, which becomes the result of utterance classification.

We have conceived three variations of CSHMM as we describe below. They differ in how we treat utterance sequences that appear commonly in all classes and how we train the transition probabilities between independently trained SHMMs.

3.1 Ergodic CSHMM

The most basic CSHMM is the ergodic CSHMM, which is a simple concatenation of SHMMs in an ergodic manner as shown in Fig. 1. For K classes, K SHMMs are combined with the initial and transition probabilities all set to *equal*. In this CSHMM, the assignment of class labels solely depends on the output distributions of each class.

3.2 Ergodic CSHMM with Common States

This type of CSHMM is the same as the ergodic CSHMM except that it additionally has a SHMM trained from all dialogues of all classes. There-

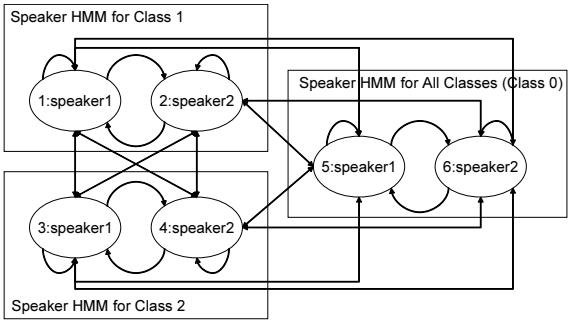

Figure 2: CSHMM with common states.

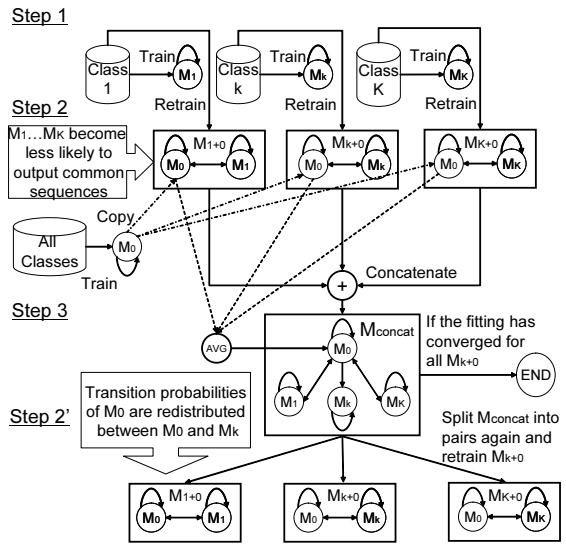

Figure 3: Three steps to create a CSHMM using concatenated training.

fore, for K classes, this CSHMM has $K + 1$ SHMMs. Figure 2 shows the model topology. This newly added SHMM works in a manner similar to the background model (Reynolds et al., 2000) representing sequences that are common to all classes. By having these *common states*, common utterance sequences can be classified as 'common', making it possible to avoid forcefully classifying common utterance sequences into one of the given classes.

Detecting common sequences is especially helpful when several classes overlap in nature. For example, most dialogues commonly start and end with greetings, and many calls at contact centers commonly contain exchanges in which the operator requests personal information about the caller for confirmation. Regarding the model topology in Fig. 2, if the most likely state sequence by the Viterbi decoding is <1,4,5,6,3,2>, we obtain a class label sequence <1,2,0,0,2,1> where the third and fourth utterances are classified as 'zero', meaning that they do not belong to any class.

3.3 CSHMM using Concatenated Training

The CSHMMs presented so far have two problems: one is that the order of utterances of different classes cannot be taken into account because of the equal transition probabilities. As a result, the very merit of HMMs, their ability to model time series data, is lost. The other is that the output distributions of common states may be overly broad because they are the averaged distributions over all classes; that is, the best path determined by the Viterbi decoding may not go through the common states at all.

Our solution to these problems is to apply concatenated training (Lee, 1989), which has been successfully used in speech recognition to model phoneme sequences in an unsupervised manner. The procedure for concatenated training is illustrated in Fig. 3 and has three steps.

step 1 Let M_k ($M_k \in M, 1 \leq k \leq K$) be the SHMM trained using dialogues D_k where $D_k = \{\forall d_j | c(d_j) = k\}$, and M_0 be the SHMM trained using all dialogues; i.e., D. Here, K means the total number of classes and $c(d_j)$ the class assigned to a dialogue d_j.

step 2 Connect each $M_k \in M$ with a copy of M_0 using equal initial and transition probabilities (we call this connected model M_{k+0}) and retrain M_{k+0} with $\forall d_j \in D_k$ where $c(d_j) = k$.

step 3 Merge all models M_{k+0} ($1 \leq k \leq K$) to produce one concatenated HMM (M_{concat}). Here, the output probabilities of the copies of M_0 are averaged over K when all models are merged to create a combined model. If the fitting of all M_{k+0} models has converged against the training data, exit this procedure; otherwise, go to step 2 by connecting a copy of M_0 and M_k for all k. Here, the transition probabilities from M_0 to $M_l (l \neq k)$ are summed and equally distributed between the copied M_0's self-loop and transitions to the states in M_k.

In concatenated training, the transition and output probabilities can be optimized between M_0 and

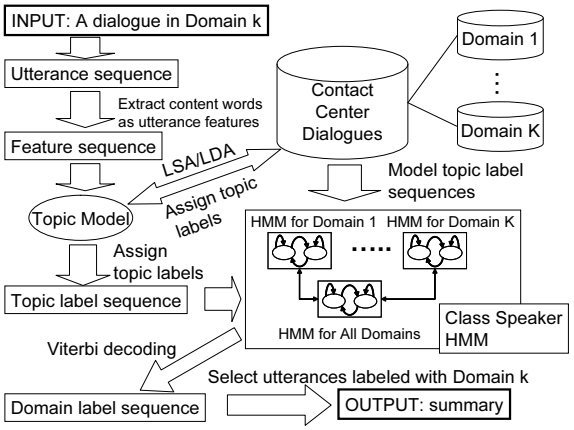

Figure 4: Overview of our summarization method.

M_k, meaning that the output probabilities of utterance sequences that are common and also found in M_k can be moved from M_k to M_0. This makes the distribution of M_k sharp (not broad/uniform), making it likely to output only the utterances representative of a class k. As regards M_0, its distribution of output probabilities can also be sharpened for utterances that occur commonly in all classes. This sharpening of distributions is likely to be helpful for class discrimination.

4 Summarization Method

We apply CSHMMs to extractive summarization of contact center dialogues because such dialogues are two-party, can be categorized into multiple classes by their call domains (e.g., inquiry types), and are likely contain many overlapping exchanges between an operator and a caller across domains, such as greetings, the confirmation of personal information, and other cliches in business (e.g., name exchanges, thanking/apologizing phrases, etc.), making them the ideal target for CSHMMs.

In our method, summarization is performed by decoding a sequence of utterances of a domain DM^k into domain labels and selecting those utterances that have domain labels DM^k. This makes it possible to extract utterances that are characteristic of DM^k in relation to other domains. Our assumption is that extracting characteristic sequences of a given domain provides a good summary for that domain because such sequences should contain important information necessitated by the domain.

Figure 4 outlines our extractive summarization process. The process consists of a training phase and a decoding phase as described below.

Training phase: Let D ($d_1 \ldots d_N$) be the entire set of contact center dialogues, DM^k ($DM^k \in DM, 1 \leq k \leq K$) the domain assigned to domain k, and $U_{d_i,1} \ldots U_{d_i,H}$ the utterances in d_i. Here, H is the number of utterances in d_i. From D, we create two models: a topic model (TM) and a CSHMM.

The topic model is used to assign a single topic to each utterance so as to facilitate the training of the CSHMM by reducing the dimensions of the feature space. The same approach has been taken in (Barzilay and Lee, 2004). The topic model can be created by such techniques as probabilistic latent semantic analysis (PLSA) (Šingliar and Hauskrecht, 2006) and latent Dirichlet allocation (LDA) (Tam and Schultz, 2005). PLSA models the latent topics of the documents and its Baysian extension is LDA, which also models the co-occurrence of topics using the Dirichlet prior. We first derive features $F_{d_1} \ldots F_{d_N}$ for the dialogues. Here, we assume a bag-of-words representation for the features; therefore, F_{d_i} is represented as $\{< w_1, c_1 > \ldots < w_V, c_V >\}$, where V means the total number of content words in the vocabulary and $< w_i, c_i >$ denotes that a content word w_i appears c_i times in a dialogue. Note that we derive the features for dialogues, not for utterances, because utterances in dialogue can be very short, often consisting of only one or two words and thus making it hard to calculate the word co-occurrence required for creating a topic model. From the features, we build a topic model that includes $\mathrm{P}(z|w)$, where w is a word and z is a topic. Using the topic model, we can assign a single topic label to every utterance in D by finding its likely topic; i.e., $\underset{z}{\mathrm{argmax}} \sum_{w \in \mathrm{words}(U_{d_i})} \mathrm{P}(z|w)$.

After labeling all utterances in D with topic labels, we train a CSHMM that learns characteristic topic label sequences in each domain as well as common topic label sequences across domains.

Decoding phase: Let d_j be the input dialogue, $DM(d_j)$ ($\in DM$) the table for obtaining the domain label of d_j, and $U_{d_j,1} \ldots U_{d_j,H_{d_j}}$ the utterances in d_j, where H_{d_j} is the number of the utterances. We use TM to map the utterances to topic

labels $T_{d_j,1} \ldots T_{d_j,H_{d_j}}$ and convert them into domain label sequences $DM_{d_j,1} \ldots DM_{d_j,H_{d_j}}$ using the trained CSHMM by the Viterbi decoding. Then, we select $U_{d_j,h}$ $(1 \leq h \leq H_{d_j})$ whose corresponding domain label $DM_{d_j,h}$ equals $DM(d_j)$ and output the selected utterances in the order of appearance in the original dialogue as a summary.

5 Experiment

We performed an experiment to verify our summarization method. We first collected simulated contact center dialogues using human subjects. Then, we compared our method with baseline systems. Finally, we analyzed the created summaries to investigate what had been learned by our CSHMMs.

5.1 Dialogue Data

Since we do not have access to actual contact center data, we recruited human subjects to collect simulated contact center dialogues. A total of 90 participants (49 males and 41 females) took the roles of operator or a caller and talked over telephones in separate rooms. The callers were given realistic scenarios that included their motivation for a call as well as detailed instructions about what to ask. The operators, who had experience of working at contact centers, were given manuals containing the knowledge of the domain and explaining how to answer questions in specific scenarios.

The dialogues took place in six different domains: Finance (**FIN**), Internet Service Provider (**ISP**), Local Government Unit (**LGU**), Mail Order (**MO**), PC support (**PC**), and Telecommunication (**TEL**). In each domain, there were 15–20 tasks. Table 1 shows the statistics of the task scenarios used by the callers. We cannot describe the details of each domain for lack of space, but examples of the tasks for FIN are inquiries about insurance, notifications of the loss of credit cards, and applications for finance loans, and those for ISP are inquiries about fees for Internet access, requests to forward emails, and reissuance of passwords. Figure 5 shows one of the task scenarios in the MO domain.

MO task No. 3: It is becoming a good season for the Japanese Nabe (pan) cuisine. You own a Nabe restaurant and it is going well. When you were searching on the Internet, thinking of creating a new dish, you saw that drop-shipped Shimonoseki puffer fish was on sale. Since you thought the puffer fish cuisine would become hot in the coming season, you decided to order it as a trial. ... You ordered a puffer fish set on the Internet, but you have not received the confirmation email that you were supposed to receive. ... You decided to call the contact center to make an inquiry, ask them whether the order has been successful, and request them to send you the confirmation email.

Figure 5: Task scenario in the MO domain. The scenario was originally in Japanese and was translated by the authors.

We collected data on two separate occasions using identical scenarios but different participants, which gave us two sets of dialogue data. We used the former for training our summarization system and the latter for testing. We only use the transcriptions in this paper so as to avoid particular problems of speech. All dialogues were in Japanese. Tables 2 and 3 show the statistics of the training data and the test data, respectively. As can be seen from the tables, each dialogue is quite long, which attests to the complexity of the tasks.

5.2 Training our Summarization System

For training our system, we first created a topic model using LDA. We performed a morphological analysis using ChaSen[1] to extract content words from each dialogue and made its bag-of-words features. We defined content words as nouns, verbs, adjectives, unknown words, and interjections (e.g., "yes", "no", "thank you", and "sorry"). We included interjections because they occur very frequently in dialogues and often possess important content, such as agreement and refusal, in transactional communication. We use this definition of content words throughout the paper.

Then, using an LDA software package[2], we built a topic model. We tentatively set the number

of topics to 100. Using this topic model, we labeled all utterances in the training data using these 100 topic labels.

We trained seven different CSHMMs in all: one ergodic CSHMM (**ergodic0**), three variants of ergodic CSHMMs with common states (**ergodic1**, **ergodic2**, **ergodic3**), and three variants of CSHMMs with concatenated training (**concat1**, **concat2**, **concat3**). The difference within the variants is in the number of common states. The numbers 0–3 after 'ergodic' and 'concat' indicate the number of SHMMs containing common states. For example, ergodic3 has nine SHMMs (six SHMMs for the six domains plus three SHMMs containing common states). Since more states would enable more minute modeling of sequences, we made such variants in the hope that common sequences could be more accurately modeled. We also wanted to examine the possibility of creating sharp output distributions in common states without the concatenated training by such minute modeling. These seven CSHMMs make seven different summarization systems.

5.3 Baselines

Baseline-1: BL-TF We prepared two baseline systems for comparison. One is a simple summarizer based on the maximum coverage of high term frequency (TF) content words. We call this baseline BL-TF. This baseline summarizes a dialogue by maximizing the following objective function:

$$\max \sum_{z_i \in Z} \text{weight}(w_i) \cdot z_i$$

where 'weight' returns the importance of a content word w_i and z_i is a binary value indicating whether to include w_i in the summary. Here, 'weight' returns the count of w_i in a given dialogue. The maximization is done using ILP (we used an off-the-shelf solver `lp_solve`[3]) with the following three constraints:

$$x_i, z_i \in \{0, 1\}$$

$$\sum_{x_i \in X} l_i x_i \leq K$$

$$\sum_i m_{ij} x_i \geq z_j \quad (\forall z_j \in Z)$$

where x_i is a binary value that indicates whether to include the i-th utterance in the summary, l_i is the length of the i-th utterance, K is the maximum number of characters to include in a summary, and m_{ij} is a binary value that indicates whether w_i is included in the j-th utterance. The last constraint means that if a certain utterance is included in the summary, all words in that utterance have to be included in the summary.

Baseline-2: BL-DD Although BL-TF should be a very competitive baseline because it uses the state-of-the-art formulation as noted in (Gillick and Favre, 2009), having only this baseline is rather unfair because it does not make use of the training data, whereas our proposed method uses them. Therefore, we made another baseline that learns domain-specific dictionaries (DDs) from the training data and incorporates them into the weights of content words of the objective function of BL-TF. We call this baseline BL-DD. In this baseline, the weight of a content word w_i in a domain DM^k is

$$\text{weight}(w_{i,DM^k}) = \frac{\log(\text{P}(w_i|DM^k))}{\log(\text{P}(w_i|DM \backslash DM^k))}$$

Table 4: F-measure, precision, and recall averaged over all 307 dialogues (cf. Table 3) in the test set for the proposed methods and baselines BL-TF and BL-DD configured to output the same-length summaries as the proposed systems. The averaged compression rate for each proposed system is shown at the bottom. The columns (ergodic0–concat3) indicate our methods as well as the character lengths used by the baselines. Asterisks, '+', e0–e3, and c1–c3 indicate our systems' statistical significance by the Wilcoxon signed-rank test ($p<0.01$) over BL-TF, BL-DD, ergodic0–3, and concat1–3, respectively. Statistical tests for the precision and recall were only performed between the proposed systems and their same-length baseline counterparts. **Bold font** indicates the best score in each row.

where $\mathrm{P}(w_i|DM^k)$ denotes the occurrence probability of w_i in the dialogues of DM^k, and $\mathrm{P}(w_i|DM\backslash DM^k)$ the occurrence probability of w_i in all domains except for DM^k. This log likelihood ratio estimates how much a word is characteristic of a given domain. Incorporating such weights would make a very competitive baseline.

5.4 Evaluation Procedure

We made our seven proposed systems and two baselines (BL-TF and BL-DD) output extractive summaries for the test data. Since one of the shortcomings of our proposed method is its inability to set the compression rate, we made our systems output summaries first and made the baseline systems output their summaries within the character lengths of our systems' summaries.

We used scenario texts (See Fig. 5) as reference data; that is, a dialogue dealing with a certain task is evaluated using the scenario text for that task. As an evaluation criterion, we used the F-measure (F1) to evaluate the retrieval accuracy on the basis of the recall and precision of retrieved content words. We used the scenarios as references because they contain the basic content exchanged between an operator and a caller, the retrieval accuracy of which should be important for quality analysts.

We could have used ROUGE (Lin and Hovy, 2003), but we did not because ROUGE does not correlate well with human judgments in conversational data (Liu and Liu, 2008). Another benefit of using the F-measure is that summaries of varying lengths can be compared.

5.5 Results

Table 4 shows the evaluation results for the proposed systems and the baselines. It can be seen that concat3 shows the best performance in F-measure among all systems, having a statistically better performance over all systems except for concat2. The CSHMMs with concatenated training were all better than ergodic0–3. Here, the performance (and output) of ergodic0–3 was exactly the same. This happened because of the broad distributions in their common states; no paths went through the common states and all paths went through the SHMMs of the six domains instead.

The evaluation results in Table 4 may be rather in favor of our systems because the summarization lengths were set by the proposed systems. Therefore, we performed another experiment to investigate the performance of the baselines with varying compression rates and compared their performance with the proposed systems in F-measure. We found that the best performance was achieved by BL-DD when the compression rate was 0.4 with the F-measure of 0.191, which concat3 significantly outperformed by the Wilcoxon signed-rank test ($p<0.01$). Note that the performance shown in Table 4 may seem low. However, we found that the maximum recall is 0.355 (cal-

culated by using summaries with no compression). This means that the maximum F-measure we could attain is lower than 0.524 (when the precision is ideal with 1). This is because of the differences between the scenarios and the actual dialogues. We want to pursue ways to improve our evaluation methodology in the future.

Despite such issues in evaluation, from the results, we conclude that our extractive summarization method is effective and that having the common states and training CSHMMs with concatenated training are useful in modeling domain-specific sequences of contact center dialogues.

5.6 Example of System Output

Figure 6 shows an example output of concat3 for the scenario MO task No. 3 (cf. Fig. 5). **Bold font** indicates utterances that were NOT included in the summary of concat3's same-length-BF-DD counterpart. It is clear that sequences related to the MO domain were successfully extracted. When we look at the summary of BF-DD, we see such utterances as "*Can I have your address from the postcode*" and "*Finally, can I have your email address*", which are obvious cliches in contact center dialogues. This indicates the usefulness of common states for ignoring such common exchanges.

6 Summary and Future Work

This paper proposed a novel extractive summarization method for contact center dialogues. We devised a particular type of HMM called CSHMM, which processes operator/caller utterance sequences of multiple domains simultaneously to model domain-specific utterance sequences and common sequences at the same time. We trained a CSHMM using the transcripts of simulated contact center dialogues and verified its effectiveness for the summarization of calls.

There still remain several limitations in our approach. One is its inability to change the compression rate, which we aim to solve in the next step using the forward-backward algorithm (Rabiner and Juang, 1986). This algorithm can calculate the posterior probability of each state at each time frame given an input dialogue sequence, enabling us to extract top-N domain-specific sequences. We also need to find the appropriate topic number for the topic model. In our implementation, we used a tentative value of 100, which may not be appropriate. In addition, we believe the topic model and the CSHMM can be unified because these models are fundamentally similar, especially when LDA is employed. Model topologies may also have to be reconsidered. In our CSHMM with concatenated training, the states in domain-specific SHMMs are only connected to the common states, which may be inappropriate because there could be a case where a domain changes from one to another without having a common sequence. Applying CSHMMs to speech and other NLP tasks is another challenge. As a near-term goal, we aim to apply our method to the summarization of meetings, where we will need to extend our CSHMMs to deal with more than two participants. Finally, we also want to build a contact center dialogue agent by extending the CSHMMs to partially observable Markov decision processes (POMDPs) (Williams and Young, 2007) by following the recent work on building POMDPs from dialogue data in the dynamic Bayesian network (DBN) framework (Minami et al., 2009).

Acknowledgments

We thank the members of the Spoken Dialog System Group, especially Noboru Miyazaki and Satoshi Kobashikawa, for their effort in dialogue data collection.

Abstract

This paper proposes a supervised learning method to recognize expressions that show a relation between two named entities, e.g., person, location, or organization. The method uses two novel features, 1) whether the candidate words inherently express relations and 2) how the candidate words are influenced by the past relations of two entities. These features together with conventional syntactic and contextual features are organized as a tree structure and are fed into a boosting-based classification algorithm. Experimental results show that the proposed method outperforms conventional methods.

1 Introduction

Much attention has recently been devoted to using enormous amount of web text covering an exceedingly wide range of domains as a huge knowledge resource with computers. To use web texts as knowledge resources, we need to extract information from texts that are merely sequences of words and convert them into a structured form. Although extracting information from texts as a structured form is difficult, relation extraction is a way that makes it possible to use web texts as knowledge resources.

The aim of relation extraction is to extract semantically related named entity pairs, X and Y, and their relation, R, from a text as a structured form [X, Y, R]. For example, the triple [Yukio Hatoyama, Japan, prime minister] would be extracted from the text "Yukio Hatoyama is the prime minister of Japan". This extracted triple provides important information used in information retrieval (Zhu et al., 2009) and building an ontology (Wong et al., 2010).

It is possible to say that all named entity pairs that co-occur within a text are semantically related in some way. However, we define that named entity pairs are semantically related if they satisfy either of the following rules:

- One entity is an attribute value of the other.
- Both entities are arguments of a predicate.

Following the above definition, explicit and implicit relations should be extracted. An explicit relation means that there is an expression that shows the relation between a named entity pair in a given text, while an implicit relation means that there is no such expression. For example, the triple [Yukio Hatoyama, Kunio Hatoyama, brother] extracted from the text "Yukio Hatoyama, the Democratic Party, is Kunio Hatoyama's brother" is an explicit relation. In contrast, the triple [Yukio Hatoyama, the Democratic Party, member] extracted from the same text is an implicit relation because there is no expression showing the relation (e.g. member) between "Yukio Hatoyama" and "the Democratic Party" in the text.

Extracting triples [X, Y, R] from a text involves two tasks. One is detecting semantically related pairs from named entity pairs that co-occur in a text and the other is determining the relation between a detected pair. For the former task, various supervised learning methods (Culotta and Sorensen, 2004; Zelenko et al., 2003; Hirano et al., 2007) and bootstrapping methods (Brin, 1998; Pantel and Pennacchiotti, 2006) have been explored to date. In contrast, for the latter task,

Coling 2008: Poster Volume, pages 409–417,
Beijing, August 2010

only a few methods have been proposed so far (Hasegawa et al., 2004; Banko and Etzioni, 2008; Zhu et al., 2009). We therefore addressed the problem of how to determine relations between a given pair.

We used a three-step approach to address this problem. The first step is to recognize an expression that shows explicit relations between a given named entity pair in a text. If no such expression is recognized, the second step is to estimate the relationship that exists between a given named entity pair that has an implicit relation. The last step is to identify synonyms of the relations that are recognized or estimated in the above steps. In this paper, we focus on the first step. The task is selecting a phrase from the text that contains a relation expression linking a given entity pair and outputting the expression as one showing the relationship between the pair.

In our preliminary experiment, it was found that using only structural features of a text, such as syntactic or contextual features, is not good enough for a number of examples. For instance, the two Japanese sentences shown in Figure 1 have the same syntactic structure but (a) contains a relation expression and (b) does not. We therefore assume there are clues for recognizing relation expressions other than conventional syntactic and contextual information. In this paper, we propose a supervised learning method that includes two novel features of relational words as well as conventional syntactic and contextual features. The novel features of our method are:

Inherent Feature: Some words are able to express the relations between named entities and some are not. Thus, it would be useful to know the words that inherently express these relations.

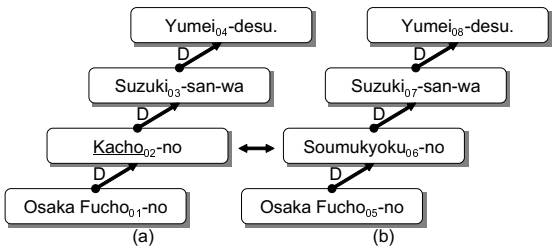
Context-dependent Feature: There are a number of typical relationships that change as time passes, such as "dating" ⇒ "engagement" ⇒ "marriage" between persons. Furthermore, present relations are influenced by the past relations of a given named entity pair. Thus, it would be useful to know the past relations between a given pair and how the relations change as time passes.

In the rest of this paper, Section 2 references related work, Section 3 outlines our method's main features and related topics, Section 4 describes our experiments and experimental results, and Section 5 briefly summarizes key points and future work to be done.

2 Related Work

The "Message Understanding Conference" and "Automatic Content Extraction" programs have promoted relational extraction. The task was studied so as to extract predefined semantic relations of entity pairs in a text. Examples include the supervised learning method cited in (Kambhatla, 2004; Culotta and Sorensen, 2004; Zelenko et al., 2003) and the bootstrapping method cited in (Pantel and Pennacchiotti, 2006; Agichtein and Gravano, 2000). Recently, open information extraction (Open IE), a novel domain-independent extraction paradigm, has been suggested (Banko and Etzioni, 2008; Hasegawa et al., 2004). The task is to detect semantically related named entity pairs and to recognize the relation between them without using predefined relations.

Our work is a kind of open IE, but our approach differs from that of previous studies. Banko (2008) proposed a supervised learning method using conditional random fields to recognize the relation expressions from words located between a given pair. Hasegawa (2004) also proposed a rule-based method that selects all words located between a given pair as a relation expression if a given named entities appear within ten words. The point of these work is that they selected relation expressions only from the words located between



(a) Mr.Suzuki$_{03}$, a manager$_{02}$ of Osaka Prefectural Government$_{01}$, is famous$_{04}$.
(b) Mr.Suzuki$_{07}$, administration office$_{06}$ in Osaka Prefectural Government$_{05}$, is famous$_{08}$.

Figure 1: Same syntactic examples

given entities in the text, because as far as English texts are concerned, 86% of the relation expressions of named entity pairs appear between the pair (Banko and Etzioni, 2008). However, our target is Japanese texts, in which only 26% of entity pair relation expressions appear between the pair. Thus, it is hard to incorporate previous approaches into a Japanese text.

To solve the problem, our task was to select a phrase from the entire text that would include a relation expression for connecting a given pair.

3 Recognizing Relation Expressions between Named Entities

To recognize the relation expression for a given pair, we need to select a phrase that includes an expression that shows the relation between a given entity pair from among all noun and verb phrases in a text. Actually, there are two types of candidate phrases in this case. One is from a sentence that contains a given pair (intra-sentential), and the other is from a sentence that does not (inter-sentential). For example, the triple [Miyaji$_{21}$, Ishii$_{22}$, taiketsu$_{12}$] extracted from the following text is inter-sentential.

(S-1) Chumokoku$_{11}$-no taiketsu$_{12}$-ga mamonaku$_{13}$ hajimaru$_{14}$.
(The showcase$_{11}$ match$_{12}$ will start$_{14}$ soon$_{13}$.)

(S-2) Ano Miyaji$_{21}$-to Ishii$_{22}$-toiu kanemochi$_{23}$-niyoru yume$_{24}$-no kikaku$_{25}$.
(The dream$_{24}$ event$_{25}$ between the rich mens$_{23}$, Miyaji$_{21}$ and Ishii$_{22}$.)

According to our annotated data shown in Table 2, 53% of the semantically-related named entity pairs are intra-sentential and 12% are inter-sentential. Thus, we first select a phrase from those in a sentence that contains a given pair, and if no phrase is selected, select one from the rest of the sentences in a text.

We propose a supervised learning method that uses two novel features of relational words as well as conventional syntactic and contextual features. These features are organized as a tree structure and are fed into a boosting-based classification algorithm (Kudo and Matsumoto, 2004). The highest-scoring phrase is then selected if the score exceeds a given threshold. Finally, the head of the selected phrase is output as the relation expression of a given entity pair.

The method consists of four parts: preprocessing (POS tagging and parsing), feature extraction, classification, and selection. In this section, we describe the idea behind using our two novel features and how they are implemented to recognize the relation expressions of given pairs. Before that, we will describe our proposed method's conventional features.

3.1 Conventional Features

Syntactic feature

To recognize the intra-sentential relation expressions for a given pair, we assume that there is a discriminative syntactic structure that consists of given entities and their relation expression. For example, there is a structure for which the common parent phrase of the given pair, X = "Hatoyama Yukio$_{32}$" and Y = "Hatoyama Kunio$_{33}$", has the relation expression, R = "ani$_{34}$" in the Japanese sentence S-3. Figure 2 shows the dependency tree of sentence S-3.

(S-3) Minshuto$_{31}$-no Hatoyama Yukio$_{32}$-wa Hatoyama Kunio$_{33}$-no ani$_{34}$-desu.
(Yukio Hatoyama$_{32}$, the Democratic Party$_{31}$, is Kunio Hatoyama$_{33}$'s brother$_{34}$.)

To use a discriminative structure for each candidate, we make a minimum tree that consists of given entities and the candidate where each phrase is represented by a case marker "CM", a dependency type "DT", an entity class, and the string and POS of the candidate (See Figure 3).

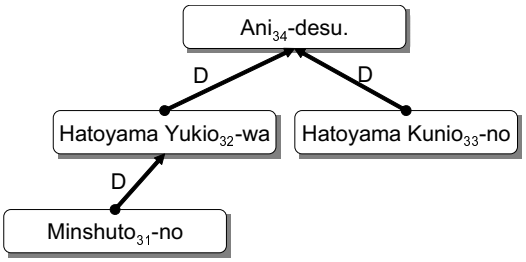


Figure 2: Dependency tree of sentence S-3

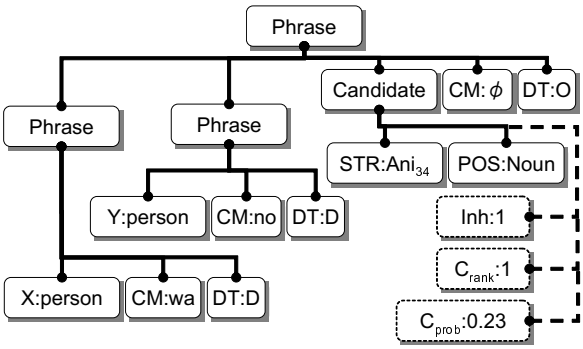

Figure 3: Intra-sentential feature tree

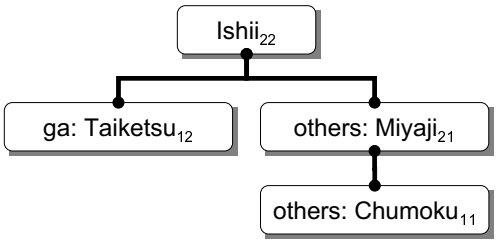

Figure 4: Salient referent list tree

Contextual Feature

To recognize the inter-sentential relation expressions for a given pair, we assume that there is a discriminative contextual structure that consists of given entities and their relation expression. Here, we use a Salient Referent List (SRL) to obtain contextual structure. The SRL is an empirical sorting rule proposed to identify the antecedent of (zero) pronouns (Nariyama, 2002), and Hirano (2007) proposed a way of applying SRL to relation detection. In this work, we use this way to apply SRL to recognize inter-sentential relation expressions.

We applied SRL to each candidate as follows. First, from among given entities and the candidate, we choose the one appearing last in the text as the root of the tree. We then append noun phrases, from the chosen one to the beginning of the text, to the tree depending on case markers, "wa" (topicalised subject), "ga" (subject), "ni" (indirect object),"wo" (object), and "others", with the following rules. If there are nodes of the same case marker already in the tree, the noun phrase is appended as a child of the leaf node of them. In other cases, the noun phrase is appended as a child of the root node. For example, we get the SRL tree shown in Figure 4 with the given entity pair, X = "Miyaji$_{21}$" and Y = "Ishii$_{22}$", and the candidate, "taiketsu$_{12}$", with the text (S-1, S-2).

To use a discriminative SRL structure, we make a minimum tree that consists of given entities and the candidate where each phrase is represented by an entity class, and the string and POS of the candidate (See Figure 5). In this way, there is a problem when the candidate is a verb phrase, because only noun phrases are appended to the SRL tree. If the candidate is a verb phrase, we cannot make a minimum tree that consists of given entities and the candidate.

To solve this problem, a candidate verb phrase is appended to the feature tree using a syntactic structure. In a dependency tree, almost all verb phrases have some parent or child noun phrases that are in the SRL tree. Thus, candidate verb phrases are appended as offspring of these noun phrases represented syntactically as "parent" or "child". For example, when given the entity pair, X = "Miyaji$_{21}$" and Y = "Ishii$_{22}$", and the candidate, "hajimaru$_{14}$" from the text (S-1, S-2), a feature tree cannot be made because the candidate is not in an SRL tree. By extending the way the syntactic structure is used, "hajimaru$_{14}$" has a child node "taiketsu$_{12}$", which is in an SRL tree, and this makes it possible to make the feature tree shown in Figure 6.

3.2 Proposed Features

To recognize intra-sentential or inter-sentential relation expressions for given pairs, we assume there are clues other than syntactic and contextual information. Thus, we propose inherent and

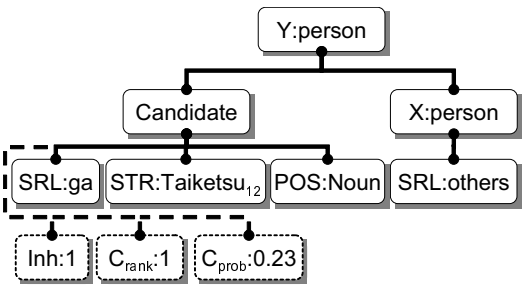

Figure 5: Inter-sentential feature tree

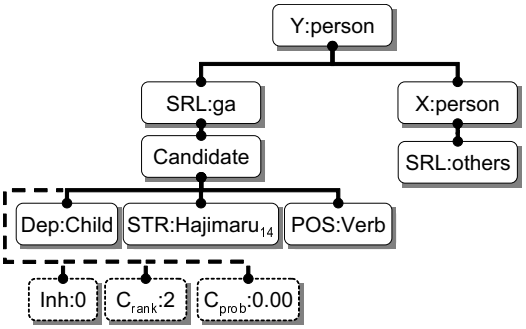

Figure 6: Extended inter-sentential feature tree

context-dependent features of relational words.

Inherent Feature of Relational words

Some words are able to express the relations between named entities and some are not. For example, the word "mother" can express a relation, but the word "car" cannot. If there were a list of words that could express relations between named entities, it would be useful to recognize the relation expression of a given pair. As far as we know, however, no such list exists in Japanese. Thus, we estimate which words are able to express relations between entities. Here, we assume that almost all verbs are able to express relations, and accordingly we focus on nouns.

When the relation expression, R, of an entity pair, X and Y, is a noun, it is possible to say "Y is R of X" or "Y is X's R". Here, we can say noun R takes an argument X. In linguistics, this kind of noun is called a relational noun. Grammatically speaking, a relational noun is a simple noun, but because its meaning describes a "relation" rather than a "thing", it is used to describe relations just as prepositions do. To estimate which nouns are able to express the relations between named entities, we use the characteristics of relational nouns. In linguistics, many researchers describe the relationship between possessives and relational nouns (Chris, 2008). Thus, we use the knowledge that in the patterns "B of A" or "A's B", if word B is a relational noun, the corresponding word A belongs to a certain semantic category. In contrast, if word B is not a relational noun, the corresponding word A belongs to many semantic categories (Tanaka et al., 1999). Figure 7 shows scattering of the semantic categories of "mother" and "car"

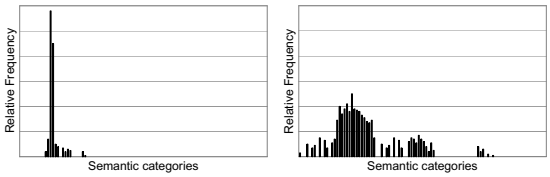

Figure 7: Scattering of semantic category of "mother" (left) and "car" (right).

acquired by the following way.

First, we acquired A and B using the patterns "A no B"[1] from a large Japanese corpus, then mapped words A into semantic categories C= $\{$ $c_1, c_2, \cdots, c_m$ $\}$ using a Japanese lexicon (Ikehara et al., 1999). Next, for each word B, we calculated a scattering score $\mathcal{H}c(B)$ using the semantic category of corresponding words A. Finally, we estimated whether a word is a relational noun by using k-NN estimation with positive and negative examples. As estimated results, "Inh:1" shows that it is a relational noun and "Inh:0" shows that it is not. In both cases, the result is appended to the feature tree as a child of the candidate node (See Figure 3, 5, or 6).

$$\mathcal{H}c(B) = -\sum_{c \in C} P(c|B) log_m P(c|B)$$

$$P(c|B) = \frac{freq(c, B)}{freq(B)}$$

In our experiments, we acquired 55,412,811 pairs of A and B from 1,698,798 newspaper articles and 10,499,468 weblog texts. As training data, we used the words of relation expressions as positive examples and other words as negative examples.

Context-dependent Feature of Relational words

There are a number of typical relationships that change as time passes, such as "dating" ⇒ "engagement" ⇒ 'marriage" between persons. Furthermore, present relations are affected by the past relations of a given named entity pair. For instance, if the past relations of a given pair are "dating" and "engagement" and one of the candidates is "marriage", "marriage" would be selected as the relation expression of the given pair. Therefore, if

[1] "B of A" or "A's B" in English.

Table 1: Examples of calculated relation trigger model between entity classes defined by IREX

we know the past relations of the given pair and the typical relational change that occurs as time passes, it would be useful to recognize the relation expression of a given pair.

In this paper, we represent typical relational changes that occur as time passes by a simple relation trigger model $P_T(r_n|r_m)$. Note that r_m is a past relation and r_n is a relation affected by r_m. This model disregards the span between r_n and r_m. To make the trigger model, we automatically extract triples [X, Y, R] from newspaper articles and weblog texts, which have time stamps of the document creation. Using these triples with time stamps for each entity pair, we sort relations in order of time and count pairs of present and previous relations. For example, if we extract "dating" occurring for an entity pair on January 10, 1998, "engagement" occurring on February 15, 2001, and "marriage" occurring on December 24, 2001, the pairs ⟨dating, engagement⟩, ⟨dating, marriage⟩, and ⟨engagement, marriage⟩ are counted. The counted score is then summed up by the pair of entity class and the trigger model is calculated by the following formula.

$$P_T(r_n|r_m) = \frac{Count(r_m, r_n)}{\sum_{r_n} Count(r_m, r_n)}$$

For the evaluation, we extracted triples by named entity recognition (Suzuki et al., 2006), relation detection (Hirano et al., 2007), and the proposed method using the inherent features of relational words described in Section 3.2. A total of 10,463,232 triples were extracted from 8,320,042 newspaper articles and weblog texts with time stamps made between January 1, 1991 and June 30, 2006. As examples of the calculated relation trigger model, Table 1 shows the top three probability relations r_n of several relations r_m between Japanese standard named entity classes defined in the IREX workshop[2]. For instance, the relation "fellow" has the highest probability of being changed from the relation "researcher" between person and organization as time passes.

[2]http://nlp.cs.nyu.edu/irex/

To obtain the past relations of a given pair in the input text, we again used the triples with time stamps extracted as above. The only relations we use as past relations, $R_m = \{r_{m_1}, r_{m_2}, \cdots, r_{m_k}\}$, are those of a given pair whose time stamps are older than the input text. Finally, we calculated probabilities with the following formula using the past relations R_m and the trigger model $P_T(r_n|r_m)$.

$$P_T(r_n|R_m) = max\{P_T(r_n|r_{m_1}), P_T(r_n|r_{m_2}), \cdots, P_T(r_n|r_{m_k})\}$$

Using this calculated probability, we ranked candidates and appended the rank "C$_{rank}$" and the probability score "C$_{prob}$" to the feature tree as a child of the candidate node (See Figure 3, 5, or 6). For example, if the past relations R_m were "dating" and "engagement" and candidates were "marriage", "meeting', "eating", or "drinking", the candidates probabilities were calculated and ranked as "marriage" (C$_{prob}$:0.15, C$_{rank}$:1), "meeting" (C$_{prob}$:0.08, C$_{rank}$:2), etc.

3.3 Classification Algorithms

Several structure-based learning algorithms have been proposed so far (Collins and Duffy, 2002; Suzuki et al., 2003; Kudo and Matsumoto, 2004). The experiments tested Kudo and Matsumoto's boosting-based algorithm using sub-trees as features, which is implemented as a BACT system.

Given a set of training examples each of which is represented as a tree labeling whether the candidate is the relation expression of a given pair or not, the BACT system learns that a set of rules is effective in classifying. Then, given a test instance, the BACT system classifies using a set of learned rules.

4 Experiments

We conducted experiments using texts from Japanese newspaper articles and weblog texts to test the proposed method for both intra- and inter-sentential tasks. In the experiments, we compared the following methods:

Conventional Features: trained by conventional syntactic features for intra-sentential tasks as described in Section 3.1, and contextual features for inter-sentential tasks as described in Section 3.1.

+Inherent Features: trained by conventional features plus inherent features of relational words described in Section 3.2.

++Context-dependent Features$_{\mathrm{TM}}$: trained by conventional and inherent features plus context-dependent features of relational words with the **trigger model** described in Section 3.2.

++Context-dependent Features$_{\mathrm{CM}}$: trained by conventional and inherent features plus context-dependent features of relational words with a **cache model**. We evaluated this method to compare it with Context-dependent Features$_{\mathrm{TM}}$ to show the effectiveness of the proposed trigger model. The cache model is a simple way to use past relations in which the probability $P_C(r_{cand})$ calculated by the following formula and the rank based on the probability is appended to every candidate feature tree.

$$P_C(r_{cand}) = \frac{|r_{cand} \text{ in past relations}|}{|\text{past relations}|}$$

Relation Types		#
Explicit	Intra-sentential	9,178
	Inter-sentential	2,058
Implicit		5,992
Total		17,228

Table 2: Details of the annotated data

4.1 Settings

We used 6,200 texts from Japanese newspapers and weblogs dated from January 1, 2004 to June 30, 2006, manually annotating the semantic relations between named entities for experiment purposes. There were 17,228 semantically-related entity pairs as shown in Table 2. In an intra-sentential experiment, 17,228 entity pairs were given, but only 9,178 of them had relation expressions. In contrast, in an inter-sentential experiment, 8,050 entity pairs excepted intra-sentential

	$Precision$	$Recall$	F
Conventional Features	63.5 % (3,436/5,411)	37.4 % (3,436/9,178)	0.471
+Inherent Features	67.2 % (4,036/6,001)	43.9 % (4,036/9,178)	0.531
++Context-dependent Features$_{\mathbf{TM}}$	70.7 % (4,460/6,312)	48.6 % (4,460/9,178)	**0.576**
++Context-dependent Features$_{\mathbf{CM}}$	67.5 % (4,042/5,987)	44.0 % (4,042/9,178)	0.533

Table 3: Experimental results of intra-sentential

	$Precision$	$Recall$	F
Conventional Features	70.1 % (579/825)	28.1 % (579/2,058)	0.401
+Inherent Features	77.1 % (719/932)	34.9 % (719/2,058)	0.480
++Context-dependent Features$_{\mathbf{TM}}$	75.2 % (794/1,055)	38.5 % (794/2,058)	**0.510**
++Context-dependent Features$_{\mathbf{CM}}$	74.3 % (732/985)	35.5 % (732/2,058)	0.481

Table 4: Experimental result of inter-sentential

were given, but only 2,058 of them had relation expressions.

We conducted five-fold cross-validation over 17,228 entity pairs so that sets of pairs from a single text were not divided into the training and test sets. In the experiments, all features were automatically acquired using a Japanese POS tagger (Fuchi and Takagi, 1998) and dependency parser (Imamura et al., 2007).

4.2 Results

Tables 3 and 4 show the performance of several methods for intra-sentential and inter-sentential. $Precision$ is defined as the percentage of correct relation expressions out of recognized ones. $Recall$ is the percentage of correct relation expressions from among the manually annotated ones. The F measure is the harmonic mean of precision and recall.

A comparison with the Conventional Features and Inherent Features method for intra-/inter-sentential tasks indicates that the proposed method using inherent features of relational words improved intra-sentential tasks F by 0.06 points and inter-sentential tasks F by 0.08 points. Using a statistical test (McNemar Test) demonstrably showed the proposed method's effectiveness.

A comparison with the Inherent Features and Context-dependent Features$_{\mathbf{TM}}$ method showed that the proposed method using context-dependent features of relational words improved intra-/inter-sentential task performance by 0.045 and 0.03 points, respectively. McNemar test results also showed the method's effectiveness.

To further compare the usage of context-dependent features, trigger models, and cache models, we also used Context-dependent Features$_{\mathbf{CM}}$ method for comparison. Tables 3 and 4 show that our proposed trigger model performed better than the cache model, and McNemar test results showed that there was a significant difference between the models. The reason the trigger model performed better than the cache model is that the trigger model correctly recognized the relation expressions that did not appear in the past relations of a given pair. Thus, we can conclude that using typical relationships that change as time passes helps to recognize relation expressions between named entities.

5 Conclusion

We proposed a supervised learning method that employs inherent and context-dependent features of relational words and uses conventional syntactic or contextual features to improve both intra- and inter-sentential relation expression recognition. Our experiments demonstrated that the method improves the F measure and thus helps to recognize relation expressions between named entities.

In future work, we plan to estimate implicit relations between named entities and to identify relational synonyms.

Abstract

Previous works tend to compute the similarity between two sentences based on the comparison of their nearest meanings. However, the nearest meanings do not always represent their actual meanings. This paper presents a method which computes the similarity between two sentences based on a comparison of their actual meanings. This is achieved by transforming an existing most-outstanding corpus-based measure into a knowledge-based measure, which is then integrated with word sense disambiguation. The experimental results on a standard data set show that the proposed method outperforms the baseline and the improvement achieved is statistically significant at 0.025 levels.

1 Introduction

Although measuring sentence similarity is a complicated task, it plays an important role in natural language processing applications. In text categorization (Yang and Wen, 2007), documents are retrieved based on similar or related features. In text summarization (Zhou et al., 2006) and machine translation (Kauchak and Barzilay, 2006), summaries comparison based on sentence similarity has been applied for automatic evaluation. In text coherence (Lapata and Barzilay, 2005), different sentences are linked together based on the sequence of similar or related words.

Two main issues are investigated in this paper: 1) the performance between corpus-based measure and knowledge-based measure, and 2) the influence of word sense disambiguation (WSD) on measuring sentence similarity. WSD is the task of determining the sense of a polysemous word within a specific context (Wang et al., 2006). Corpus-based methods typically compute sentence similarity based on the frequency of a word's occurrence or the co-occurrence between collocated words. Although these methods benefit from the statistical information derived from the corpus, this statistical information is closer to syntactic representation than to semantic representation. In comparison, knowledge-based methods compute the similarity between two sentences based on the semantic information collected from knowledge bases. However, this semantic information is applied in a way that, for any two sentences, the comparison of their nearest meanings is taken into consideration instead of the comparison of their actual meanings. More importantly, the nearest meaning does not always represent the actual meaning. In this paper, a solution is proposed that seeks to address these two issues. Firstly, the most outstanding existing corpus-based sentence similarity measure is transformed into a knowledge-based measure. Then, its underlying concept, which is the comparison of the nearest meanings, is replaced by another underlying concept, the comparison of the actual meanings.

The rest of this paper is organized into five sections. Section 2 presents an overview of the related works. Section 3 details the problem of the existing method and the improvement of the proposed method. Section 4 describes the experimental design. In Section 5, the experimental results are discussed. Finally, the implications and contributions are addressed in Section 6.

2 Related Work

In general, related works can be categorized into corpus-based, knowledge-based and hybrid-based methods. Islam and Inkpen (2008) proposed a corpus-based sentence similarity measure as a function of string similarity, word similarity and common word order similarity (CWO). They claimed that a corpus-based measure has the advantage of large coverage when compared to a knowledge-based measure. However, the judgment of similarity is situational and time dependent (Feng et al., 2008). This suggests that the statistical information collected from the past corpus may not be relevant to sentences present in the current corpus. Apart from that, the role of string similarity is to identify any misspelled word. A malfunction may occur whenever string similarity deals with any error-free sentences because the purpose for its existence is no longer valid.

For knowledge-based methods, Li et al. (2009) adopted an existing word similarity measure to deal with the similarities of verbs and nouns while the similarities of adjectives and adverbs were measured only based on simple word overlaps. However, Achananuparp et al. (2008) previously showed that the word overlap-based method performed badly in measuring text similarity. Liu et al. (2007) integrated the Dynamic Time Warping (DTW) technique into the similarity measure to identify the distance between words. The main drawback of DTW is that the computational cost and time will increase proportionately with the sentence's length. Wee and Hassan (2008) proposed a method that takes into account the directionality of similarity in which the similarity of any two words is treated as asymmetric. The asymmetric issue between a pair of words was resolved by considering both the similarity of the first word to the second word, and vice versa.

Corley and Mihalcea (2005) proposed a hybrid method by combining six existing knowledge-based methods. Mihalcea et al. (2006) further combined those six knowledge-based methods with two corpus-based methods and claimed that they usually achieved better performance in terms of precision and recall respectively. However, those methods were only combined by using simple average calculation.

Perhaps the most closely related work is a recently proposed query extension technique. Perez-Agüera and Zaragoza (2008) made use of WSD information to map the original query words and the expansion words to WordNet senses. However, without the presence of or considering the surrounding words, the meaning of the expansion words alone tend to be represented by their most general meanings instead of the disambiguated meanings, which results in the possibility of WSD information not being useful for word expansions. In contrast to their work, which is more suitable to be applied on word-to-word similarity task, the method proposed in this paper is more suitable for application on sentence-to-sentence similarity tasks.

Overall, the above-mentioned related works compute similarity based either on statistical information or on a comparison of the nearest meanings in terms of words. None of them compute sentence similarity based on the comparison of actual meanings. Our proposed method, which is a solution to this issue, will be explained in detail in the next section.

3 Sentence Similarity

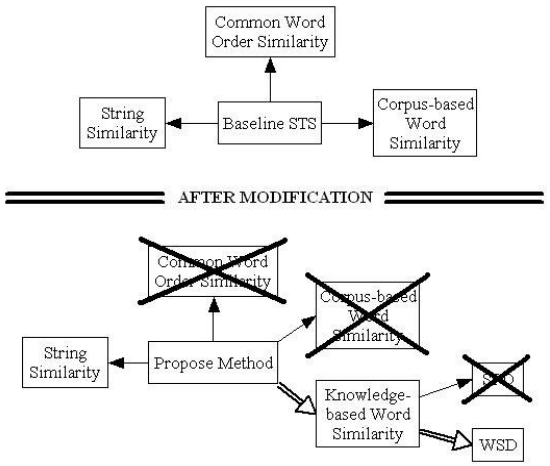

Figure 1. The proposed method

Our proposed method shown in Figure 1, is the outcome of some modifications on an existing method, which is also the most outstanding method, the Semantic Text Similarity (STS) model (Islam and Inkpen, 2008). First of all, CWO is removed from STS as the previous works (Islam and Inkpen, 2007; Islam and Inkpen, 2008) have shown that the presence of CWO has no influence on the outcome. Then,

the corpus-based word similarity function of STS is replaced by an existing knowledge-based word similarity measure called YP (Yang and Powers, 2005). Finally, the underlying concept of YP is modified by the integration of WSD and is based on the assumption that any disambiguated sense of a word represents its actual meaning. Thus, the proposed method is also called WSD-STS.

3.1 String similarity measure

The string similarity between two words is measured by using the following equations:

$$v_1 = NLCS(w_i^a, w_j^b) = \frac{l(LCS(w_i^a, w_j^b))^2}{l(w_i) \times l(w_j)} \quad (1)$$

$$v_2 = NMCLCS_1(w_i^a, w_j^b) = \frac{l(MCLCS_1(w_i^a, w_j^b))^2}{l(w_i) \times l(w_j)} \quad (2)$$

$$v_3 = NMCLCS_n(w_i^a, w_j^b) = \frac{l(MCLCS_n(w_i^a, w_j^b))^2}{l(w_i) \times l(w_j)} \quad (3)$$

$$Sim_{string}(X,Y) = 0.33v_1 + 0.33v_2 + 0.33v_3 \quad (4)$$

where $l(x)$ represents the length of x; a and b represent the lengths of sentences X and Y respectively after removing stop words; w_i represents the i-th word in sequence a; w_j represents the j-th word in sequence b; and $Sim_{string}(X,Y)$ represents the overall string similarity. The underlying concept of string similarity is based on character matching. *NLCS* represents the normalized version of the traditional longest common subsequence (LCS) technique in which the lengths of the two words are taken into consideration. $MCLCS_1$ represents the modified version of the traditional LCS in which the string matching must start from the first character while $MCLCS_n$ represents the modified version of the traditional LCS in which the string matching may start from any character. $NMCLCS_1$ and $NMCLCS_n$ represent the normalized versions of $MCLCS_1$ and $MCLCS_n$ respectively. More detailed information regarding string similarity measure can be found in the original paper (Islam and Inkpen, 2008).

3.2 Adopted word similarity measure

Yang and Powers (2005) proposed YP based on the assumptions that every single path in the hierarchical structure of WordNet 1) is identical; and 2) represents the shortest distance between any two connected words. The similarity between two words in sequence a and sequence b can be represented by the following equation:

$$Sim_{word}(w_i^a, w_j^b) = \begin{cases} \alpha_t \prod_{i=1}^{l-1} \beta_{t_i}, & l < \gamma \\ 0, & l \geq \gamma \end{cases} \quad (5)$$

where $0 \leq Sim_{word}(w_i^a, w_j^b) \leq 1$; d is the depth of LCS; l is the length of path between disambiguated w_i^a and w_j^b; t represents the type of path (hypernyms/hyponym, synonym or holonym/meronym) which connects them; α_t represents their path type factor; β_t represents their path distance factor; and γ represents an arbitrary threshold on the distance introduced for efficiency, representing human cognitive limitations. The values of α_t, β_t and γ have already been empirically tuned as 0.9, 0.85 and 12 respectively. More detailed information regarding YP can be found in the original paper (Yang and Powers, 2005).

In order to adapt a different underlying concept, which is the comparison of actual meanings, l has to be redefined as the path distance between disambiguated words, w_i^a and w_j^b. Since YP only differs from the modified version of YP (MYP) in terms of the definition of l, MYP can also be represented by equation (5).

3.3 The proposed measure

The gap

Generally, all the related works in Section 2 can be abstracted as a function of word similarity. This reflects the importance of a word similarity measure in measuring sentence similarity. However, measuring sentence similarity is always a more complicated task than measuring word similarity. The reason is that while a word similarity measure only involves a single pair of words, a sentence similarity measure has to deal with multiple pairs of words. In addition, due to the presence of the surrounding words in a sentence, the possible meaning of a word is always being restricted (Kolte and Bhirud, 2008). Thus, without some modifications, the traditional word similarity measures, which are based on the concept of a comparison of the nearest meanings, are inapplicable in the context of sentence similarity measures.

The importance of WSD in reducing the gap

Before performing the comparison of actual meanings, WSD has to be integrated so that the most suitable sense can be assigned to any polysemous word. The importance of WSD can be investigated by using a simple example. Consider a pair of sentences, collected from WordNet 2.1, which use two words, "*dog*" and "*cat*":

X: The dog barked all night.

Y: What a cat she is!

Based on the definition in WordNet 2.1, the word "*dog*" in *X* is annotated as the first sense which means "*a member of the genus Canis* (*probably descended from the common wolf*) *that has been domesticated by man since prehistoric times*". Meanwhile, the word "*cat*" in *Y* is annotated as the third sense with the definition of "*a spiteful woman's gossip*". The path distance between "*cat*" and "*dog*" based on their actual senses is equal to 7. However, their shortest path distance (SPD), which is based on their nearest senses, is equal to 4. SPD is the least number of edges connecting two words in the hierarchical structure of WordNet. In other words, "*cat*" and "*dog*" in *X* and *Y* respectively, are not as similar as the one measured by using SPD. The presence of the additional path distances is significant as it is almost double the actual path distance between "*cat*" and "*dog*".

WSD-STS

The adopted sentence similarity measure, STS, can be represented by the following equations:

$$Sim_{semantic}(X,Y) = \frac{(\delta + \sum_{i=1}^{c} \tau_i) \times (a+b)}{2ab} \quad (6)$$

$$SIM(X,Y) = \frac{Sim_{smeantic}(X,Y) + Sim_{string}(X,Y)}{2} \quad (7)$$

where for equation (6): δ represents the number of overlapped words between the words in sequence *a* and sequence *b*; *c* represents the number of semantically matched words between the words in sequence *a* and sequence *b*, in which *c* = *a* if *a* < *b* or *c* = *b* if *b* < *a*, τ_i represents the highest matching similarity score of *i*-th word in the shorter sequence with respect to one of the words in the longer sequence; and $\Sigma\tau$ represents the sum of the highest matching similarity score between the words in sequence *a* and sequence *b*.

For STS, the similarity between two words is measured by using a corpus-based measure. For WSD-STS, this corpus-based measure is replaced by MYP. Finally, the overall sentence similarity is represented by equation (7).

4 Experimental Design

4.1 Data set

Li et al., (2006) constructed a data set which consists of 65 pairs of human-rated sentences by applying the similar experimental design for creating the standard data set for the word similarity task (Rubenstein and Goodenough, 1965). These 65 sentence pairs were the definitions collected from the Collin Cobuild Dictionary. Out of these, 30 sentence pairs with rated similarity scores that ranged from 0.01 to 0.96 were selected as test data set. The corresponding 30 word pairs for these 30 sentence pairs are shown in the second column of Table 1. A further set of 66 sentence pairs is still under development and it will be combined with the existing data set in the future (O'Shea et al., 2008b).

4.2 Procedure

Firstly, Stanford parser[1] is used to parse each sentence and to tag each word with a part of speech (POS). Secondly, Structural Semantic Interconnections[2] (SSI), which is an online WSD system, is used to disambiguate and to assign a sense for each word in the 30 sentences based on the assigned POS. SSI is applied based on the assumption that it is able to perform WSD correctly. The main reason for choosing SSI to perform WSD is its promising results reported in a study by Navigli and Verladi (2006). Thirdly, all the stop words which exist in these 30 pairs of sentences are removed. It is important to note that the 100 most frequent words collected from British National Corpus (BNC) were applied as the stop words list on the baseline, STS. However, due to the limited accessibility to BNC, a different stop words list[3], which is available online, is applied in this paper.

Table 1. Data Set Results

Finally, the remaining content words are lemmatized by using Natural Language Toolkit[4] (NLTK). Nevertheless, those words which can be found in WordNet and which have different definitions from their lemmatized form will be excluded from lemmatization. For instance,

Cooking[NN] can be a great art.

The word in the bracket represents the tagged POS for its corresponding word. Since based on the definitions provided by WordNet, "*cooking*", which is tagged as a noun, has a different meaning from its lemmatized form "*cook*", which is also tagged as a noun. Therefore, "*cooking*" is excluded from lemmatization.

4.3 Experimental conditions

Sentence similarity is measured under the following three conditions:

- **OLP-STS**: A modified version of the baseline, STS (Islam and Inkpen, 2008), in which it only relies on the presence of overlapped words. This means that the component $\sum_{i=1}^{c}\tau_i$, which represents the word similarity, is removed from equation (6).
- **SPD-STS**: The corpus-based word similarity measure of the baseline, STS, which is represented by $\sum_{i=1}^{c}\tau_i$ in equation (6), is replaced by a knowledge-based word similarity measure, YP.
- **WSD-STS**: A modified version of SPD-STS in which the knowledge-based measure, YP, is replaced by MYP.

As mentioned in Section 4.2, different stop words lists were applied between the baseline and the proposed methods under different ex-

[4] http://www.nltk.org/

perimental conditions in this paper. Since this issue may be questioned due to the unfair comparison, the performance of WSD-STS is evaluated on top of a number of different stop words lists which are available online in order to investigate any influence which may be caused by stop words list.

5 Results and Discussion

Table 1 presents the similarity scores obtained from the mean of human ratings, the benchmarks, and different experimental conditions of the proposed methods. Figure 2 presents the corresponding Pearson correlation coefficients of various measures as listed in Table 1.

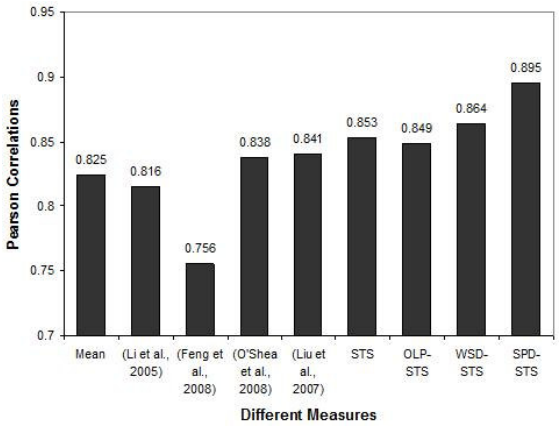

Figure 2. Pearson Correlation Coefficient

Figure 2 shows that STS appears to be the most outstanding measure among the existing works with a correlation coefficient of 0.853. However, Figure 2 also shows that both the proposed methods in this paper, WSD-STS and SPD-STS, outperform STS. This result indicates that knowledge-based method tends to perform better than a corpus-based method. The reason is that a knowledge base is much closer to human representation of knowledge (WordNet is the knowledge base applied in this paper) than a corpus. A corpus only reflects the usage of languages and words while WordNet is a model of human knowledge constructed by many expert lexicographers (Li et al., 2006). In other words, a corpus is more likely to provide unprocessed raw data while a knowledge base tends to provide ready-to-use information.

The results of the performance of the two proposed methods are as expected. SPD-STS achieved a bigger but statistically insignificant improvement while WSD-STS achieved a smaller but statistically significant improvement at 0.01 levels. The significance of a correlation is calculated by using an online calculator, *VassarStats*[5]. The reason for the variance in the outcomes between SPD-STS and WSD-STS is obvious; it is the difference in terms of their underlying concepts. In other words, sentence similarity computation, which is based on a comparison of the nearest meanings, results in insignificant improvement while sentence similarity computation, which is based on a comparison of actual meanings, achieves statistically significant improvement. These explanations indicate that WSD is essential in confirming the validity of the task of measuring sentence similarity.

Figure 2 also reveals that a relatively low correlation is achieved by OLP-STS. This is not at all surprising since Achananuparp et al. (2008) has already demonstrated that the overlapped word-based method tends to perform badly in measuring sentence similarity. However, it is interesting to find that the difference in performance between STS and OLP-STS is very small. This indirectly suggests that the presence of the string similarity measure and the corpus-based word similarity measure has only a slight improvement on the performance of OLP-STS.

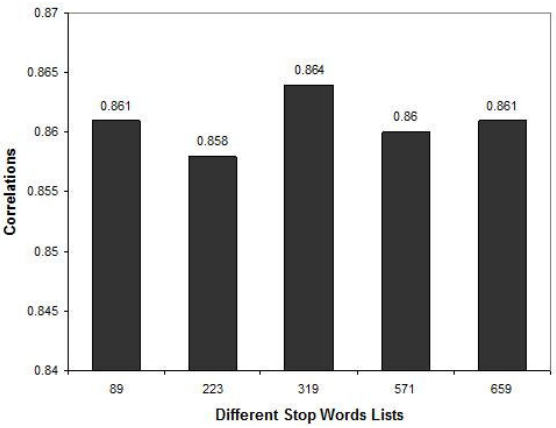

Figure 3. The performance of the WSD-SPD versus different stop words lists

Next, in order to address the issue of unfair comparison due to the usage of different stop words lists, the performance of WSD-SPD has been evaluated on top of a number of different

[5] http://faculty.vassar.edu/lowry/rdiff.html?

stop words lists. A total of five stop words lists with different lengths (89[6], 223[7], 319, 571[8] and 659[9]) of stop words were applied. The performances of WSD-SPD with respect to these stop words lists are portrayed in Figure 3. They are found to be in a comparable condition. This result connotes that the influence caused by the usage of different stop words lists is small and can be ignored. Hence, the unfair comparison between our proposed method and the baseline should not be treated as an issue for the benchmarking purpose of this paper.

On the other hand, although an assumption is made that SSI performs WSD correctly, we noticed that not all the words were disambiguated confidently. The confident scores which were assigned to the disambiguated words by SSI range between 30% and 100%. These confident scores reflect the confidence of SSI in performing WSD. Thus, it is possible that some of those words which were assigned with low confident scores were disambiguated incorrectly. Consequently, the final sentence similarity score is likely to be affected negatively. In order to reduce the negative effect which may be caused by incorrect WSD, any words pair which is not confidently disambiguated is assigned the similarity score based on the concept of comparing the nearest meanings instead of comparing the actual meanings. In other words, WSD-STS and SPD-STS are combined and results in WSD-SPD. The performance of WSD-SPD across a range of confident scores is essential in revealing the impact of WSD and SPD on the task of measuring sentence similarity.

Figure 4 outlines the performance achieved by WSD-SPD across different confident scores assigned by SSI. The confident score of at least 0.7 is identified as the threshold in which SSI optimizes its performance. The performance of WSD-SPD is found to be statistically insignificant for those confident scores above the threshold. The explanation for this phenomenon can be found in Figure 5. Figure 5 illustrates the percentage of the composition between WSD and SPD in WSD-SPD. It is obvious that once the portion of WSD exceeds the portion of SPD, the performance of WSD-SPD is found to be statistically insignificant. This finding suggests that SPD, which reflects the application of the concept of nearest meaning comparison, is likely to decrease the validity of sentence similarity measurement while WSD, which reflects the application of the concept of actual meaning comparison, is essential in confirming the validity of sentence similarity measurement.

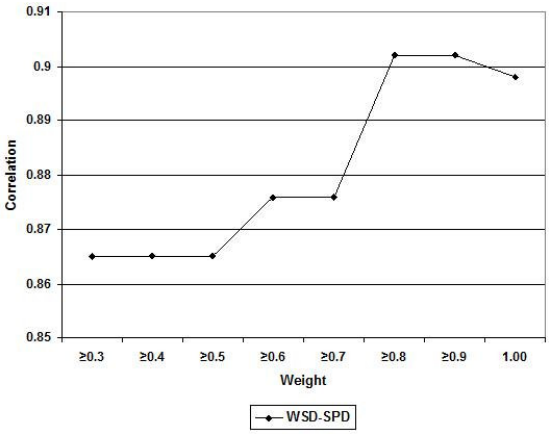

Figure 4. The performance of WSD-SPD versus confident scores

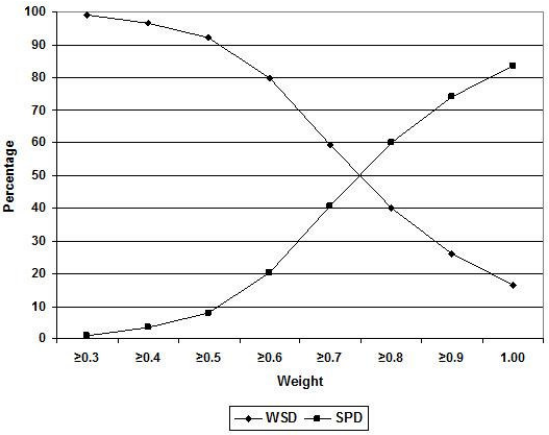

Figure 5. The percentage of WSD/SPD versus confident score

The trend of the performance of string similarity measure and word similarity measure with respect to different weight assignments is delineated in Figure 6. The lowest correlation of 0.856 is obtained when only the string similarity function is considered while the word similarity

[6] http://msdn.microsoft.com/en-us/library/bb164590.aspx
[7] http://snowball.tartarus.org/algorithms/english/stop.txt
[8] http://truereader.com/manuals/onix/stopwords2.html
[9] http://www.link-assistant.com/seo-stop-words.html

function is excluded. A better performance is achieved by taking the two measures into consideration where more weight is given to the measure of word similarity. This trend intimates that the string similarity measure offers a smaller contribution in measuring sentence similarity than word similarity measure. In contrast to a word similarity measure, a string similarity measure is purposely proposed to address the issue of misspelled words. Since the data set applied in this experiment does not contain any misspelled words, it is obvious that a string similarity measure performs badly. In addition, the underlying concept of string similarity is questionable. Does it make sense to determine the similarity of two words based on the matching between their characters or the matching of the sequence of characters? Consider four pairs of words: "*play*" versus "*pray*", "*plant*" versus "*plane*", "*plane*" versus "*plan*" and "*stationary*" versus "*stationery*". These word pairs are highly similar in terms of characters but they are semantically dissimilar or unrelated.

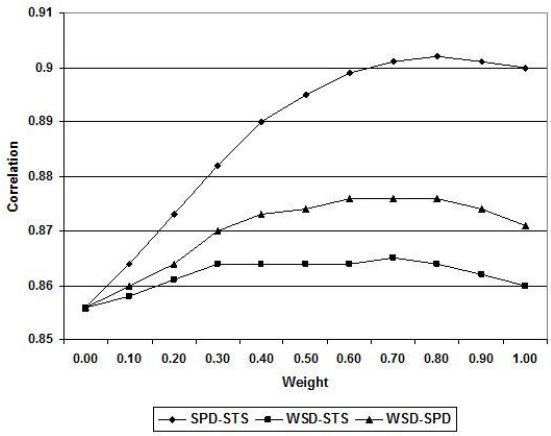

Figure 6. The performance of the different measures versus the weight between string similarity and word similarity

Figure 6 also depicts that the combination of word similarity measure (70%) and string similarity measure (30%) performs better than the measure which is solely based on word similarity function. It is obvious that the difference is caused by the presence of string similarity measure. The combination assigns similarity scores to all word pairs while the word similarity measure only assigns similarity scores to those word pairs which fulfill two requirements: 1) any two words which share an identical POS, and 2) any two words which must either be a pair of nouns or a pair of verbs. In fact, adjectives and adverbs do contribute to representing the meaning of a sentence although their contribution is relatively smaller than the contribution of nouns and verbs (Liu et al., 2007; Li et al., 2009). Therefore, by ignoring the presence of adjectives and adverbs, the performance will definitely be affected negatively.

6 Conclusion

This paper has presented a knowledge-based method which measures the similarity between two sentences based on their actual meaning comparison. The result shows that the proposed method, which is a knowledge-based measure, performs better than the baseline, which is a corpus-based measure. The improvement obtained is statistically significant at 0.025 levels. This result also shows that the validity of the output of measuring the similarity of two sentences can be improved by comparing their actual meanings instead of their nearest meanings. These are achieved by transforming the baseline into a knowledge-based method and then by integrating WSD into the adopted knowledge-based measure.

Although the proposed method significantly improves the quality of measuring sentence similarity, it has a limitation. The proposed method only measures the similarity between two words with an identical part of speech (POS) and these two words must either be a pair of nouns or a pair of verbs. By ignoring the importance of adjectives and adverbs, and the relationship between any two words with different POS, a slight decline is observed in the obtained result. In future research, these two issues will be addressed by taking into account the relatedness between two words instead of only considering their similarity.

Towards Automated Related Work Summarization

Abstract

We introduce the novel problem of automatic related work summarization. Given multiple articles (*e.g.*, conference/journal papers) as input, a related work summarization system creates a topic-biased summary of related work specific to the target paper. Our prototype **Re**lated **Wo**rk **S**ummarization system, **ReWoS**, takes in set of keywords arranged in a hierarchical fashion that describes a target paper's topics, to drive the creation of an extractive summary using two different strategies for locating appropriate sentences for general topics as well as detailed ones. Our initial results show an improvement over generic multi-document summarization baselines in a human evaluation.

1 Introduction

In many fields, a scholar needs to show an understanding of the context of his problem and relate his work to prior community knowledge. A related work section is often the vehicle for this purpose; it contextualizes the scholar's contributions and helps readers understand the critical aspects of the previous works that current work addresses. Creating such a summary requires the author to position his own work within the contextual research to showcase the advantages of his method.

We envision an NLP application that assists in creating a related work summary. We propose this *related work summarization* task as a challenge to the automatic summarization community. In its full form, it is a topic-biased, multi-document summarization problem that takes as input a target scientific document for which a related work section needs to be drafted. The output goal is to create a related work section that finds the relevant related works and contextually describes them in relationship to the scientific document at hand.

We dissect the full challenge as bringing together work of disparate interests; 1) in finding relevant documents; 2) in identifying the salient aspects of these documents in relation to the current work worth summarizing; and 3) in generating the final topic-biased summary. While it is clear that current NLP technology does not let us build a complete solution for this task, we believe that tackling the individual components will help bring us towards an eventual solution.

In fact, existing works in the NLP and recommendation systems communities have already begun work that fits towards the completion of the first two tasks. Citation prediction (Nallapati et al., 2008) is a growing research area that has aimed both at predicting citation growth over time within a community and at individual paper citation patterns. This year, an automatic keyphrase extraction task from scientific articles was first fielded in SemEval-2, partially addressing Task 1[1]. Also, automatic survey generation (Mohammad et al., 2009) is becoming a growing field within the summarization community. However, to date, we have not yet seen any work that examines topic-biased summarization of multiple scientific articles. For these reasons, we focus on Task 3 here – *the creation of a related work section, given a structured input of the topics for summary.*. The remaining contributions of our paper

[1] http://semeval2.fbk.eu/semeval2.php

Coling 2008: Poster Volume, pages 427–435,
Beijing, August 2010

consists of work towards this goal:

• We conduct a study of the argumentative patterns used in related work sections, to describe the plausible summarization tactics for their creation in Section 3.

• We describe our approach to generate an extractive related work summary given an input topic hierarchy tree, using two separate strategies to differentiate between summarizing shallow internal nodes from deep detailed leaf nodes of the topic tree in Section 4.

2 Related Work

Fully automated related work summarization is significantly different from traditional summarization. While there are no existing studies on this specific problem, there are closely related endeavors. The iOPENER[2] project works towards automated creation of technical surveys, given a research topic (Mohammad et al., 2009). Standard generic multi-document summarization algorithms were applied to generate technical surveys. They showed that citation information was effective in the generation process. This was also validated earlier in (Nakov et al., 2004), which showed that the citing sentences in other papers can give a useful description of a target work.

Other studies focus mainly on single-document scientific article summarization. The pioneers of automated summarization (Luhn, 1958; Baxendale, 1958; Edmundson, 1969) had envisioned their approaches being used for the automatic creation of scientific summaries. They examined various features specific to scientific texts (*e.g.*, frequency-based, sentence position, or rhetorical clues features) which were proven effective for domain-specific summarization tasks.

Further, Mei and Zhai (2008) and Qazvinian and Radev (2008) utilized citation information in creating summaries for a single scientific article in computational linguistics domain. Also, Schwartz and Hearst (2006) also utilized the citation sentences to summarize the key concepts and entities in bioscience texts, and argued that citation sentences may contain informative contributions of a paper that complement its original abstract.

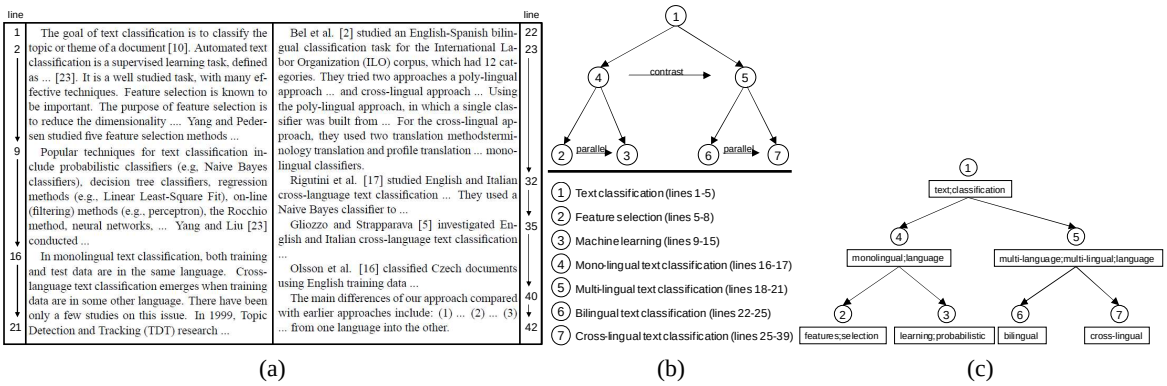
[2]http://clair.si.umich.edu/clair/iopener/

These works all center on the role of citations and their contexts in creating a summary, using citation information to rank content for extraction. However, they did not study the rhetorical structure of the intended summaries, targeting more on deriving useful content. For working along this vein, we turn to studies on the rhetorical structure of scientific articles. Perhaps the most relevant is work by (Teufel, 1999; Teufel and Moens, 2002) who defined and studied argumentative zoning of texts, especially ones in computational linguistics. While they studied the structure of an entire article, it is clear from their studies that a related work section would contain general background knowledge (BACKGROUND zone) as well as specific information credited to others (OTHER and BASIS zones). This vein of work has been followed by many, including Teufel et al. (2009; Angrosh et al. (2010).

3 Structure of Related Work Section

We first extend the work on rhetorical analysis, concentrating on related work sections. By studying examples in detail, we gain insight on how to approach related work summarization. We focus on a concrete related work example for illustration, an excerpt of which is shown in Figure 1a. Focusing on the argumentative progression of the text, we note the flow through different topics is hierarchical and can be represented as a topic tree as in Figure 1b.

This summary provides background knowledge for a paper on text classification, which is the root of the topic tree (node 1; lines 1–5). Two topics ("feature selection" and "machine learning") are then presented in parallel (nodes 2 & 3; lines 5–8 & 9–15), where specific details on relevant works are selected to describe two topics. These two topics are implicitly understood as subtopics of a more general topic, namely "mono-lingual text classification" (node 4; lines 16–17). The authors use the monolingual topic to contrast it with the subsequent subtopic "multi-lingual text classification" (node 5; lines 18–21). This topic is described by elaborating its details through two subtopics: "bilingual text classification" and "cross-lingual text classification" (nodes 6 & 7; lines 22–25 & 25–39) where again, various example works



(a) (b) (c)

Figure 1: a) A related work section extracted from (Wu and Oard, 2008); b) An associated topic hierarchy tree of a); c) An associated topic tree, annotated with key words/phrases.

are described and cited. The authors then conclude by contrasting their proposed approach with the introduced relevant approaches (lines 40–42).

This summary illustrates three important points. First, the topic tree is an essential input to the summarization process. The topic tree can be thought of as a high-level rhetorical structure for which a process then attaches content. While it is certainly non-trivial to build such a tree, modifications to hierarchical topic modeling (M. et al., 2004) or keyphrase extraction algorithms (Witten et al., 1999) we believe can be used to induce a suitable form. A resulting topic hierarchy from such a process would provide an associated set of key words or phrases that would describe the node, as shown in Figure 1c.

Second, while summaries can be structured in many ways, they can be viewed as moves along the topic hierarchy tree. In the example, nodes 2 and 3 are discussed before their parent, as the parent node (node 4) serves as a useful contrast to introduce its sibling (node 5). We find variants of depth-first traversal common, but breadth-first traversals of nodes with multiple descendants are more rare. They may be structured this way to ease the reader's burden on memory and attention. This is in line with other summary genres where information is ordered by high-level logical considerations that place macro level constraints (Barzilay et al., 2002).

Third, there is a clear distinction between sentences that describe a general topic and those that describe work in detail. Generic topics are often represented by background information, which is not tied to a particular prior work. These include definitions or descriptions of a topic's purpose. In contrast, detailed information forms the bulk of the summary and often describes key related work that is attributable to specific authors. Recently, Jaidka et al. (2010) also present the beginnings of a corpus study of related work sections, where they differentiate integrative and descriptive strategies in presenting discourse work. We see our differentiation between general and detailed topics as a natural parallel to their notion of integrative and descriptive strategies.

To introspect on these findings further, we created a related work data set (called **RWSData**[3]), which includes 20 articles from well-respected venues in NLP and IR, namely SIGIR, ACL, NAACL, EMNLP and COLING. We extracted the related work sections directly from those research articles as well as references the sections cited. References to books and Ph.D. theses were removed, as their verbosity would change the problem drastically (Mihalcea and Ceylan, 2007). Since we view each related work summary as a topic-biased summary originating from a topic hierarchy tree, annotation of such topical information for our data set is necessary. Each article's data consists of the reference related work summary, the collection of the input research articles

Table 1: **The demographics of RWSData**. No, RW, RA, SbL, WbL, TS, and TD are labeled as (N)umber (o)f, (R)elated (W)orks, (R)eferenced (A)rticles, (S)entence-(b)ased (L)ength of, (W)ord-(b)ased (L)ength of, (T)ree (S)ize, and (T)ree (D)epth, respectively.

that were referenced and a manually-constructed topic descriptions in a hierarchical fashion (topic tree). More details on the demographics of RWSData are shown in Table 1. RWSData summaries average 17.9 sentences, 522 words in length, citing an average of 10.9 articles. While hierarchical, the topic trees are simple, averaging 3.3 topic nodes in size and average depth of 1.8. Their simplicity furthers our claim that automated methods would be able to create such trees.

4 ReWoS: Paired General and Specific Summarization

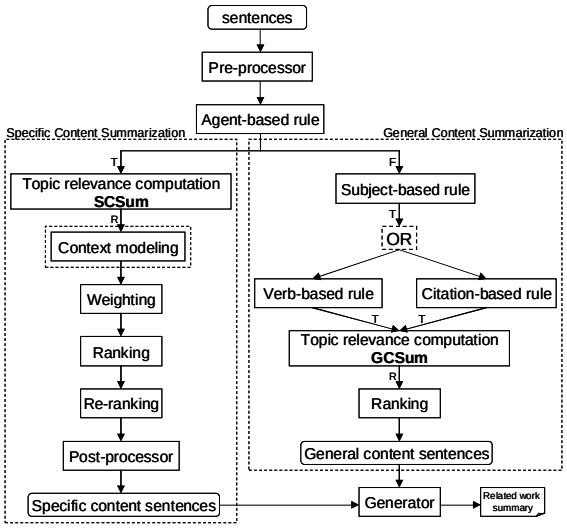

Figure 2: **The ReWoS architecture**. Decision edges labeled as **T**rue, **F**alse and **R**elevant.

Inspired by the above observations, we propose a novel strategy for related work summarization with respect to a given topic tree. Note that while the construction of the topic tree is central to the process, we consider this outside the scope of the current work (see §1); our investigation focuses on how such input could be utilized to construct a reasonable topic-biased related work summary.

We posit that sentences within a related work section come about by means of two separate processes – a process that gives general background information and another that describes specific author contributions. A key realization in our work is that these processes are easily mapped to the topic tree topologically: general content is described in tree-internal nodes, whereas leaf nodes contribute detailed specifics. In our approach, these two processes are independent, and combined to construct the final summary.

We have implemented our idea in **ReWoS** (**Re**lated **Wo**rk **S**ummarizer), whose general architecture is shown in Figure 2. ReWoS is a largely heuristic system, featuring both a **G**eneral **C**ontent **Sum**marization (**GCSum**) and a **S**pecific **C**ontent **Sum**marization (**SCSum**) modules, prefixed by preprocessing. A natural language template **generation** system fills out the end of the summary.

ReWoS first applies a set of preprocessing steps (shown in the top of Figure 2). Input sentences (*i.e.*, the set of sentences from each related/cited article) first removes sentences that are too short (< 7 tokens) or too long (> 80 tokens), ones that use future tense (possibly future work), and example and navigation sentences. This last category is filtered out by checking for the presence of a cue phrase among a lexical pattern database: *e.g.*, "in the section", "figure x shows", "for instance". Lowercasing and stemming are also performed.

We then direct sentences to either GCSum or SCSum based on whether it describes the author's own work or not, similar in spirit and execution to (Teufel et al., 2009). If sentence contains indicative pronouns or cue phrases (*e.g.*, "we", "this ap-

proach"), the sentence is deemed to describe own work and is directed to SCSum; otherwise the sentence is directed to the GCSum workflow.

4.1 (G)eneral (C)ontent (Sum)marization

GCSum extracts sentences containing useful background information on the topics of the internal node in focus. Since general content sentences do not specifically describe work done by the authors, we only take sentences that do not have the author-as-agent as input for GCSum.

We divide such general content sentences into two groups: indicative and informative. Informative sentences give detail on a specific aspect of the problem. They often give definitions, purpose or application of the topic (*"Text classification is a task that assigns a certain number of predefined labels for a given text."*). In contrast, indicative sentences are simpler, inserted to make the topic transition explicit and rhetorically sound (*"Many previous studies have studied monolingual text classification."*).

Indicative sentences can be easily generated by templates, as the primary information that is transmitted is the identity of the topic itself. Informative sentences, on the other hand, are better extracted from the source articles themselves, requiring a specific strategy. As informative sentences contain more content, our strategy with GCSum is to attempt to locate informative sentences to describe the internal nodes, failing which GCSum falls back to using predefined templates to generate an indicative placeholder.

To implement GCSum's informative extractor, we use a set of heuristics in a decision cascade to first filter inappropriate sentences (as shown on the RHS of Figure 2). Remaining candidates (if any) are then ranked by relevance and the top n are selected for the summary.

The heuristic cascade's purpose is to ensure sentences fit the syntactic structure of commonly-observed informative sentences. A useful sentence should discuss the topic directly, so GCSum first checks the subject of each candidate sentence, filtering sentences whose subject do not contain at least one topic keyword. We observed that background sentences often feature specific verbs or citations. GCSum thus also checks whether stock verb phrases (*i.e.*, "based on", "make use of" and 23 other patterns) are used as the main verb. Otherwise, GCSum checks for the presence of at least one citation – general sentences may list a set of citations as examples. If both the cue verb and citation checks fail, the sentence is dropped.

GCSum's topic relevance computation ranks remaining sentences based on keyword content. We state that the topic of an internal node is affected by its surrounding nodes – ancestor, descendants and siblings. Based on this idea, the score of a sentence is computed in a discriminative way using the following linear combination:

$$score_S \rightarrow score_S^{QA} + score_S^{Q} - score_S^{QR} \quad (1)$$

where $score_S$ is the final relevance score, and $score_S^{QA}$, $score_S^{Q}$, and $score_S^{QR}$ are the component scores of the sentence S with respect to the ancestor, current or other remaining nodes. We give positive credit to a sentence that contains keywords from an ancestor node, but penalize sentences with keywords from other topics (as such sentences would be better descriptors for those other topics). Component relevance scores are calculated using Term Frequency $\times$ Inverse Sentence Frequency (TF$\times$ISF) (Otterbacher et al., 2005):

$$\begin{aligned} score_S^{Q} &= \frac{rel(S,Q)}{\sum_{Q'} rel(S,Q')} \quad (2) \\ &= \frac{\sum_{w \in Q} \log(tf_w^S + 1) \times \log(tf_w^Q + 1) \times isf_w}{Norm} \end{aligned}$$

where $rel(S,Q)$ is the relevance of S with respect to topic Q, $Norm$ is a normalization factor of $rel(S,Q)$ over all input sentences, tf_w^S and tf_w^Q are the term frequencies of token w within S or sentences that discuss topic Q, respectively. isf_w is the inverse sentence frequency of w.

4.2 (S)pecific (C)ontent (Sum)marization

SCSum aims to extract sentences that contain detailed information about a specific author's work that is relevant to the input leaf node's topic from the set of sentences that exhibit the author-as-agent. SCSum starts by computing the topic relevance of each candidate sentence as shown in Equation (3). This process is identical to the step in GCSum, except that the term $score_S^{QR}$ in Equation (1) is replaced by $score_S^{QS}$, which is the relevance of S with respect to its sibling nodes. We

hypothesize that given a leaf node, sibling node topics may have an even more pronounced negative effect than other remaining nodes in the topic tree.

$$score_S \rightarrow score_S^{QA} + score_S^{Q} - score_S^{QS} \quad (3)$$

Context Modeling. We note that single sentences occasionally do not contain enough contexts to clearly express the idea mentioned in original articles. In fact, an agent-based sentence often introduces a concept but pertinent details are often described later. Extracting just the agent-based sentence may incompletely describe a concept and lead to false inferences. Consider the example in Figure 3. Here Sentences 0-5 are an contiguous extract of a source article being summarized, where Sentence 0 is an identified agent-based sentence. Sentence 6 shows a related work section sentence from a citing article that describes the original article. It is clear that the citing description is composed of information taken not only from the agent-based sentence but its context in the following sentences as well. This observation

0) To evaluate the quality of produced paraphrases, **we** picked at random 500 paraphrasing pairs from the lexical paraphrases produced by our algorithm.

---

1) These **pairs** were used as test data and also to evaluate whether **humans** agree on **paraphrasing judgments**.
2) The judges were given a page of guidelines, defining **paraphrase** as **approximate conceptual equivalence.**
3) The main dilemma in designing the evaluation is whether to include the context: should the **human judge** see only a paraphrase pair or should a pair of sentences containing these paraphrases also be given?
4) In a similar MT task evaluation of word-to-word translation context is usually included (Melamed, 2001).
5) Although paraphrasing is considered to be context dependent, there is no agreement on the extent.

---

6) (Barzilay and McKeown 2001) **evaluated** their **paraphrases** by asking **judges** whether **paraphrases** were "**approximately conceptually equivalent**".

Figure 3: A context modeling example.

motivates us to choose nearby sentences within a contextual window after the agent-based sentence to represent the topic. We set the contextual window to 5 and extract a maximum of 2 additional sentences. These additions are chosen based on their relevance scores to the topic, using Equation (3). Sentences with non-zero scores are then added as contexts of the anchor agent-based sentence, otherwise they are excluded. As a result, some topics may contain only a single sentence, but others may be described by additional contextual sentences.

Weighting. The score of a candidate content sentence is computed from topic relevance computation (SCSum) that includes contributions for keywords present in the current, ancestor and sibling nodes. We observe that the presence of one or more of current, ancestor and sibling nodes may affect the final score from the computation. Thus, to partially address this, we add a new weighting coefficient for the score computed from the topic relevance computation (SCSum) (Equation (3)) as follows:

$$score_S^* = w_S^{QA,Q,QS} \times score_S \quad (4)$$

where: $w_S^{QA,Q,QS}$ is a weighting coefficient that takes on differing values based on the presence of keywords in the sentence. Q, QA, and QS denote keywords from current, ancestor and sibling nodes. If the sentence contains keywords from other sibling nodes, we assign a penalty of 0.1. Otherwise, we assign a weight of 1.0, 0.5, or 0.25, based on whether keywords are present from both the ancestor node and current node, just the current node or just the ancestor node.

To build the final summary, ReWoS selects the top scoring sentence and iteratively adds the next most highly ranked sentence, until the n sentence budget is reached. We use SimRank (Li et al., 2008) to remove the next sentence to be added, if it is too similar to the sentences already in the summary.

4.3 Generation

ReWoS generates its summaries by using depth-first traversal to order the topic nodes, as in RWS-Data we observed this to be the most prevalent discourse pattern. It calls GCSum and SCSum to summarize individual nodes, distributing the total sentence budget equally among nodes.

ReWoS post-processes sentences to improve fluency where possible. We first replace agentive forms with a citation to the articles (*e.g.*, "we" $\rightarrow$ "(Wu and Oard, 2008)"). ReWoS also replaces found abbreviations with their corresponding long forms, by connecting abbreviation with their expansions by utilizing dependency relation output from the Stanford dependency parser.

System	ROUGE Recall Scores				Human Evaluation Scores			
	ROUGE-1	ROUGE-2	ROUGE-S4	ROUGE-SU4	Correctness	Novelty	Fluency	Usefulness
LEAD	0.501	0.096	0.116	0.181	3.027	2.764	3.082	2.745
MEAD	0.663	0.178	0.211	0.287	3.009	3.109	2.591	2.700

Table 2: Evaluation results for ReWoS variants and baselines.

5 Evaluation

We wish to assess the quality of ReWoS, comparing to state-of-the-art generic summarization systems. We first detail our baseline systems used for performance comparison, and defined evaluation measures specific to related work summary evaluation. In our evaluation, we use our manually-compiled RWSData data set.

We benchmark ReWoS against two baseline systems: LEAD and MEAD. The LEAD baseline represents each of the cited article with an equal number of sentences. The first n sentences are drawn from the article, meaning that the title and abstract are usually extracted. The order of the article leads used in the resulting summary was determined by the order of articles to be processed. MEAD is a well-documented baseline extractive multi-document summarizer, developed in (Radev et al., 2004). MEAD offers a set of different features that can be parameterized to create resulting summaries. We conducted an internal tuning of MEAD to maximize its performance on the RWSData. The optimal configuation uses just two tuned features of *centroid* and *cosine similarity*. Note that the MEAD baseline does use the topic tree keywords in computing cosine similarity score. Our ReWoS system is the only system that leverages the topic tree *structure* which is central to our approach. In our experiments, we used MEAD toolkit[4] to produce the summaries for LEAD and MEAD baseline systems.

Automatic evaluation was performed with ROUGE (Lin, 2004), a widely used and recognized automated summarization evaluation method. We employed a number of ROUGE variants, which have been proven to correlate with human judgments in multi-document summarization (Lin, 2004). However, given the small size of our summarization dataset, we can only draw notional evidence from such an evaluation; it is not possible to find statistically significant conclusion from our evaluation.

To partially address this, we also conducted a human evaluation to assess more fine-grained qualities of our system. We asked 11 human judges to follow an evaluation guideline that we prepared, to evaluate the summary quality, consisting of the following evaluation measures:

• **Correctness:** Is the summary content actually relevant to the hierarchical topics given?

• **Novelty**: Does the summary introduce novel information that is significant in comparison with the human created summary?

• **Fluency**: Does the summary's exposition flow well, in terms of syntax as well as discourse?

• **Usefulness**: Is the summary useful in supporting the researchers to quickly grasp the related works given hierarchical topics?

Each judge was asked to grade the four summaries according to the measures on a 5-point scale of 1 (very poor) to 5 (very good). Summaries 1 and 2 come from LEAD-based and MEAD systems, respectively. Summaries 3 and 4 come from our proposed ReWoS systems, without (ReWoS−WCM) and with (ReWoS−CM) the context modeling in SCSum. All summarizers were set to yield a summary with the same length (1% of the original relevant articles, measured in sentences). Due to limited time, only 10 out of 20 evaluation sets were assessed by the evaluators. Each set was graded at least 3 times by 3 different evaluators; evaluators did not know the identities of the systems, which were randomized for each set examined.

6 Results

ROUGE results are summarized in Table 2. Surprisingly, the MEAD baseline system outperforms both LEAD baseline and ReWoS–WCM (without context modeling). Only ReWoS–CM (with

[4] `http://www.summarization.com/mead/`

context modeling) is significantly better than others, in terms of all ROUGE variants. Here are some possible reasons to explain this. First, ROUGE evaluation seems to work unreasonably when dealing with verbose summaries, often produced by MEAD. Second, related work summaries are multi-topic summaries of multi-article references. This may cause miscalculation from overlapping n-grams that occur across multiple topics or references.

Since automatic evaluation with ROUGE does not allow much introspection, we turn to our human evaluation. Results are also summarized in Table 2. They show that both ReWoS–WCM and ReWoS–CM perform significantly better than baselines in terms of correctness, novelty, and usefulness. This is because our system utilized features developed specifically for related work summarization. Also, our proposed systems compare favorably with LEAD, showing that necessary information is not only located in titles or abstracts, but also in relevant portions of the research article body.

ReWoS–CM (with context modeling) performed equivalent to ReWoS–WCM (without it) in terms of correctness and usefulness. For novelty, ReWoS–CM is better than ReWoS–WCM. It proved that the proposed component of context moding is useful in providing new information that is necessary for the related work summaries. For fluency, only ReWoS–CM is better than baseline systems. This is a negative result, but is not surprising because the summaries from the ReWoS–CM which uses context modeling seems to be longer than others. It makes the summaries quite hard to digest; some evaluators told us that they preferred the shorter summaries. A future extension is that using information fusion techniques to fuse the contextual sentences with its anchor agentive sentence.

A detailed error analysis of the results revealed that there are three main types of errors produced by our systems. The first issue is in calculating topic relevance. In the context of related work summarization, our heuristics-based strategies for sentence extraction cannot capture fully this issue. Some sentences that have high relevant scores to topics are not actually semantically relevant to the topics. The second issue of anaphoric expression is more addressable. Some extracted sentences still contain anaphoric expression (*e.g.*, "they", "these", "such", ...), making final generated summaries incoherent. The third issue is paraphrasing, where substituted paraphrases replace the original words and phrases in the source articles.

7 Conclusion and Future Work

According to the best of our knowledge, automated related work summarization has not been studied before. In this paper, we have taken the initial steps towards solving this problem, by dividing the task into general and specific summarization processes. Our initial results show an improvement over generic multi-document summarization baselines in human evaluation. However, our work shows that there is much room for additional improvement, for which we have outlined a few challenges.

A shortcoming of our current work is that we assume that a topic hierarchy tree is given as input. We feel that this is an acceptable limitation because we feel existing techniques will be able to create such input, and that the topic trees used in this study were quite simple. We plan to validate this by generating these topic trees automatically in our future work.

Exploring related work summarization comes at a timely moment, as scholars now have access to a preponderous amount of scholarly literature. Automated assistance in interpreting and organizing scholarly work will help build future applications for integration with digital libraries and reference management tools.

Negative Feedback: The Forsaken Nature Available for Re-ranking

Yu Hong, Qing-qing Cai, Song Hua, Jian-min Yao, Qiao-ming Zhu

jyao@suda.edu.cn

ABSTRACT

Re-ranking for Information Retrieval aims to elevate relevant feedbacks and depress negative ones in initial retrieval result list. Compared to relevance feedback-based re-ranking method widely adopted in the literature, this paper proposes a new method to well use three features in known negative feedbacks to identify and depress unknown negative feedbacks. The features include: 1) the minor (lower-weighted) terms in negative feedbacks; 2) hierarchical distance (HD) among feedbacks in a hierarchical clustering tree; 3) obstinateness strength of negative feedbacks. We evaluate the method on the TDT4 corpus, which is made up of news topics and their relevant stories. And experimental results show that our new scheme substantially outperforms its counterparts.

1. INTRODUCTION

When we start out an information retrieval journey on a search engine, the first step is to enter a query in the search box. The query seems to be the most direct reflection of our information needs. However, it is short and often out of standardized syntax and terminology, resulting in a large number of negative feedbacks. Some researches focus on exploring long-term query logs to acquire query intent. This may be helpful for obtaining information relevant to specific interests but not to daily real-time query intents. Especially it is extremely difficult to determine whether the interests and which of them should be involved into certain queries. Therefore, given a query, it is important to "locally" ascertain its intent by using the real-time feedbacks.

Intuitively it is feasible to expand the query using the most relevant feedbacks (Chum et al., 2007). Unfortunately search engines just offer "farraginous" feedbacks (viz. pseudo-feedback) which may involve a great number of negative feedbacks. And these negative feedbacks never honestly lag behind relevant ones in the retrieval results, sometimes far ahead because of their great literal similarity to query. These noisy feedbacks often mislead the process of learning query intent.

For so long, there had no effective approaches to confirm the relevance of feedbacks until the usage of the web click-through data (Joachims et al., 2003). Although the data are sometimes incredible due to different backgrounds and habits of searchers, they are still the most effective way to specify relevant feedbacks. This arouses recent researches about learning to rank based on supervised or semi-supervised machine learning methods, where the click-through data, as the direct reflection of query intent, offer reliable training data to learning the ranking functions.

Although the learning methods achieve substantial improvements in ranking, it can be found that lots of "obstinate" negative feedbacks still permeate retrieval results. Thus an interesting question is why the relevant feedbacks are able to describe what we really need, but weakly repel what we do not need. This may attribute to the inherent characteristics of pseudo-feedback, i.e. their high literal similarity to queries. Thus no matter whether query expansion or learning to rank, they may fall in the predicament that "favoring" relevant feedbacks may result in "favoring" negative ones, and that "hurting" negative feedbacks may result in "hurting" relevant ones.

However, there are indeed some subtle differences between relevant and negative feedbacks, e.g. the minor terms (viz. low-weighted terms in texts). Although these terms are often ignored in

Coling 2008: Poster Volume, pages 436–444,
Beijing, August 2010

relevance measurement because their little effect on mining relevant feedbacks that have the same topic or kernel, they are useful in distinguishing relevant feedbacks from negative ones. As a result, these minor terms provides an opportunity to differentiate the true query intent from its counterpart intents (called "opposite intents" thereafter in this paper). And the "opposite intents" are adopted to depress negative feedbacks without "hurting" the ranks of relevant feedbacks. In addition, hierarchical clustering tree is helpful to establish the natural similarity correlation among information. So this paper adopts the hierarchical distance among feedbacks in the tree to enhance the "opposite intents" based division of relevant and negative feedbacks. Finally, an obstinateness factor is also computed to deal with some obstinate negative feedbacks in the top list of retrieval result list. In fact, Teevan (Teevan et al., 2008) observed that most searchers tend to browse only a few feedbacks in the first one or two result pages. So our method focuses on improving the precision of highly ranked retrieval results.

The rest of the paper is organized as follows. Section 2 reviews the related work. Section 3 describes our new irrelevance feedback-based re-ranking scheme and the HD measure. Section 4 introduces the experimental settings while Section 5 reports experimental results. Finally, Section 6 draws the conclusion and indicates future work.

2. RELATED WORK

Our work is motivated by information search behaviors, such as eye-tracking and click through (Joachims, 2003). Thereinto, the click-through behavior is most widely used for acquiring query intent. Up to present, several interesting features, such as click frequency and hit time on click graph (Craswell et al., 2007), have been extracted from click-through data to improve search results. However, although effective on query learning, they fail to avoid the thorny problem that even when the typed query and the click-through data are the same, their intents may not be the same for different searchers.

A considerable number of studies have explored pseudo-feedback to learn query intent, thus refining page ranking. However, most of them focus on the relevant feedbacks. It is until recently that negative ones begin to receive some attention. Zhang (Zhang et al., 2009) utilize the irrelevance distribution to estimate the true relevance model. Their work gives the evidence that negative feedbacks are useful in the ranking process. However, their work focuses on generating a better description of query intent to attract relevant information, but ignoring that negative feedbacks have the independent effect on repelling their own kind. That is, if we have a king, we will not refuse a queen. In contrast, Wang (Wang et al., 2008) benefit from the independent effect from the negative feedbacks. Their method represents the opposite of query intent by using negative feedbacks and adopts that to discount the relevance of each pseudo-feedback to a query. However, their work just gives a hybrid representation of opposite intent which may overlap much with the relevance model. Although another work (Wang et al., 2007) of them filters query terms from the opposite intent, such filtering makes little effect because of the sparsity of the query terms in pseudo-feedback.

Other related work includes query expansion, term extraction and text clustering. In fact, query expansion techniques are often the chief beneficiary of click-through data (Chum et al., 2007). However, the query expansion techniques via clicked feedbacks fail to effectively repel negative ones. This impels us to focus on un-clicked feedbacks. Cao (Cao et al., 2008) report the effectiveness of selecting good expansion terms for pseudo-feedback. Their work gives us a hint about the shortcomings of the one-sided usage of high-weighted terms. Lee (Lee et al., 2008) adopt a cluster-based re-sampling method to emphasize the core topic of a query. Their repeatedly feeding process reveals the hierarchical relevance of pseudo-feedback.

3. RE-RANKING SCHEME

3.1 Re-ranking Scheme

The re-ranking scheme, as shown in Figure 1, consists of three components: acquiring negative feedbacks, measuring irrelevance feedbacks and re-ranking pseudo-feedback.

Given a query and its search engine results, we start off the re-ranking process after a trigger point. The point may occur at the time when searchers click on "next page" or any hyperlink.

All feedbacks before the point are assumed to have been seen by searchers. Thus the un-clicked feedbacks before the point will be treated as the known negative feedbacks because they attract no attention of searchers. This may be questioned because searchers often skip some hyperlinks that have the same contents as before, even if the links are relevant to their interests. However, such skip normally reflects the true searching intent because novel relevant feedbacks always have more attractions after all.

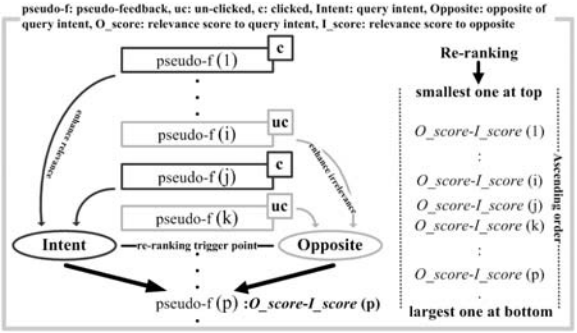

Figure 1. Re-ranking scheme

Another crucial step after the trigger point is to generate the opposite intent by using the known negative feedbacks. But now we temporarily leave the issue to Section 3.2 and assume that we have obtained a good representation of the opposite intent, and meanwhile that of query intent has been composed of the highly weighted terms in the known relevant feedbacks and query terms. Thus, given an unseen pseudo-feedback, we can calculate its overall ranking score predisposed to the opposite intent as follows:

$$R\_score = O\_score - \alpha \cdot I\_score \quad (1)$$

where the *O_score* is the relevance score to the opposite intent, *I_score* is that to the query intent and α is a weighting factor. On the basis, we re-rank the unseen feedbacks in ascending order. That is, the feedback with the largest score appears at the bottom of the ranked list.

It is worthwhile to emphasize that although the overall ranking score, i.e. *R_score*, looks similar to Wang (Wang et al., 2008) who adopts the inversely discounted value (i.e. the relevance score is calculated as $I\_score - \alpha \cdot O\_score$) to re-rank feedbacks in descending order, they are actually quite different because our overall ranking score as shown in Equation (1) is designed to depress negative feedbacks, thereby achieving the similar effect to filtering.

3.2 Representing Opposite Intent

It is necessary for the representation of opposite intent to obey two basic rules: 1) the opposite intent should be much different from the query intent; and 2) it should reflect the independent effect of negative feedbacks.

Given a query, it seems easy to represent its opposite intent by using a vector of high-weighted terms of negative feedbacks. However, the vector is actually a "close relative" of query intent because the terms often have much overlap with that of relevant feedbacks. And the overlapping terms are exactly the source of the highly ranked negative feedbacks. Thus we should throw off the overlapping terms and focus on the rest instead.

In this paper, we propose two simple facilities in representing opposite intent. One is a vector of the weighted terms (except query terms) occurring in the known negative feedbacks, named as $O(-q)$, while another further filters out the high-weighted terms occurring in the known relevant feedbacks, named as $O(-q-r)$. Although $O(-q)$ filters out query terms, the terms are so sparse that they contribute little to opposite intent learning. Thus, we will not explore $O(-q)$ further in this paper (Our preliminary experiments confirm our reasoning). In contrast, $O(-q-r)$ not only differs from the representation of query intent due to its exclusion of query terms but also emphasize the low-weighted terms occurring in negative feedbacks due to exclusion of high-weighted terms occurring in the known relevant feedbacks.

3.3 Employing Opposite Intent

Another key issue in our re-ranking scheme is how to measure the relevance of all the feedbacks to the opposite intent, i.e. *O_score*, thereby the ranking score *R_score*. For simplicity, we only consider Boolean measures in employing opposite intent to calculate the ranking score *R_score*.

Assume that given a query, there are N known relevant feedbacks and $\overline{N}$ known negative ones. First, we adopt query expansion to acquire the representation of query intent. This is done by pouring all terms of the N relevant feedbacks and query terms into a bag of words, where all the occurring weights of each term are

accumulated, and extracting *n* top-weighted terms to represent the query intent as $I(+q+r)$. Then, we use the $\bar{N}$ negative feedbacks to represent the *n*-dimensional opposite intents $O(-q-r)$. For any unseen pseudo-feedback *u*, we also represent it using an *n*-dimensional vector $V(u)$ which contains its *n* top-weighted terms. In all the representation processes, the TFIDF weighting is adopted.

Thus, for an unseen pseudo-feedback *u*, the relevance scores to the query intent and the opposite intent can be measured as:

$$\begin{aligned} I\_score(u) &= B\{\ V(u),\ I(+q+r)\ \} \\ O\_score(u) &= B\{\ V(u),\ O(-q-r)\ \} \end{aligned} \tag{2}$$

where $B\{*,*\}$ indicates Boolean calculation:

$$\begin{aligned} B\{X,Y\} &= \sum b\{x_i,Y\},\ x_i \in X \\ b\{x_i,Y\} &= \begin{cases} 1, & if\ \ x_i \in Y \\ 0, & if\ \ x_i \notin Y \end{cases} \end{aligned} \tag{3}$$

In particular, we simply set the factor α, as mentioned in Equation (1), to 1 so as to balance the effect of query intent and its opposite intent on the overall ranking score. The intuition is that if an unseen pseudo-feedback has more overlapping terms with $O(-q-r)$ than $I(+q+r)$, it will has higher probability of being depressed as an negative feedback.

Two alternatives to the above Boolean measure are to employ the widely-adopted VSM cosine measure and Kullback-Liebler (KL) divergence (Thollard et al., 2000). However, such term-weighting alternatives will seriously eliminate the effect of low-weighted terms, which is core of our negative feedback-based re-ranking scheme.

3.4 Hierarchical Distance (HD) Measure

The proposed method in Section 3.3 ignores two key issues. First, given a query, although search engine has thrown away most opposite intents, it is unavoidable that the pseudo-feedback still involves more than one opposite intent. However, the representation $O(-q-r)$ has the difficulty in highlighting all the opposite intents because the feature fusion of the representation smoothes the independent characteristics of each opposite intent. Second, given several opposite intents, they have different levels of effects on the negative score $O\_score(u)$. And the effects cannot be measured by the unilateral score.

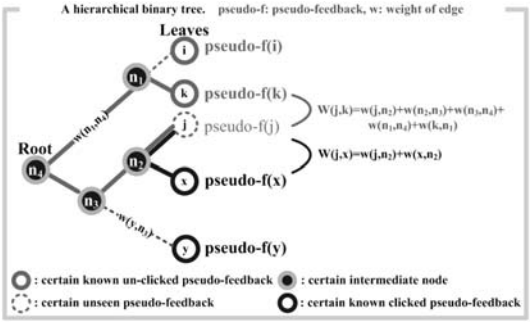

Figure 2. Weighted distance calculation

To solve the issues, we propose a hierarchical distance based negative measure, abbr. HD, which measures the distances among feedbacks in a hierarchical clustering tree, and involves them into hierarchical division of relevance score. Given two random leaves *u* and *v* in the tree, their HD score is calculated as:

$$HD\_score(u,v) = \frac{rel(u,v)}{W(u,v)} \tag{4}$$

where $rel(*,*)$ indicates textual similarity, $W(*,*)$ indicates the weighted distance in the tree, which is calculated as:

$$W(u,v) = \sum_{i \in m} w_i(u,v) \tag{5}$$

where *m* is the total number of the edges between two leaves, $w_i(*,*)$ indicates the weight of the *i-th* edge. In this paper, we adopt CLUTO to generate the hierarchical binary tree, and simply let each $w_i(*,*)$ equal 1. Thus the $W(*,*)$ becomes to be the number of edges *m*, for example, the $W(j,k)$ equals 5 in Figure 2.

On the basis, given an unseen feedback *u*, we can acquire its modified re-ranking score R'_score by following steps. First, we regard each known negative feedback as an opposite intent, following the two generative rules (mentioned in section 3.2) to generate its *n*-dimensional representation $O(-q-r)$. Additionally we represent both the known relevant feedbacks and the unseen feedback *u* as *n*-dimensional term vectors. Second, we cluster these feedbacks to generate a hierarchical binary tree and calculate the HD score for each pair of $(u,*)$, where $*$ denotes a leaf in the tree except *u*. Thus the modified ranking score is calculated as:

$$R'\_score = \sum_{i \in \bar{N}} HDI\_score(u,\bar{v}_i) - \sum_{j \in N} HDI\_score(u,v_j) \tag{6}$$

where $\bar{v}_i$ indicates the *i-th* known negative feedback in the leaves, $\bar{N}$ is the total number of

$\bar{v}$, v_j indicates the *j-th* known relevant feedback, N is the total number of v. Besides, we still adopt Boolean value to measure the textual similarity $rel(*,*)$ in both clustering process and ranking score calculation, thus the HD score in the formula (6) can be calculated as follows:

$$HD\_score(u,v) = \frac{B\{\ V(u),\ V(v)\ \}}{W(u,v)}$$
$$HD\_score(u,\bar{v}) = \frac{O\_score(u)}{W(u,\bar{v})} \qquad (7)$$

3.5 Obstinateness Factor

Additionally we involve an interesting feature, i.e. the obstinate degree, into our re-ranking scheme. The degree is represented by the rank of negative feedbacks in the original retrieval results. That is, the more "topping the list" an negative feedback is, the more obstinate it is.

Therefore we propose a hypothesis that if a feedback is close to the obstinate feedback, it should be obstinate too. Thus given an unseen feedback *u*, its relevance to an opposite intent in HD can be modified as:

$$O\_score(u)' = (1 + \frac{\beta}{rnk}) \cdot O\_score(u) \qquad (8)$$

where rnk indicates the rank of the opposite intent in original retrieval results (Note: in HD, every known negative feedback is an opposite intent), β is a smoothing factor. Because ascending order is used in our re-ranking process, by the weighting coefficient, i.e. $(1 + \beta / rnk)$, the feedback close to the obstinate opposite intents will be further depressed. But the coefficient is not commonly used. In HD, we firstly ascertain the feedback closest to *u*, and if the feedback is known to be negative, set to $\bar{v}_{\max}$, we will use the Equation (8) to punish the pair of (u, $\bar{v}_{\max}$) alone, otherwise without any punishment.

4. EXPERIMENTAL SETTING

4.1 Data Set

We evaluate our methods with two TDT collections: TDT 2002 and TDT 2003. There are 3,085 stories in the TDT 2002 collection are manually labeled as relevant to 40 news topics, 30,736 ones irrelevant to any of the topics. And 3,083 news stories in the TDT 2003 collection are labeled as relevant to another 40 news topics, 15833 ones irrelevant to them. In our evaluation, we adopt TDT 2002 as training set, and TDT 2003 as test set. Besides, only English stories are used, both Mandarin and Arabic ones are replaced by their machine-translated versions (i.e. mttkn2 released by LDC).

Corpus	good	fair	poor
TDT 2002	26	7	7
TDT 2003	22	10	8

Table 1. Number of queries referring to different types of feedbacks (Search engine: Lucene 2.3.2)

In our experiments, we realize a simple search engine based on Lucene 2.3.2 which applies document length to relevance measure on the basis of traditional literal term matching. To emulate the real retrieval process, we extract the title from the interpretation of news topic and regard it as a query, and then we run the search engine on the TDT sets and acquire the first 1000 pseudo-feedback for each query. All feedbacks will be used as the input of our re-ranking process, where the hand-crafted relevant stories default to the clicked feedbacks. By the search engine, we mainly obtain three types of pseudo-feedback: "*good*", "*fair*" and "*poor*", where "*good*" denotes that more than 5 clicked (viz. relevant) feedbacks are in the top 10, "*fair*" denotes more than 2 but less than 5, "*poor*" denotes less than 2. Table 1 shows the number of queries referring to different types of feedbacks.

4.2 Evaluation Measure

We use three evaluation measures in experiments, *P@n*, *NDCG@n* and *MAP*. Thereinto, *P@n* denotes the precision of top *n* feedbacks. On the basis, *NDCG* takes into account the influence of position to precision. *NDCG* at position *n* is calculated as:

$$NDCG@n = \frac{1}{Z_n} \cdot DCG@N = \frac{\sum_{i=1}^{n} \frac{2^{r(u_i)} - 1}{\log(1+i)}}{Z_n} \qquad (9)$$

where i is the position in the result list, Z_n is a normalizing factor and chosen so that for the perfect list *DCG* at each position equals one, and $r(u_i)$ equals 1 when u_i is relevant feedback, else 0. While *MAP* additionally takes into account recall, calculated as:

$$MAP = \frac{1}{m} \sum_{i=1}^{m} \frac{1}{R_i} (\sum_{j=1}^{k} r_i(u_j) \cdot (p@j)_i) \qquad (10)$$

where m is the total number of queries, so *MAP* gives the average measure of precision and recall

for multiple queries, R_i is the total number of feedbacks relevant to query *i*, and *k* is the number of pseudo-feedback to the query. Here *k* is indicated to be 1000, thus *Map* can give the average measure for all positions of result list.

4.3 Systems

We conduct experiments using four main systems, in which the search engine based on Lucene 2.3.2, regarded as the basic retrieval system, provides the pseudo-feedback for the following three re-ranking systems.

Exp-sys: Query is expanded by the first *N* known relevant feedbacks and represented by an *n*-dimensional vector which consists of *n* distinct terms. The standard TFIDF-weighted cosine metric is used to measure the relevance of the unseen pseudo-feedback to query. And the relevance-based descending order is in use.

Wng-sys: A system realizes the work of Wang (Wang et al., 2008), where the known relevant feedbacks are used to represent query intent, and the negative feedbacks are used to generate opposite intent. Thus, the relevance score of a feedback is calculated as $I\_score_{wng} - \alpha_w \cdot O\_score_{wng}$, and the relevance-based descending order is used in re-ranking.

Our-sys: A system is approximately similar to *Wng-sys* except that the relevance is measured by $O\_score_{our} - \alpha \cdot I\_score_{our}$ and the pseudo-feedback is re-ranked in ascending order.

Additionally both *Wng-sys* and *Our-sys* have three versions. We show them in Table 2, where "*I*" corresponds to the generation rule of query intent, "*O*" to that of opposite intent, *Rel*. means relevance measure, *u* is an unseen feedback, *v* is a known relevant feedback, $\bar{v}$ is a known negative feedback.

5. RESULTS

5.1 Main Training Result

We evaluate the systems mainly in two circumstances: when both N and $\bar{N}$ equal 1 and when they equal 5. In the first case, we assume that retrieval capability is measured under given few known feedbacks; in the second, we emulate the first page turning after several feedbacks have been clicked by searchers. Besides, the approximately optimal value of *n* for the *Exp-sys*, which is trained to be 50, is adopted as the global value for all other systems. The training results are shown in Figure 3, where the *Exp-sys* never gains much performance improvement when *n* is greater than 50. In fairness to effects of "*I*" and "*O*" on relevance measure, we also make $\bar{n}$ equal 50. In addition, all the discount factors (viz. α, α_{w2} and α_{w3}) initially equal 1, and the smoothing factor β is trained to be 0.5.

Wng-sys1	***"I"***	*n*-dimensional vector for each *v*, Number of *v* in use is *N*
	"O"	None
	Rel.	$R\_score_{w1} = (\sum_{i=1}^{N} \cos(u,v))/N$
Wng-sys2	***"I"***	Number of *v* in use is *N*, all *v* combine into a *n*-dimensional bag of words b_{w2}
	"O"	Number of $\bar{v}$ in use is *N*, all *v* combine into a *n*-dimensional words bag $\bar{b}_{w2}$
	Rel.	$R\_score_{w2} = \cos(u, b_{w2}) - \alpha_{w2} \cdot \cos(u, \bar{b}_{w2})$
Wng-sys3	***"I"***	Similar generation rules to *Wng-sys2* except that query terms are removed from bag of words b_{w3} and $\bar{b}_{w3}$
	"O"	
	Rel.	$R\_score_{w3} = \cos(u, b_{w3}) - \alpha_{w3} \cdot \cos(u, \bar{b}_{w3})$
Our-sys1	***"I"***	$I(+q+r)$ in section 3.3
	"O"	$O(-q-r)$ in section 3.2
	Rel.	$R\_score = O\_score - \alpha \cdot I\_score$
Our-sys2	***"I"***	The same generation rules to *Our-sys1*
	"O"	
	Rel.	HD algorithm: $R'\_score = \sum_{i \in \bar{N}} HDI\_score(u, \bar{v}_i) - \sum_{j \in N} HDI\_score(u, v_j)$
Our-sys3	***"I"***	The same generation rules to *Our-sys1*
	"O"	
	Rel.	HD algorithm + obstinateness factor: $O\_score(u)' = (1 + \frac{\beta}{rnk}) \cdot O\_score(u)$

Table 2. All versions of both *Wngs* and *Ours*

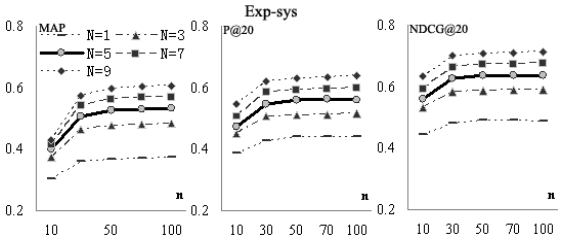

Figure 3. Parameter training of *Exp-sys*

For each query we re-rank all the pseudo-feedback, including that defined as known, so P@20 and NDCG@20 are in use to avoid over-fitting (such as P@10 and NDCG@10 given both N and $\bar{N}$ equal 5). We show the main training results in Table 3, where our methods achieve much better performances than the re-ranking methods based on relevant feedback learning when ***N***= $\bar{N}$ =5. Thereinto, our basic system, i.e. *Our-sys1*, at least achieves approximate 5% improvement on P@20, 3% on NDCG@20 and 1% on MAP than the optimal *wng-sys* (viz. *wng-sys1*). And obvi-

ously the most substantial improvements are contributed by the HD measure which even increases the P@20 of *Our-sys1* by 8.5%, NDCG@20 by 13% and MAP by 9%. But it is slightly disappointing that the obstinateness factor only has little effectiveness on performance improvement, although *Our-sys3* nearly wins the best retrieval results. This may stem from "soft" punishment on obstinateness, that is, for an unseen feedback, only the obstinate companion closest to the feedback is punished in relevance measure.

-	*Our-sys1*	*Our-sys2*	*Exp-sys*	*Wng-sys1*	*Basic*
P@20	0.6603	0.8141	0.63125	0.7051	0.6588
NDCG@20	0.7614	0.8587	0.8080	0.7797	0.6944
MAP	0.6583	0.7928	0.5955	0.7010	0.6440

Table 3. Main training results

It is undeniable that all the re-ranking systems work worse than the basic search engine when the known feedbacks are rare, such as $N = \overline{N} = 1$. This motivates an additional test on the higher values of both N and $\overline{N}$ ($N = \overline{N} = 9$), as shown in Table 4. Thus it can be found that most of the re-ranking systems achieve much better performance than the basic search engine. An important reason for this is that more key terms can be involved into representations of both query intent and its opposite intent. So it seems that more manual intervention is always reliable. However in practice, seldom searchers are willing to use an unresponsive search engine that can only offer relatively satisfactory feedbacks after lots of click-through and page turning. And in fact at least two pages (if one page includes 10 pseudo-feedback) need to be turned in the training corpus when both N and $\overline{N}$ equal 9. So we just regard the improvements benefiting from high click-through rate as an ideal status, and still adopt the practical numerical value of N and $\overline{N}$, i.e. $N = \overline{N} = 5$, to run following test.

5.2 Constraint from Query

A surprising result is that *Exp-sys* always achieves the worst MAP value, even worse than the basic search engine even if high value of *N* is in use, such as the performance when *N* equal 9 in Table 4. It seems to be difficult to question the reasonability of the system because it always selects the most key terms to represent query intent by query expansion. But an obvious difference between *Exp-sys* and other re-ranking systems could explain the result. That is the query terms consistently involved in query representation by *Exp-sys*.

systems	$N = \overline{N}$	*P@20*	*NDCG@20*	*MAP*	*Factor*
Basic	-	**0.6588**	**0.6944**	**0.6440**	-
Exp-sys	1	0.4388	0.4887	0.3683	-
	5	**0.5613**	**0.6365**	**0.5259**	-
Wng-sys1	1	0.5653	0.6184	0.5253	-
	5	**0.6564**	**0.7361**	**0.6506**	-
Wng-sys2	1	0.5436	0.6473	0.4970	α_{w2} =1
	5	**0.5910**	**0.7214**	**0.5642**	α_{w2} =1
Wng-sys3	1	0.5436	0.6162	0.4970	α_{w3} =1
	5	**0.5910**	**0.6720**	**0.5642**	α_{w3} =1
Our-sys1	1	0.5628	0.6358	0.4812	α =1
	5	**0.7031**	**0.7640**	**0.6603**	α =1
Our-sys2	1	0.6474	0.6761	0.5967	α =1
	5	**0.7885**	**0.8381**	**0.7499**	α =1
Our-sys3	1	0.6026	0.6749	0.5272	β =0.5
	5	**0.7897**	**0.8388**	**0.7464**	β =0.5

Table 4. Effects of N and $\overline{N}$ on re-ranking performance (when $N = \overline{N} = 9$, $n = \overline{n} = 50$)

In fact, *Wng-sys1* never overly favor the query terms because they are not always the main body of an independent feedback, and our systems even remove the query terms from the opposite intent directly. Conversely *Exp-sys* continuously enhances the weights of query terms which result in over-fitting and bias. The visible evidence for this is shown in Figure 4, where *Exp-sys* achieves better Precision and NDCG than the basic search engine at the top of result list but worse at the subsequent parts. The results illustrate that too much emphasis placed on query terms in query expansion is only of benefit to elevating the originally high-ranked relevant feedback but powerless to pull the straggler out of the bottom of result list.

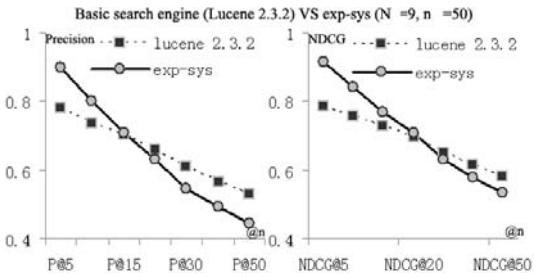

Figure 4. MAP comparison (basic vs *Exp*)

5.3 Positive Discount Loss

Obviously Wang (Wang et al., 2008) has noticed the negative effects of query terms on re-ranking. Therefore his work (reproduced by *Wng-sys1*, *2*, *3* in this paper) avoids arbitrarily enhancing the terms in query representation, even removes them as *Wng-sys3*. This indeed contributes to the

improvement of the re-ranking system, such as the better performances of *Wng-sys1, 2, 3* shown in Table 3, although *Wng-sys3* has no further improvement than *Wng-sys2* because of the sparsity of query terms. On the basis, the work regards the terms in negative feedbacks as noises and reduces their effects on relevance measure as much as possible. This should be a reasonable scheme, but interestingly it does not work well in our experiments. For example, although *Wng-sys2* and *Wng-sys3* eliminate the relevance score calculated by using the terms in negative feedbacks, they perform worse than *Wng-sys1* which never make any discount.

systems	$\alpha_* = 0.5$	$\alpha_* = 1$	$\alpha_* = 2$
Our-sys1	0.4751	0.6603	0.6901
Wng-sys2	0.6030	0.5642	0.4739
Wng-sys3	0.6084	0.5642	0.4739

Table 5. Effects on MAP

Additionally when we increase the discount factor α_{w2} and α_{w3}, as shown in Table 5, the performances (MAP) of *Wng-sys2* and *Wng-sys3* further decrease. This illustrates that the high-weighted terms of high-ranked negative feedbacks are actually not noises. Otherwise why do the feedbacks have high textual similarity to query and even to their neighbor relevant feedbacks? Thus it actually hurts real relevance to discount the effect of the terms.

Conversely *Our-sys1* can achieve further improvement when the discount factor α increases, as shown in Table 5. It is because the discount contributes to highlighting minor terms of negative feedbacks, and these terms always have little overlap with the kernel of relevant feedbacks. Additionally the minor terms are used to generate the main body of opposite intent in our systems, thus the discount can effectively separate opposite intent from positive query representation. Thereby we can use relatively pure representation of opposite intent to detect and repel subsequent negative feedbacks.

5.4 Availability of Minor Terms

Intuitively we can involve more terms into query representation to alleviate the positive discount loss. But it does not work in practice. For example, *Wng-sys2* shown in Figure 5 has no obvious improvement no matter how many terms are included in query representation. Conversely *Our-sys1* can achieve much more improvement when it involves more terms into the opposite intent. For example, when the number of terms increases to 150, *Our-sys1* has approximately 5% better MAP than *Wng-sys2*, shown in Figure 5.

	30	50	100	150
our-sys1	0.6034	0.6603	0.6873	0.706
wng-sys2	0.6386	0.6506	0.6556	0.6563

Figure 5. Effects on MAP in modifying the dimensionality n (when $N=\overline{N}=5$, $\alpha=1$)

This result illustrates that minor terms are available for repelling negative feedbacks, but too weak to recall relevant feedbacks. In fact, the minor terms are just the low-weighted terms in text. Current text representation techniques often ignore them because of their marginality. However minor terms can reflect fine distinctions among feedbacks, even if they have the same topic. And the distinctions are of great importance when we determine why searchers say "Yes" to some feedbacks but "No" to others.

systems	*metric*	*good*	*fair*	*poor*	*global*	*Factor*
Wng-sys1	**P@20**	0.7682	0.5450	0.2643	0.6205	-
	NDCG@20	0.8260	0.6437	0.4073	0.7041	
	MAP	**0.6634**	**0.4541**	**0.9549**	**0.6620**	
Our-sys1	**P@20**	0.8273	0.5700	0.2643	0.6603	$\alpha=2$, $\beta=0.5$
	NDCG@20	0.8679	0.6620	0.4017	0.7314	
	MAP	**0.6740**	**0.4573**	**0.9184**	**0.6623**

	NDCG@20	0.8937	0.8200	0.4180	0.7894	
	MAP	**0.7145**	**0.6292**	**0.9897**	**0.7420**	

Table 6. Main test results

5.5 Test Result

We run all systems on test corpus, i.e. TDT2003, but only report four main systems: *Wng-sys1*, *Our-sys1*, *Our-sys2* and *Our-sys3*. Other systems are omitted because of their poor performances. The test results are shown in Table 6 which includes not only global performances for all test queries but also local ones on three distinct types of queries, i.e. "good", "fair" and "poor". Thereinto, *Our-sys2* achieves the best performance around all types of queries. So it is believable

that hierarchical distance of clustering tree always plays an active role in distinguishing negative feedbacks from relevant ones. But it is surprising that *Our-sys3* achieves little worse performance than *Our-sys2*. This illustrates poor robustness of obstinateness factor.

Interestingly, the four systems all achieve very high MAP scores but low P@20 and NDCG@20 for "poor" queries. This is because the queries have inherently sparse relevant feedbacks: less than 6‰ averagely. Thus the highest p@20 is only approximate 0.3, i.e. 6/20. And the low NDCG@20 is in the same way. Besides, all MAP scores for "fair" queries are the worst. We find that this type of query involves more macroscopic features which results in more kernels of negative feedbacks. Although we can solve the issue by increasing the dimensionality of opposite intent, it undoubtedly impairs the efficiency of re-ranking.

6. CONCLUSION

This paper proposes a new re-ranking scheme to well explore the opposite intent. In particular, a hierarchical distance-based (HD) measure is proposed to differentiate the opposite intent from the true query intent so as to repel negative feedbacks. Experiments show substantial outperformance of our methods.

Although our scheme has been proven effective in most cases, it fails on macroscopic queries. In fact, the key difficulty of this issue lies in how to ascertain the focal query intent given various kernels in pseudo-feedback. Fortunately, click-through data provide some useful information for learning real query intent. Although it seems feasible to generate focal intent representation by using overlapping terms in clicked feedbacks, such representation is just a reproduction of macroscopic query since the overlapping terms can only reflect common topic instead of focal intent. Therefore, it is important to segment clicked feedbacks into different blocks, and ascertain the block of greatest interest to searchers.

Morphological analysis can improve a CCG parser for English

Matthew Honnibal, Jonathan K. Kummerfeld and James R. Curran

University of Sydney
{mhonn, jono, james}@it.usyd.edu.au

Abstract

Because English is a low morphology language, current statistical parsers tend to ignore morphology and accept some level of redundancy. This paper investigates how costly such redundancy is for a lexicalised grammar such as CCG.

We use morphological analysis to split verb inflectional suffixes into separate tokens, so that they can receive their own lexical categories. We find that this improves accuracy when the splits are based on correct POS tags, but that errors in gold standard or automatically assigned POS tags are costly for the system. This shows that the parser can benefit from morphological analysis, so long as the analysis is correct.

1 Introduction

English is a configurational language, so grammatical functions are mostly expressed through word order and function words, rather than with inflectional morphology. Most English verbs have four forms, and none have more than five. Most of the world's languages have far richer inflectional morphology, some with millions of possible inflection combinations.

There has been much work on addressing the sparse data problems rich morphology creates, but morphology has received little attention in the English statistical parsing literature. We suggest that English morphology may prove to be an underutilised aspect of linguistic structure that can improve the performance of an English parser. English also has a rich set of resources available, so an experiment that is difficult to perform with another language may be easier to conduct in English, and a technique that makes good use of English morphology may transfer well to a morphologically rich language. under-exploited in English natural language

In this paper, we show how morphological information can improve an English statistical parser based on a lexicalised formalism, Combinatory Categorial Grammar (CCG, Steedman, 2000), using a technique suggested for Turkish (Bozsahin, 2002) and Korean (Cha et al., 2002). They describe how a morphologically rich language can be analysed efficiently with CCG by splitting off inflectional affixes as morphological tokens. This allows the affix to receive a category that performs the feature coercion. For instance, *sleeping* would ordinarily be assigned the category $S[ng]\backslash NP$: a sentence with the $[ng]$ feature requiring a leftward NP argument. We split the word into two tokens:

sleep	-ing
$S[b]\backslash NP$	$(S[ng]\backslash NP)\backslash(S[b]\backslash NP)$

The additional token creates a separate space for inflectional information, factoring it away from the argument structure information.

Even with only 5 verb forms in English, we found that accurate morphological analysis improved parser accuracy. However, the system had trouble recovering from analysis errors caused by incorrect POS tags.

We then tested how inflection categories interacted with *hat categories*, a linguistically-motivated extension to the formalism, proposed by Honnibal and Curran (2009), that introduces some sparse data problems but improves parser effiency. The parser's accuracy improved by 0.8% when gold standard POS tags were used, but not with automatic POS tags. Our method addresses problems caused by even low morphology, and future work will make the system more robust to POS tagging errors.

Coling 2008: Poster Volume, pages 445–453,
Beijing, August 2010

2 Combinatory Categorial Grammar

Combinatory Categorial Grammar (CCG, Steedman, 2000) is a lexicalised grammar, which means that each word in the sentence is associated with a category that specifies its argument structure and the type and features of the constituent that it heads. For instance, *in* might head a PP-typed constituent with one NP-typed argument, written as PP/NP. The $/$ operator denotes an argument to the right; $\backslash$ denotes an argument to the left. For example, a transitive verb is a function from a rightward NP to and a leftward NP to a sentence, $(S\backslash NP)/NP$. The grammar consists of a few schematic rules to combine the categories:

$$\begin{array}{rcll} X/Y & Y & \Rightarrow_{>} & X \\ Y & X\backslash Y & \Rightarrow_{<} & X \\ X/Y & Y/Z & \Rightarrow_{>\mathbf{B}} & X/Z \\ Y\backslash Z & X\backslash Y & \Rightarrow_{<\mathbf{B}} & X\backslash Z \\ Y/Z & X\backslash Y & \Rightarrow_{<\mathbf{B}_{\times}} & X/Z \end{array}$$

CCGbank (Hockenmaier and Steedman, 2007) extends this grammar with a set of type-changing rules, designed to strike a better balance between sparsity in the category set and ambiguity in the grammar. We mark such productions **TC**.

In wide-coverage descriptions, categories are generally modelled as typed feature structures (Shieber, 1986), rather than atomic symbols. This allows the grammar to include head indices, and to unify under-specified features. In our notation features are annotated in square-brackets, e.g. $S[dcl]$. Head-finding indices are annotated on categories as subscripts, e.g. $(NP_y\backslash NP_y)/NP_z$. We occasionally abbreviate $S\backslash NP$ as VP, and $S[adj]\backslash NP$ as ADJ.

2.1 Statistical CCG parsing and morphology

In CCGbank, there are five features that are largely governed by the inflection of the verb:

writes/wrote	$(S[dcl]\backslash NP)/NP$
(was) written	$(S[pss]\backslash NP)/NP$
(has) written	$(S[pt]\backslash NP)/NP$
(is) writing	$(S[ng]\backslash NP)/NP$
(to) write	$(S[b]\backslash NP)/NP$

The features are necessary for satisfactory analyses. Without inflectional features, there is no way to block over-generation like *has running* or *was ran*. However, the inflectional features also create a level of redundancy if the different inflected forms are treated as individual lexical entries. The different inflected forms of a verb will all share the same set of potential argument structures, so some way of grouping the entries together is desirable.

Systems like the PET HPSG parser (Oepen et al., 2004) and the XLE LFG parser (Butt et al., 2006) use a set of lexical rules that match morphological operations with transformations on the lexical categories. For example, a lexical rule is used to ensure that an intransitive verb like *sleeping* receives the same argument structure as the base form *sleep*, but with the appropriate inflectional feature. This scheme works well for rule-based parsers, but it is less well suited for statistical parsers, as the rules propose categories but do not help the model estimate their likelihood or assign them feature weights.

Statistical parsers for lexicalised formalisms such as CCG are very sensitive to the number of categories in the lexicon and the complexity of the mapping between words and categories. The sub-task of assigning lexical categories, *supertagging* (Bangalore and Joshi, 1999), is most of the parsing task. Supertaggers mitigate sparse data problems by using a label frequency threshold to prune rare categories from the search space. Clark and Curran (2007) employ a tag dictionary that restricts the model to assigning word/category pairs seen in the training data for frequent words.

The tag dictionary causes some level of undergeneration, because not all valid word/category pairs will occur in the limited training data available. The morphological tokens we introduce help to mitigate this, by bringing together what were distinct verbs and argument structures, using lemmatisation and factoring inflection away from argument structures. The tag dictionaries for the inflectional morphemes will have very high coverage, because there are only a few inflectional categories and a few inflectional types.

3 Inflectional Categories

We implement the morphemic categories that have been discussed in the CCG literature

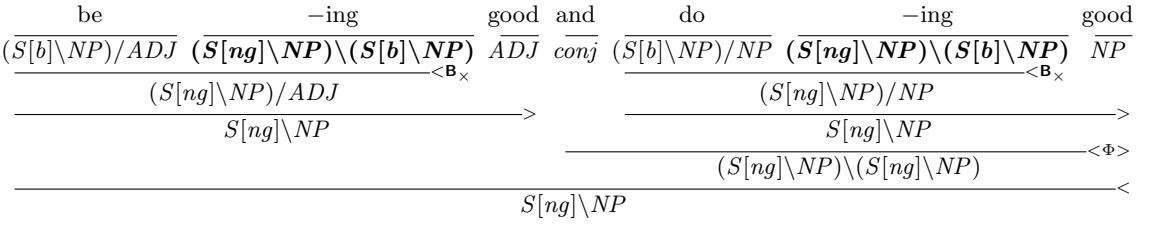

Figure 1: A single inflection category (in bold) can serve many different argument structures.

(Bozsahin, 2002; Cha et al., 2002). The inflected form is broken into two morphemes, and each is assigned a category. The category for the inflectional suffix is a function from a category with the bare-form feature $[b]$ to a category that has an inflectional feature. This prevents verbal categories from having to express their inflectional features directly. Instead, their categories only have to express their argument structure.

The CCG combinators allow multiple argument structures to share a single inflectional category. For instance, the $(S[ng]\NP)\(S[b]\NP)$ category can supply the $[ng]$ feature to all categories that have one leftward NP argument and any number of rightward arguments, via the generalised backward composition combinator. Figure 1 shows this category transforming two different argument structures, using the backward crossed composition rule ($<\mathbf{B}_\times$).

Table 1 shows the most frequent inflection categories we introduce. The majority of inflected verbs in the corpus have a subject and some number of rightward arguments, so we can almost assign one category per feature. The most frequent exceptions are participles that function as pre-nominal modifiers and verbs of speech.

Table 2 shows the inflectional token types we introduce and which features they correspond to. Our scheme largely follows the Penn Treebank tag set (Bies et al., 1995), except we avoided distinguishing past participles from past tense (*-en* vs *-ed*), because this distinction was a significant source of errors for our morphological analysis process, which relies on the part-of-speech tag.

3.1 Creating Training Data

We prepared a version of CCGbank (Hockenmaier and Steedman, 2007) with inflectional tokens. This involved the following steps:

Correcting POS tags: Our morphological analysis relies on the part-of-speech tags provided with CCGbank. We identified and corrected words whose POS tags were inconsistent with their lexical category, as discussed in Section 3.2.

Freq.	Category	Example
32.964	$(S[dcl]\NP)\(S[b]\NP)$	*He ran*
11,431	$(S[pss]\NP)\(S[b]\NP)$	*He was run down*
11,324	$(S[ng]\NP)\(S[b]\NP)$	*He was running*
4,343	$(S[pt]\NP)\(S[b]\NP)$	*He has run*
3,457	$(N/N)\(S[b]\NP)$	*the running man*
2,011	$S[dcl]\S$	*"..", he says*
1,604	$(S[dcl]\S)\(S[b]\S)$	*"..", said the boy*
169	$(S[dcl]\ADJ)\(S[b]\ADJ)$	*Here 's the deal*
55	$(S[dcl]\PP)\(S[b]\PP)$	*On it was a bee*

Table 1: The inflectional categories introduced.

Token	POS	Feat	Example
-es	VBZ	dcl	*He write -es letters*
-e	VBP	dcl	*They write -e letters*
-ed	VBD	dcl	*They write -ed letters*
-ed	VBN	pt	*They have write -ed letters*
-ed	VBN	pss	*Letters were write -ed*
-ing	VBG	ng	*They are write -ing letters*

Table 2: The inflectional token types introduced.

Lemmatising verbs and removing features: We used the morphy WordNet lemmatiser implemented in NLTK[1] to recover the lemma of the inflected verbs, identified by their POS tag (VBP, VBG, VBN or VBZ). The verb's categories were updated by switching their features to $[b]$.

Deriving inflectional categories: The generalised backward composition rules allow a functor to generalise over some sequence of argument categories, so long as they all share the same directionality. For instance, a functor $(S\NP)\(S\NP)$ could backward cross-compose into a category $((S\NP)/NP)/PP$ to its left, generalising over the two rightward arguments that were not specified by the functor's argument. It could not, however, compose into a category like $((S\NP)\NP)/PP$, because the two arguments (NP and PP) have differing direc-

334	All others		
2,815	Total		

Table 3: The most frequent POS tag conversions.

tionalities (leftward and rightward).

Without this restriction, we would only require one inflection category per feature, using inflectional categories like $S[ng]\backslash S[b]$. Instead, our inflectional categories must subcategorise for every argument except the outermost directionally consistent sequence. We discard this outermost consistent sequence, remove all features, and use the resulting category as the argument and result. We then restore the result's feature, and set the argument's feature to $[b]$.

Inserting inflectional tokens: Finally, the inflectional token is inserted after the verb, with a new node introduced to preserve binarisation.

3.2 POS tag corrections

Hockenmaier and Steedman (2007) corrected several classes of POS tag errors in the Penn Treebank when creating CCGbank. We follow Clark and Curran (2007) in using their corrected POS labels, but found that there were still some words with inconsistent POS tags and lexical categories, such as `building|NN|(S[dcl]\NP)/NP`.

In order to make our morphological analysis more consistent, we identify and correct such POS tagging errors as follows. We use two regular expressions to identify verbal lexical categories and verbal POS tags: `^\(*S\[(dcl|pss|ng|pt|b)\]` and `AUX|MD|V..` respectively. If a word has a verbal lexical category and non-verbal POS, we correct its POS tag with reference to its suffix and its category's inflectional feature. If a word has a verbal POS tag and a non-verbal lexical category, we select the POS tag that occurs most frequently with its lexical category.

The only exception are verbs functioning as nominal modifiers, such as *running* in *the running man*, which are generally POS tagged VBG but receive a lexical category of N/N. We leave these POS tagged as verbs, and instead analyse their suffixes as performing a form-function transformation that turns them from $S[b]\backslash NP$ verbs into N/N adjectives — $(N/N)\backslash(S[b]\backslash NP)$.

Table 3 lists the most common before-and-after POS tag pairs from our corrections, and the words that most frequently exemplified the pair. When compiling the table some clear errors came to light, such as the 'correction' of `is|VBZ` to `is|NN`. These errors may explain why the POS tagger's accuracy drops by 0.1% on the corrected set, and suggest that the problem of aligning POS tags and supertags is non-trivial.

In light of these errors, we experimented with an alternate strategy. Instead of correcting the POS tags, we introduced null inflectional categories that compensated for bad morphological tokenisation such as `accord|VBG|(S/S)/PP -ing|VIG|-`. The null inflectional category does not interact with the rest of the derivation, much like a punctuation symbol. This performed little better than the baseline, showing that the POS tag corrections made an important contribution, despite the problems with our technique.

3.3 Impact on CCGbank Lexicon

Verbal categories in CCGbank (Hockenmaier and Steedman, 2007) record both the valency and the inflectional morphology of the verb they are assigned to. This means $v \times i$ categories are required, where v and i are the number of distinct argument structures and inflectional features in the grammar respectively.

The inflectional tokens we propose allow inflectional morphology to be largely factored away from the argument structure, so that roughly $v + i$ verbal categories are required. A smaller category set leads to lower category ambiguity, making the assignment decision easier.

Table 4 summarises the effects of inflection categories on the lexicon extracted from CCGbank. Clark and Curran (2007) extract a set of 425 categories from the training data (Sections 02-21) that

consists of all categories that occur at least 10 times. The frequency cut off is used because the model will not have sufficient evidence to assign the other 861 categories that occur at least once, and their distribution is heavy tailed: together, they only occur 1,426 times. We refer to the frequency filtered set as the lexicon. The parser cannot assign a category outside its lexicon, so gaps in it cause under-generation.

The CCGbank lexicon includes 159 verbal categories. There are 74 distinct argument structures and 5 distinct features among these verbal categories. The grammar Clark and Curran (2007) learn therefore under-generates, because 211 of the 370 (5×74) argument structure and feature combinations are rare or unattested in the training data. For instance, there is a $(S[dcl]\backslash NP)/PP$ category, but no corresponding $(S[b]\backslash NP)/PP$, making it impossible for the grammar to generate a sentence like *I want to talk to you*, as the correct category for *talk* in this context is missing. It would be trivial to add the missing categories to the lexicon, but a statistical model would be unable to reproduce them. There are 8 occurrences of such missing categories in Section 00, the development data.

The reduction in data sparsity brought by the inflection categories causes 22 additional argument structures to cross the frequency threshold into the lexicon. A grammar induced from this corpus is thus able to generate 480 (96×5) argument structure and feature combinations, three times as many as could be generated before.

We introduce 15 inflectional categories in the corpus. The ten most frequent are shown in Table 1. The combinatory rules allow these 15 inflection categories to serve 96 argument structures, reducing the number of verbal categories in the lexicon from 159 to 89 ($74 + 15$).

The statistics at frequency 1 are less reliable, because many of the categories may be linguistically spurious: they may be artefacts caused by annotation noise in the Penn Treebank, or the conversion heuristics used by Hockenmaier and Steedman (2007).

	$\geq$	CCGbank	+Inflect
Inflection categories	10	0	15
Argument structures	10	74	96
Verb categories generated	10	159	480
All categories	10	425	375
Inflection categories	1	0	31
Argument structures	1	283	283
Verbs categories generated	1	498	1415
All categories	1	1285	1120

Table 4: Effect of inflection tokens on the category set for categories with frequency ≥ 10 and ≥ 1

3.4 Configuration of parsing experiments

We conducted two sets of parsing experiments, comparing the impact of inflectional tokens on CCGbank (Hockenmaier and Steedman, 2007) and *hat* CCGbank (Honnibal and Curran, 2009). The experiments allow us to gauge the impact of inflectional tokens on versions of CCGbank with differing numbers of verbal categories.

We used revision 1319 of the C&C parser[2] (Clark and Curran, 2007), using the best-performing configuration they describe, which used the hybrid dependency model. The most important hyper-parameters in their configuration are the β and K values, which control the workflow between the supertagger and parser. We use the Honnibal and Curran (2009) values of these parameters in our hat category experiments, described in Section 5.

Accuracy was evaluated using labelled dependency F-scores (LF). CCG dependencies are labelled by the head's lexical category and the argument slot that the dependency fills. We evaluated the baseline and inflection parsers on the unmodified dependencies, to allow direct comparison. For the inflection parsers, we pre-processed the POS-tagged input to introduce inflection tokens, and post-processed it to remove them.

We follow Clark and Curran (2007) in not evaluating accuracy over sentences for which the parser returned no analysis. The percentage of sentences analysed is described as the parser's *coverage* (C). Speed (S) figures refer to sentences parsed per second (including failures) on a dual-CPU Pentium 4 Xeon with 4GB of RAM.

4 Parsing Results on CCGbank

Table 5 compares the performance of the parser on Sections 00 and 23 with and without inflection tokens. Section 00 was used for development experiments to test different approaches, and Section 23 is the test data. Similar effects were observed on both evaluation sections.

The inflection tokens had no significant impact on speed or coverage, but did improve accuracy by 0.49% F-measure when gold standard POS tags were used, compared to the baseline. However, some of the accuracy improvement can be attributed to the POS tag corrections described in Section 3.2, so the improvement from the inflection tokens alone was 0.39%.

The POS tag corrections caused a large drop in performance when automatic POS tags were used. We attribute this to the imperfections in our correction strategy. The inflection tokens improved the accuracy by 0.39%, but this was not large enough to correct for the drop in accuracy caused by the POS changes.

Another possibility is that our morphological analysis makes POS tagger errors harder to recover from. Instead of an incorrect feature value, POS tag errors can now induce poor morphological splits such as `starl|VBG -ing|VIG`. POS tagging errors are already problematic for the C&C parser, because only the highest ranked tag is forwarded to the supertagger as a feature. Our morphological analysis strategy seems to exacerbate this error propagation problem. Curran et al. (2006) showed that using a beam of POS tags as features in the supertagger and parser mitigated the loss of accuracy from POS tagging errors. Unfortunately, with our morphological analysis strategy, POS tag variations change the tokenisation of a sentence, making parsing more complicated. Perhaps the best solution would be to address the tagging errors in the treebank more thoroughly, and reform the annotation scheme to deal with particularly persistant error cases. This might improve POS tag accuracy to a level where errors are rare enough to be unproblematic.

Despite the limited morphology in English, the inflectional tokens improved the parser's accuracy when gold standard POS tags were supplied. We attribute the increase in accuracy to the more efficient word-to-category mapping caused by replacing inflected forms with lemmas, and feature-bearing verb categories with ones that only refer to the argument structure. We examined this hypothesis by performing a further experiment, to investigate how inflection tokens interact with *hat categories*, which introduce additional verbal categories that represent form-function discrepancies.

		Gold POS			Auto POS		
		LF	S	C	LF	S	C
Baseline	00	87.19	22	99.22	85.28	24	99.11
+POS	00	87.46	24	99.16	85.04	23	99.05
+Inflect	00	87.81	24	99.11	85.33	23	98.95
Baseline	23	87.69	36	99.63	85.50	36	99.58
+POS	23	87.79	36	99.63	85.06	36	99.50
+Inflect	23	88.18	36	99.58	85.42	33	99.34

Table 5: Effect of POS changes and inflection tokens on accuracy (LF), speed (S) and coverage (C) on 00 and 23.

5 Inflection Tokens and Hat Categories

Honnibal and Curran (2009) introduce an extension to the CCG formalism, *hat categories*, as an alternative way to solve the modifier category proliferation (MCP) problem. MCP is caused when a modifier is itself modified by another modifier. For instance, in the sentence *he was injured running with scissors*, *with* modifies *running*, which modifies *injured*. This produces the category $((VP\backslash VP)\backslash(VP\backslash VP))/NP$ for *with*, a rare category that is sensitive to too much of the sentence's structure.

Hockenmaier and Steedman (2007) address MCP by adding type-changing rules to CCGbank. These type-changing rules transform specific categories. They are specific to the analyses in the corpus, unlike the standard combinators, which are schematic and language universal. Honnibal and Curran's (2009) contribution is to extend the formalism to allow these type-changing rules to be lexically specified, restoring universality to the grammar — but at the cost of sparse data problems in the lexicon. Figure 2 shows how a reduced relative clause is analysed using hat categories. The hat category $(S[pss]\backslash NP)^{NP\backslash NP}$ is subject to the *unhat* rule, which unarily replaces it with its hat, $NP\backslash NP$, allowing it to function as a modifier.

Hat categories have a practical advantage for a parser that uses a supertagging phase (Bangalore

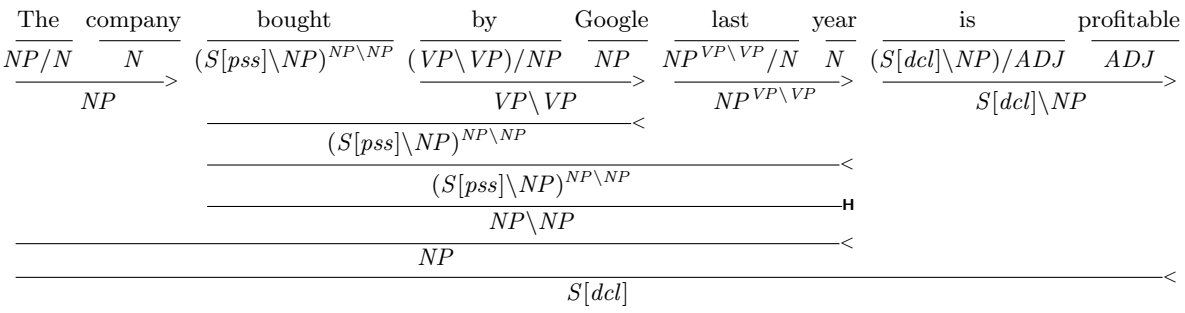

Figure 2: CCG derivation showing hat categories and the unhat rule.

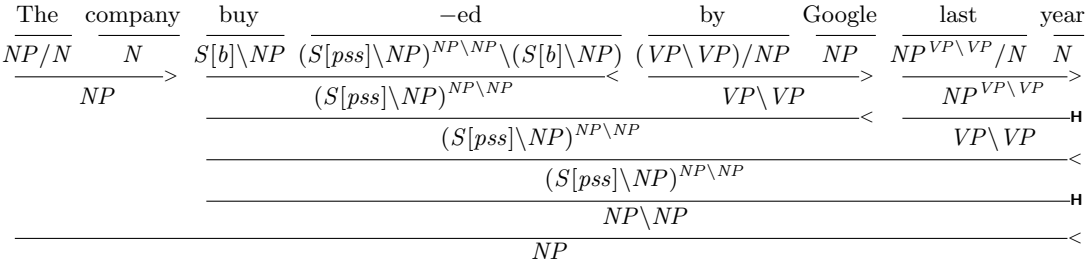

Figure 3: CCG derivation showing how inflectional tokens interact with hat categories.

and Joshi, 1999), such as the C&C system (Clark and Curran, 2007). By replacing type-changing rules with additional lexical categories, more of the work is shifted to the supertagger. The supertagging phase is much more efficient than the chart parsing stage, so redistribution of labour makes the parser considerably faster.

Honnibal and Curran (2009) found that the parser was 37% faster on the test set, at a cost of 0.5% accuracy. They attribute the drop in accuracy to sparse data problems for the supertagger, due to the increase in the number of lexical categories. We hypothesised that inflectional categories could address this problem, as the two analyses interact well.

5.1 Analyses with inflectional hat categories

Using hat categories to lexicalise type-changing rules offers attractive formal properties, and some practical advantages. However, it also misses some generalisations. A type-changing operation such as $S[ng]\backslash NP \rightarrow NP\backslash NP$ must be available to any VP. If we encounter a new word, *The company is blagging its employees*, we can generalise to the reduced relative form, *She works for that company blagging its employees* with no additional information.

This property could be preserved with some form of lexical rule, but a novel word-category pair is difficult for a statistical model to assign. Inflection tokens offer an attractive solution to this problem, as shown in Figure 3. Assigning the hat category to the suffix makes it available to any verb the suffix follows — it is just another function the inflectional suffix can perform. This generality also makes it much easier to learn, because it does not matter whether the training data happens to contain examples of a given verb perfoming that grammatical function.

We prepared a version of the Honnibal and Curran (2009) hat CCGbank, moving hats on to inflectional categories wherever possible. The hat CCGbank's lexicon contained 105 hat categories, of which 77 were assigned to inflected verbs. We introduced 33 inflection hat categories in their place, reducing the number of hat categories by 27.9%. Fewer hat categories were required because different argument structures could be served by the same inflection category. For instance, the $(S[ng]\backslash NP)^{NP\backslash NP}$ and $(S[ng]\backslash NP)^{NP\backslash NP}/NP$ categories were both replaced by the $(S[ng]\backslash NP)^{NP\backslash NP}\backslash(S[b]\backslash NP)$ category. Table 6 lists the most frequent inflection hat categories we introduce.

Freq.	Category
3332	$(S[pss]\backslash NP)^{NP\backslash NP}\backslash(S[b]\backslash NP)$
1518	$(S[ng]\backslash NP)^{NP\backslash NP}\backslash(S[b]\backslash NP)$
1231	$(S[ng]\backslash NP)^{(S\backslash NP)\backslash(S\backslash NP)}\backslash(S[b]\backslash NP)$
360	$((S[dcl]\backslash NP)/NP)^{NP\backslash NP}\backslash((S[b]\backslash NP)/NP)$
316	$(S[ng]\backslash NP)^{NP}\backslash(S[b]\backslash NP)$
234	$((S[dcl]\backslash NP)/S)^{S/S}\backslash((S[b]\backslash NP)/S)$
209	$(S[ng]\backslash NP)^{S/S}\backslash(S[b]\backslash NP)$
162	$(S[dcl]^{NP\backslash NP}\backslash NP)\backslash(S[b]\backslash NP)$
157	$((S[dcl]\backslash NP)/S)^{VP/VP}\backslash((S[b]\backslash NP)/S)$
128	$(S[pss]\backslash NP)^{S/S}\backslash(S[b]\backslash NP)$

Table 6: The most frequent inflection hat categories.

5.2 Parsing results

Table 7 shows the hat parser's performance with and without inflectional categories. We used the values for the β and K hyper-parameters described by Honnibal and Curran (2009). These hyper-parameters were tuned on Section 00, and some over-fitting seems apparent. We also followed their dependency conversion procedure, to allow evaluation over the original CCGbank dependencies and thus direct comparison with Table 5. We also merged the parser changes they described into the development version of the C&C parser we are using, for parse speed comparison.

Interestingly, incorporating the hat changes into the current version has increased the advantage of the hat categories. Honnibal and Curran report a 37% improvement in speed for the hybrid model (which we are using) on Section 23, using gold standard POS tags. With our version of the parser, the improvement is 86% (36 vs. 67 sentences parsed per second).

With gold standard POS tags, the inflection tokens improved the hat parser's accuracy by 0.8%, but decreased its speed by 24%. We attribute the decrease in speed to the increase in sentence length coupled with the new uncertainty on the inflectional tokens. Coverage increased slightly with gold standard POS tags, but decreased with automatic POS tags. We attribute this to the fact that POS tagging errors lead to morphological analysis errors.

The accuracy improvement on the hat corpus was more robust to POS tagging errors than the CCGbank results, however. This may be because POS tagging errors are already quite problematic for the hat category parser. POS tag features are more important for the supertagger than the parser, and the supertagger performs more of the work for the hat parser.

		Gold POS			Auto POS		
		LF	S	C	LF	S	C

Hat baseline	23	87.26	67	99.50	84.93	53	99.58
Hat inflect	23	88.06	54	99.63	85.25	43	99.38

Table 7: Effect of inflection tokens on accuracy (LF), speed (S) and coverage (C) on Sections 00 and 23.

6 Conclusion

Lexicalised formalisms like CCG (Steedman, 2000) and HPSG (Pollard and Sag, 1994) have led to high-performance statistical parsers of English, such as the C&C CCG parser (Clark and Curran, 2007) and the ENJU HPSG (Miyao and Tsuji, 2008) parser. The performance of these parsers can be partially attributed to their theoretical foundations. This is particularly true of the C&C parser, which exploits CCG's lexicalisation to divide the parsing task between two integrated models (Clark and Curran, 2004).

We have followed this formalism-driven approach by exploiting morphology for English syntactic parsing, using a strategy designed for morphologically rich languages. Combining our technique with hat categories leads to a 20% improvement in efficiency, with a 0.25% loss of accuracy. If the POS tag error problem were addressed, the two strategies combined would improve efficiency by 50%, and improve accuracy by 0.37%. These results illustrate that linguistically motivated solutions can produce substantial practical advantages for language technologies.

Acknowledgments

We would like to thank the anonymous reviewers for their feedback, and the members of the CCG-technicians mailing list for discussion about some of our analyses. What's in a Preposition? Dimensions of Sense Disambiguation for an Interesting Word Class

Dirk Hovy, Stephen Tratz, and Eduard Hovy
Information Sciences Institute
University of Southern California
{dirkh, stratz, hovy}@isi.edu

Abstract

Choosing the right parameters for a word sense disambiguation task is critical to the success of the experiments. We explore this idea for prepositions, an often overlooked word class. We examine the parameters that must be considered in preposition disambiguation, namely context, features, and granularity. Doing so delivers an increased performance that significantly improves over two state-of-the-art systems, and shows potential for improving other word sense disambiguation tasks. We report accuracies of 91.8% and 84.8% for coarse and fine-grained preposition sense disambiguation, respectively.

1 Introduction

Ambiguity is one of the central topics in NLP. A substantial amount of work has been devoted to disambiguating prepositional attachment, words, and names. Prepositions, as with most other word types, are ambiguous. For example, the word *in* can assume both temporal ("in May") and spatial ("in the US") meanings, as well as others, less easily classifiable ("in that vein"). Prepositions typically have more senses than nouns or verbs (Litkowski and Hargraves, 2005), making them difficult to disambiguate.

Preposition sense disambiguation (PSD) has many potential uses. For example, due to the relational nature of prepositions, disambiguating their senses can help with all-word sense disambiguation. In machine translation, different senses of the same English preposition often correspond to different translations in the foreign language. Thus, disambiguating prepositions correctly may help improve translation quality.[1] Coarse-grained PSD can also be valuable for information extraction, where the sense acts as a label. In a recent study, Hwang et al. (2010) identified preposition related features, among them the coarse-grained PP labels used here, as the most informative feature in identifying caused-motion constructions. Understanding the constraints that hold for prepositional constructions could help improve PP attachment in parsing, one of the most frequent sources of parse errors.

Several papers have successfully addressed PSD with a variety of different approaches (Rudzicz and Mokhov, 2003; O'Hara and Wiebe, 2003; Ye and Baldwin, 2007; O'Hara and Wiebe, 2009; Tratz and Hovy, 2009). However, while it is often possible to increase accuracy by using a different classifier and/or more features, adding more features creates two problems: a) it can lead to overfitting, and b) while possibly improving accuracy, it is not always clear where this improvement comes from and which features are actually informative. While parameter studies exist for general word sense disambiguation (WSD) tasks (Yarowsky and Florian, 2002), and PSD accuracy has been steadily increasing, there has been no exploration of the parameters of prepositions to guide engineering decisions.

We go beyond simply improving accuracy to analyze various parameters in order to determine which ones are actually informative. We explore the different options for context and feature se-

[1] See (Chan et al., 2007) for the relevance of word sense disambiguation and (Chiang et al., 2009) for the role of prepositions in MT.

Coling 2008: Poster Volume, pages 454–462,
Beijing, August 2010

lection, the influence of different preprocessing methods, and different levels of sense granularity. Using the resulting parameters in a Maximum Entropy classifier, we are able to improve significantly over existing results. The general outline we present can potentially be extended to other word classes and improve WSD in general.

2 Related Work

Rudzicz and Mokhov (2003) use syntactic and lexical features from the governor and the preposition itself in coarse-grained PP classification with decision heuristics. They reach an average F-measure of 89% for four classes. This shows that using a very small context can be effective. However, they did not include the object of the preposition and used only lexical features for classification. Their results vary widely for the different classes.

O'Hara and Wiebe (2003) made use of a window size of five words and features from the Penn Treebank (PTB) (Marcus et al., 1993) and FrameNet (Baker et al., 1998) to classify prepositions. They show that using high level features, such as semantic roles, significantly aid disambiguation. They caution that using collocations and neighboring words indiscriminately may yield high accuracy, but has the risk of overfitting. O'Hara and Wiebe (2009) show comparisons of various semantic repositories as labels for PSD approaches. They also provide some results for PTB-based coarse-grained senses, using a five-word window for lexical and hypernym features in a decision tree classifier.

SemEval 2007 (Litkowski and Hargraves, 2007) included a task for fine-grained PSD (more than 290 senses). The best participating system, that of Ye and Baldwin (2007), extracted part-of-speech and WordNet (Fellbaum, 1998) features using a word window of seven words in a Maximum Entropy classifier. Tratz and Hovy (2009) present a higher-performing system using a set of 20 positions that are syntactically related to the preposition instead of a fixed window size.

Though using a variety of different extraction methods, contexts, and feature words, none of these approaches explores the optimal configurations for PSD.

3 Theoretical Background

The following parameters are applicable to other word classes as well. We will demonstrate their effectiveness for prepositions.

Analyzing the syntactic elements of prepositional phrases, one discovers three recurring elements that exhibit syntactic dependencies and define a prepositional phrase. The first one is the governing word (usually a noun, verb, or adjective)[2], the preposition itself, and the object of the preposition.

Prepositional phrases can be fronted ("*In May*, prices dropped by 5%"), so that the governor (in this case the verb "drop") occurs later in the sentence. Similarly, the object can be fronted (consider "*a dessert* to die for").

In the simplest version, we can do classification based only on the preposition and the governor or object alone.[3] Furthermore, directly neighboring words can influence the preposition, mostly two-word prepositions such as "out of" or "because of".

To extract the words discussed above, one can either employ a fixed window size, (which has to be large enough to capture the words), or select them based on heuristics or parsing information. The governor and object can be hard to extract if they are fronted, since they do not occur in their unusual positions relative to the preposition. While syntactically related words improve over fixed-window-size approaches (Tratz and Hovy, 2009), it is not clear which words contribute most. There should be an optimal context, i.e., the smallest set of words that achieves the best accuracy. It has to be large enough to capture all relevant information, but small enough to avoid noise words.[4] We surmise that earlier approaches were not utilizing that optimal context, but rather include a lot of noise.

Depending on the task, different levels of sense granularity may be used. Fewer senses increase the likelihood of correct classification, but may in-

[2]We will refer to the governing word, irrespective of class, as governor.

[3]Basing classification on the preposition alone is not feasible, because of the very polysemy we try to resolve.

[4]It is not obvious how much information a sister-PP can provide, or the subject of the superordinate clause.

correctly conflate prepositions. A finer granularity can help distinguish nuances and better fit the different contexts. However, it might suffer from sparse data.

4 Experimental Setup

We explore the different context types (fixed window size vs. selective), the influence of the words in that context, and the preprocessing method (heuristics vs. parsing) on both coarse and fine-grained disambiguation. We use a most-frequent-sense baseline. In addition, we compare to the state-of-the-art systems for both types of granularity (O'Hara and Wiebe, 2009; Tratz and Hovy, 2009). Their results show what has been achieved so far in terms of accuracy, and serve as a second measure for comparison beyond the baseline.

4.1 Model

We use the MALLET implementation (McCallum, 2002) of a Maximum Entropy classifier (Berger et al., 1996) to construct our models. This classifier was also used by two state-of-the-art systems (Ye and Baldwin, 2007; Tratz and Hovy, 2009). For fine-grained PSD, we train a separate model for each preposition due to the high number of possible classes for each individual preposition. For coarse-grained PSD, we use a single model for all prepositions, because they all share the same classes.

4.2 Data

We use two different data sets from existing resources for coarse and fine-grained PSD to make our results as comparable to previous work as possible.

For the coarse-grained disambiguation, we use data from the POS tagged version of the Wall Street Journal (WSJ) section of the Penn TreeBank. A subset of the prepositional phrases in this corpus is labelled with a set of seven classes: beneficial (BNF), direction (DIR), extent (EXT), location (LOC), manner (MNR), purpose (PRP), and temporal (TMP). We extract only those prepositions that head a PP labelled with such a class ($N = 35,917$). The distribution of classes is highly skewed (cf. Figure 1). We compare the results of this task to the findings of O'Hara and Wiebe (2009).

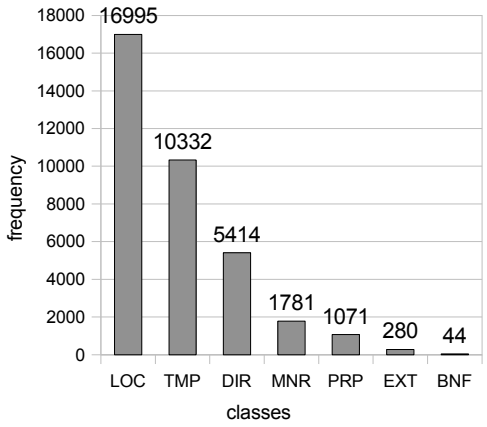

Figure 1: Distribution of Class Labels in the WSJ Section of the Penn TreeBank.

For the fine-grained task, we use data from the SemEval 2007 workshop (Litkowski and Hargraves, 2007), separate XML files for the 34 most frequent English prepositions, comprising $16,557$ training and 8096 test sentences, each instance containing one example of the respective preposition. Each preposition has between two and 25 senses (9.76 on average) as defined by The Preposition Project (Litkowski and Hargraves, 2005). We compare our results directly to the findings from Tratz and Hovy (2009). As in the original workshop task, we train and test on separate sets.

5 Results

In this section we show experimental results for the influence of word extraction method (parsing vs. POS-based heuristics), context, and feature selection on accuracy. Each section compares the results for both coarse and fine-grained granularity. Accuracy for the coarse-grained task is in all experiments higher than for the fine-grained one.

5.1 Word Extraction

In order to analyze the impact of the extraction method, we compare parsing versus POS-based heuristics for word extraction.

Both O'Hara and Wiebe (2009) and Tratz and Hovy (2009) use constituency parsers to preprocess the data. However, parsing accuracy varies,

and the problem of PP attachment ambiguity increases the likelihood of wrong extractions. This is especially troublesome in the present case, where we focus on prepositions.[5] We use the MALT parser (Nivre et al., 2007), a state-of-the-art dependency parser, to extract the governor and object.

The alternative is a POS-based heuristics approach. The only preprocessing step needed is POS tagging of the data, for which we used the system of Shen et al. (2007). We then use simple heuristics to locate the prepositions and their related words. In order to determine the governor in the absence of constituent phrases, we consider the possible governing noun, verb, and adjective. The object of the preposition is extracted as first noun phrase head to the right. This approach is faster than parsing, but has problems with long-range dependencies and fronting of the PP (e.g., the PP appearing earlier in the sentence than its governor).

extraction method	fine	coarse
MALT	84.4	94.0
Heuristics	84.8	90.9
MALT + Heuristics	84.8	91.8

Table 1: Accuracies (%) for Word-Extraction Using MALT Parser or Heuristics.

Interestingly, the extraction method does not significantly affect the final score for fine-grained PSD (see Table 1). The high score achieved when using the MALT parse for coarse-grained PSD can be explained by the fact that the parser was originally trained on that data set. The good results we see when using heuristics-based extraction only, however, means we can achieve high-accuracy PSD even without parsing.

5.2 Context

We compare the effects of fixed window size versus syntactically related words as context. Table 2 shows the results for the different types and sizes of contexts.[6]

[5]Rudzicz and Mokhov (2003) actually motivate their work as a means to achieve better PP attachment resolution.

[6]See also (Yarowsky and Florian, 2002) for experiments on the effect of varying window size for WSD.

Context	coarse	fine
2-word window	91.6	80.4
3-word window	92.0	81.4
4-word window	91.6	79.8
5-word window	91.0	78.7
Governor, prep	80.7	78.9
Prep, object	***94.2***	56.9
Governor, prep, object	94.0	***84.8***

Table 2: Accuracies (%) for Different Context Types and Sizes

The results show that the approach using both governor and object is the most accurate one. Of the fixed-window-size approaches, three words to either side works best. This does not necessarily reflect a general property of that window size, but can be explained by the fact that most governors and objects occur within this window size.[7] This distance can vary from corpus to corpus, so window size would have to be determined individually for each task. The difference between using governor and preposition versus preposition and object between coarse and fine-grained classification might reflect the annotation process: while Litkowski and Hargraves (2007) selected examples based on a search for governors[8], most annotators in the PTB may have based their decision of the PP label on the object that occurs in it. We conclude that syntactically related words present a better context for classification than fixed window sizes.

5.3 Features

Having established the context we want to use, we now turn to the details of extracting the feature words from that context.[9] Using higher-level features instead of lexical ones helps accounting for sparse training data (given an infinite amount of data, we would not need to take any higher-level

[7]Based on such statistics, O'Hara and Wiebe (2003) actually set their window size to 5.

[8]Personal communication.

[9]As one reviewer pointed out, these two dimensions are highly interrelated and influence each other. To examine the effects, we keep one dimension constant while varying the other.

features into account, since every case would be covered). Compare O'Hara and Wiebe (2009).

Following the prepocessing, we use a set of rules to select the feature words, and then generate feature values from them using a variety of feature-generating functions.[10] The word-selection rules are listed below.

Word-Selection Rules

- Governor from the MALT parse
- Object from the MALT parse
- Heuristically determined object of the preposition
- First verb to the left of the preposition
- First verb/noun/adjective to the left of the preposition
- Union of (First verb to the left, First verb/noun/adjective to the left)
- First word to the left

The feature-generating functions, many of which utilize WordNet (Fellbaum, 1998), are listed below. To conserve space, curly braces are used to represent multiple functions in a single line. The name of each feature is the combination of the word-selection rule and the output from the feature-generating function.

WordNet-based Features

- {Hypernyms, Synonyms} for {1st, all} sense(s) of the word
- All terms in the definitions ('glosses') of the word
- Lexicographer file names for the word
- Lists of all link types (e.g., meronym links) associated with the word
- Part-of-speech indicators for the existence of NN/VB/JJ/RB entries for the word
- All sentence frames for the word
- All {part, member, substance}-of holonyms for the word
- All sentence frames for the word

Other Features

- Indicator that the word-finding rule found a word
- Capitalization indicator
- {Lemma, surface form} of the word
- Part-of-speech tag for the word
- General POS tag for the word (e.g. NNS → NN, VBZ → VB)
- The {first, last} {two, three} letters of each word
- Indicators for suffix types (e.g., de-adjectival, de-nominal [non]agentive, de-verbal [non]agentive)
- Indicators for a wide variety of other affixes including those related to degree, number, order, etc. (e.g., *ultra-, poly-, post-*)
- Roget's Thesaurus divisions for the word

To establish the impact of each feature word on the outcome, we use leave-one-out and only-one evaluation.[11] The results can be found in Table 3. A word that does not perform well as the only attribute may still be important in conjunction with others. Conversely, leaving out a word may not hurt performance, despite being a good single attribute.

	coarse		fine	
Word	**LOO**	**Only**	**LOO**	**Only**
MALT governor	92.1	80.1	84.3	78.9
MALT object	93.4	94.2	84.9	56.3
Heuristics VB to left	92.0	77.9	85.0	62.1
Heur. NN/VB/ADJ to left	92.1	78.7	84.3	78.5
Heur. Governor Union	92.1	78.4	84.5	81.0
Heuristics word to left	92.0	78.8	84.4	77.2
Heuristics object	91.9	93.0	84.9	56.8
none	91.8	–	84.8	–

Table 3: Accuracies (%) for Leave-One-Out (LOO) and Only-One Word-Extraction-Rule Evaluation. *none* includes all words and serves for comparison. Important words reduce accuracy for LOO, but rank high when used as only rule.

Independent of the extraction method (MALT parser or POS-based heuristics), the governor is the most informative word. Combining several heuristics to locate the governor is the best single feature for fine-grained classification. The rule looking only for a governing verb fails to account

[10] Some words may be selected by multiple word-selection rules. For example, the governor of the preposition may be identified by the *Governor from MALT parse* rule, *first noun/verb/adjective to left*, and the *first word to the left* rule.

[11] Since the feature words are not independent of one another, neither of the two measures is decisive on its own.

for noun governors, which consequently leads to a slight improvement when left out.

Curiously, the word directly to the left is a better single feature than the object (for fine-grained classification). Leaving either of them out increases accuracy, which implies that their information can be covered by other words.

	Most Frequent Sense			O'Hara/Wiebe 2009			10-fold CV

Table 5: Precision, Recall and F1 Results (%) for Coarse-Grained Classification. Comparison to O'Hara and Wiebe (2009). Classes ordered by frequency

5.4 Comparison with Related Work

To situate our experimental results within the body of work on PSD, we compare them to both a most-frequent-sense baseline and existing work for both granularities (see Table 6). The results use a syntactically selective context of preposition, governor, object, and word to the left as determined by combined extraction information (POS tagging and parsing).

	coarse	**fine**
Baseline	75.8	39.6
Related Work	89.3*	78.3**
Our system	93.9	84.8

Table 6: Accuracies (%) for Different Classifications. Comparison with O'Hara and Wiebe (2009)*, and Tratz and Hovy (2009)**.

Our system easily exceeds the baseline for both coarse and fine-grained PSD (see Table 6). Comparison with related work shows that we achieve an improvement of 6.5% over Tratz and Hovy (2009), which is significant at $p < .0001$, and of 4.5% over O'Hara and Wiebe (2009), which is significant at $p < .0001$.

A detailed overview over all prepositions for frequencies and accuracies of both coarse and fine-grained PSD can be found in Table 4.

In addition to overall accuracy, O'Hara and Wiebe (2009) also measure precision, recall and F-measure for the different classes. They omitted BNF because it is so infrequent. Due to different training data and models, the two systems are not strictly comparable, yet they provide a sense of the general task difficulty. See Table 5. We note that both systems perform better than the most-frequent-sense baseline. DIR is reliably classified using the baseline, while EXT and BNF are never selected for any preposition. Our method adds considerably to the scores for most classes. The low score for BNF is mainly due to the low number of instances in the data, which is why it was excluded by O'Hara and Wiebe (2009).

6 Conclusion

To get maximal accuracy in disambiguating prepositions—and also other word classes—one needs to consider context, features, and granularity. We presented an evaluation of these parameters for preposition sense disambiguation (PSD).

We find that selective context is better than fixed window size. Within the context for prepositions, the governor (head of the NP or VP governing the preposition), the object of the preposition (i.e., head of the NP to the right), and the word directly to the left of the preposition have the highest influence.[12] This corroborates the linguistic intuition that close mutual constraints hold between the elements of the PP. Each word syntactically and semantically restricts the choice of the other elements. Combining different extraction methods (POS-based heuristics and dependency parsing) works better than either one in isolation, though high accuracy can be achieved just using heuristics. The impact of context and features varies somewhat for different granularities.

[12] These will likely differ for other word classes.

Not surprisingly, we see higher scores for coarser granularity than for the more fine-grained one.

We measured success in accuracy, precision, recall, and F-measure, and compared our results to a most-frequent-sense baseline and existing work. We were able to improve over state-of-the-art systems in both coarse and fine-grained PSD, achieving accuracies of 91.8% and 84.8% respectively.

Abstract

Annotating scientific publications with keywords and phrases is of great importance to searching, indexing, and cataloging such documents. Unlike previous studies that focused on user-centric annotation, this paper presents our investigation of various annotation characteristics on service-centric annotation. Using a large number of publicly available annotated scientific publications, we characterized and compared the two different types of annotation processes. Furthermore, we developed an automatic approach of annotating scientific publications based on a machine learning algorithm and a set of novel features. When compared to other methods, our approach shows significantly improved performance. Experimental data sets and evaluation results are publicly available at the supplementary website[1].

1 Introduction

With the rapid development of the Internet, the online document archive is increasing quickly with a growing speed. Such a large volume and the rapid growth pose great challenges for document searching, indexing, and cataloging. To facilitate these processes, many concepts have been proposed, such as Semantic Web (Berners-Lee et al., 2001), Ontologies (Gruber, 1993), Open Directory Projects like Dmoz[2], folksonomies (Hotho et al., 2006), and social tagging systems like Flickr and CiteULike. Annotating documents or web-pages using Ontologies and Open Directories are often limited to a manually controlled vocabulary (developed by service providers) and a small number of expert annotators, which we call ***service-centric annotation***. By contrast, social tagging systems in which registered users can freely use arbitrary words to tag images, documents or web-pages, belong to ***user-centric annotation***. Although many advantages have been reported in user-centric annotation, low-quality and undesired annotations are always observed due to uncontrolled user behaviors (Xu et al., 2006; Sigurbjörnsson and Zwol, 2008). Moreover, the vocabulary involved in user-centric annotation is arbitrary, unlimited, and rapid-growing in nature, causing more difficulties in tag-based searching and browsing (Bao et al., 2007; Li et al., 2007).

Service-centric annotation is of importance for managing online documents, particularly in serving high-quality repositories of scientific literature. For example, in biomedicine, Gene Ontology (Ashburner et al., 2000) annotation has been for a decade an influential research topic of unifying reliable biological knowledge from the vast amount of biomedical literature. Document annotation can also greatly help service providers such as ACM/IEEE portals to provide better user experience of search. Much work has been devoted to digital document annotation, such as ontology-based (Corcho, 2006) and semantic-oriented (Eriksson, 2007).

This paper focuses on *service-centric annotation*. Our task is to assign an input document a list of entries. The entries are pre-defined by a controlled vocabulary. Due to the data availability, we study the documents and vocabulary in the

[1] http://www.ncbi.nlm.nih.gov/CBBresearch/Lu/indexing
[2] http://www.dmoz.org/

Coling 2008: Poster Volume, pages 463–471,
Beijing, August 2010

biomedical domain. We first analyze human annotation behaviors in two millions previously annotated documents. When compared to user-centric annotation, we found that the two annotation processes have major differences and that they also share some common grounds. Next, we propose to annotate new articles with a learning method based on the assumption that documents similar in content share similar annotations. To this end, we utilize a logistic regression algorithm with a set of novel features. We evaluate our approach with extensive experiments and compare it to the state of the art. The contributions of this work are two-fold: First, we present an in-depth analysis on annotation behaviors between service-centric and user-centric annotation. Second, we develop an automatic method for annotating scientific publications with significant improvements over other systems.

The remainder of the paper is organized as follows: We present several definitions in Section 2 and the analysis of annotation behaviors in Section 3. In Section 4, we presented the logistic regression algorithm for annotation. Benchmarking results are shown in Section 5. We surveyed related work in Section 6 and summarized our work in Section 7.

2 Definitions

A controlled vocabulary: *V*, a set of pre-specified entries for describing certain topics. Entries in the vocabulary are organized in a hierarchical structure. This vocabulary can be modified under human supervision.

Vocabulary Entry: an entry in a controlled vocabulary is defined as a triplet: *VE = (MT, synonyms, NodeLabels)*. *MT* is a *major term* describing the entry, and *NodeLabel*s are a list of node labels in the hierarchical tree. An entry is identified by its *MT*, and a *MT* may have multiple node labels as a *MT* may be mapped to several nodes of a hierarchical tree.

Entry Binary Relation: $ISA(VE_i, VE_j)$ means entry VE_j is a child of entry VE_i, and $SIB(VE_i, VE_j)$ meaning that VE_j is a sibling of entry VE_i. A set of relations determine the structure of a hierarchy.

Entry Depth: the depth of an entry relative to the root node in the hierarchy. The root node has a depth of 1 and the immediate children of a root node has a depth of 2, and so on. A major term may be mapped to several locations in the hierarchy, thus we have minimal, maximal, and average depths for each *MT*.

Given the above definitions, a controlled vocabulary is defined as $\{<VE_i, ISA(VE_i,VE_j), SIB(VE_i,VE_j)>|any\ i, j\ \}$. The annotation task is stated as follows: given a document *D*, predicting a list of entries *VEs* that are appropriate for annotating the document. In our framework, we approach the task as a ranking problem, as detailed in Section 4.

3 Analyzing Service-centric Annotation Behavior

Analyzing annotation behaviors can greatly facilitate assessing annotation quality, reliability, and consistency. There has been some work on analyzing social tagging behaviors in user-centric annotation systems (Sigurbjörnsson and Zwol, 2008; Suchanek et al., 2008). However, to the best of our knowledge, there is no such analysis on service-centric annotation. In social tagging systems, no specific skills are required for participating; thus users can tag the resources with arbitrary words (the words may even be totally irrelevant to the content, such as "*todo*"). By contrast, in service-centric annotation, the annotators must be trained, and they must comply with a set of strict guidelines to assure the consistent annotation quality. Therefore, it is valuable to study the differences between the two annotation processes.

3.1 PubMed Document Collection

To investigate annotation behaviors, we downloaded 2 million documents from PubMed[3], one of the largest search portals for biomedical articles. These articles were published from Jan. 1, 2000 to Dec. 31, 2008. All these documents have been manually annotated by National Library Medicine (NLM) human curators. The controlled vocabulary used in this system is the Medical Subject Headings (MeSH®)[4], a thesaurus describing various biomedical topics such as diseases, chemicals and drugs, and organisms. There are 25,588 entries in the vocabulary in 2010, and there are updates annually. By comparison, the vocabulary used in user-centric annotation is re-

[3] http://www.ncbi.nlm.nih.gov/pubmed/
[4] http://www.nlm.nih.gov/mesh/

markably larger (usually more than 1 million tags) and more dynamic (may be updated every day).

3.2 Annotation Characteristics

First, we examine the distribution of the number of annotated entries in the document collection. For each number of annotated entries, we counted the number of documents with respect to different numbers of annotations. The number of annotations per document among these 2 million documents varies from 1 (with 176,383 documents) to 97 (with one document only). The average number of annotations per document is 10.10, and the standard deviation is 5.95.

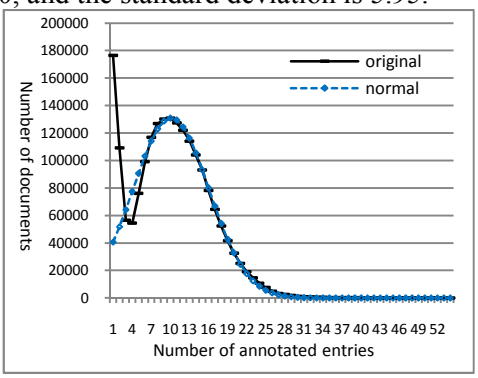

Figure 1. The original distribution and simulated normal distribution. Each data point denotes the number of documents (y-axis) that has the corresponding number of entries (x-axis).

As illustrated in Figure 1, when there are more than 4 annotations, the distribution fits a normal distribution. Comparing with user-centric annotation, there are three notable observations: a), the maximal number of annotations per document (97) is much smaller (in social tagging systems the number amounts to over 10^4) due to much less annotators involved in service-centric annotation than users in user-centric annotation; b), the number of annotations assigned to documents conforms to a normal distribution, which has not yet been reported in user-centric annotation; c), similar to user-centric annotation, the number of documents that have only one annotation accounts for a large proportion.

Second, we investigate whether the Zipf law (Zipf, 1949) holds in service-centric annotation. To this end, we ranked all the entries according to the frequency of being annotated to documents. We plotted the curve in logarithm scale, as illustrated in Figure 2. The curve can be simulated by a linear function in logarithm scale if ignoring the tail which corresponds to very infrequently used entries. To further justify this finding, we ranked all the documents according to the number of assigned annotations and plotted the curve in logarithm scale, as shown in Figure 3. Similar phenomenon is observed. In conclusion, the Zipf law also holds in service-centric annotation, just as reported in user-centric annotation (Sigurbjörnsson and Zwol, 2008).

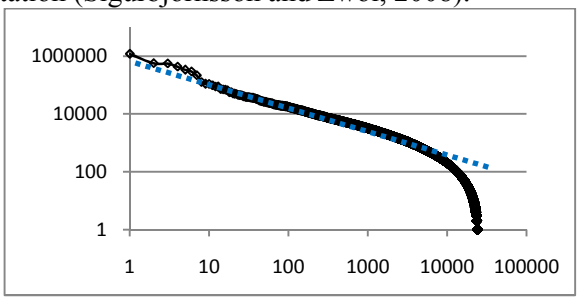

Figure 2. The distribution of annotated entry frequency. X-axis is the rank of entries (ranking by the annotation frequency), and y-axis is the frequency of an entry being used in annotation.

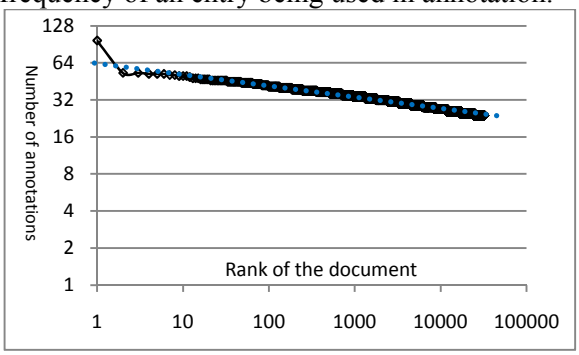

Figure 3. The distribution of the number of annotated entries. X-axis is the rank of a document (in $\log_{10}$ scale), and y-axis is the number of annotations assigned to documents (in $\log_2$ scale).

Furthermore, as mentioned in Section 2, the vocabulary corresponds to a hierarchy tree once a set of binary relations were defined. Thus we can easily obtain the minimal, maximal, and average depth of an entry. The larger depth an entry has, the more specific meaning it has.

Therefore, we investigate whether service-centric annotation is performed at very specific level (with larger depth) or general level (with smaller depth). We define prior depth and annotation depth for this study, as follows:

$$\text{PriorDepth} = \sum_{VE \in V} \frac{Dep(VE)}{|V|} \qquad (1)$$

$$\text{AnnoDepth} = \sum_{VE \in V} \Pr(VE) * Dep(VE) \quad (2)$$

$$\Pr(VE) = \frac{f(VE)}{\sum_{VE \in V} f(VE)} \quad (3)$$

where *Dep(VE)* is the minimal, maximal, or average depth of an entry, *f(VE)* is the usage frequency of *VE* in annotation, and |V| is the number of entries in the vocabulary. The two formulas are actually the mathematical expectations of the hierarchy's depth under two distributions respectively: a uniform distribution (1/|V|) and the annotation distribution (formula (3)). As shown in Table 1, the two expectations are close. This means the annotation has not been biased to either general or specific level, which suggests that the annotation quality is sound.

Dep(VE)	PriorDepth	AnnoDepth
MAX	4.88	4.56
MIN	4.25	4.02
AVG	4.56	4.29

Table 1. Annotation depth comparison.

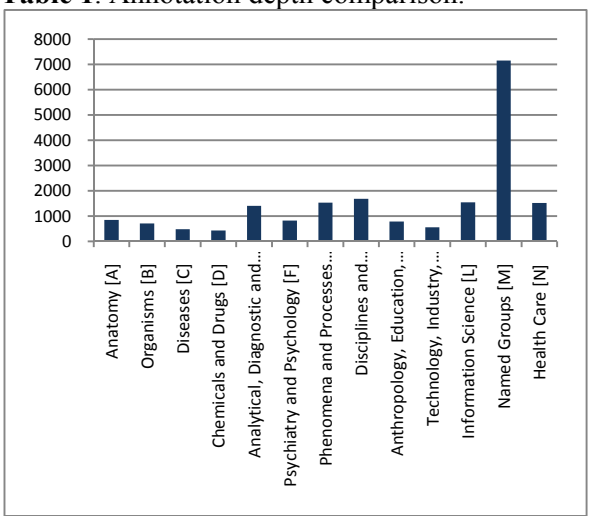

Figure 4. The imbalance frequency (y-axis) of annotated categories (x-axis).

3.3 Annotation Categorization Imbalance

We investigate here whether service-centric annotation is biased to particular categories in the hierarchy. We define a category as the label of root nodes in the hierarchy. In our vocabulary, there are 11 categories that have at least one annotation. The complete list of these categories is available at the website[5]. Three newly created categories have no annotations in the document collection. The total number of annotations within a category was divided by the number of entries in that category, as different categories may have quite different numbers of entries. If an entry is mapped to multiple locations, its annotations will be counted to corresponding categories repeatedly.

From Figure 4, we can see that there is imbalance with respect to the annotations in different categories. Category "*diseases*" has 473.5 annotations per entry (totally 4408 entries in this category). Category "*chemicals and drugs*" has 423.0 annotations per entry (with 8815 entries in total). Due to the fact that diseases and chemicals and drugs are hot scientific topics, these categories are largely under-annotated. The most frequently annotated category is: "*named groups*" (7144.4 annotations per entry), with 199 entries in total. The issue of imbalanced categorization may be due to that the topics of the document collection are of imbalance; and that the vocabulary was updated annually, so that the latest entries were used less frequently. As shown in (Sigurbjörnsson and Zwol, 2008), this imbalance issue was also observed in user-centric annotation, such as in Flickr Tagging.

4 Learning to Annotate

As shown in Section 3, there are much fewer annotations per document in service-centric annotation than in user-centric annotations. Service-centric annotation is of high quality, and is limited to a controlled vocabulary. However, manual annotation is time-consuming and labor intensive, particularly when seeking high quality. Indeed, our analysis shows that on average it takes over 90 days for a PubMed citation to be manually annotated with MeSH terms. Thus we propose **to** annotate articles automatically. Specifically, we approach this task as a ranking problem: First, we retrieve *k*-nearest neighboring (*KNN*) documents for an input document using a retrieval model (Lin and Wilbur, 2007). Second, we obtain an initial list of annotated entries from those retrieved neighboring documents. Third, we rank those entries using a logistic regression model. Finally, the top *N* ranked entries are suggested as the annotations for the target document.

4.1 Logistic Regression

We propose a probabilistic framework of directly estimating the probability that an entry can be used to annotate a document. Given a document

[5] http://www.nlm.nih.gov/mesh/2010/mesh_browser/MeSHtree.Z.html

D and an entry *VE*, we compute the probability *Pr(R(VE)|D)* directly using a logistic regression algorithm. *R(VE)* is a binary random variable indicating whether *VE* should be assigned as an annotation of the document. According to this probability, we can rank the entries obtained from neighboring documents. Much work used Logistic Regression as classification: *Pr(R=1|D)* $>\Delta$ where Δ is a threshold, but it is difficult to specify an appropriate value for the threshold in this work, as detailed in Section 5.5.

We applied the logistic regression model to this task. Logistic regression has been successfully employed in many applications including multiple ranking list merging (Si and Callan, 2005) and answer validation for question answering (Ko et al., 2007). The model gives the following probability:

$$\Pr(R(VE)\mid D)=\exp(b+\sum_{i=1}^{m}w_i*x_i)\Big/\left(1+\exp(b+\sum_{i=1}^{m}w_i*x_i)\right) \quad (4)$$

where $x=(x_1, x_2, \ldots, x_m)$ is the feature vector for *VE* and *m* is the number of features.

For an input document *D*, we can obtain an initial list of entries $\{VE_1, VE_2, \ldots, VE_n\}$ from its neighboring documents. Each entry is then represented as a feature vector as $x=(x_1, x_2, \ldots, x_m)$. Given a collection of *N* documents that have been annotated manually, each document will have a corresponding entry list, $\{VE_1, VE_2, \ldots, VE_n\}$, and each VE_i has gold-standard label $y_i=1$ if VE_i was used to annotate *D*, or $y_i=0$ otherwise. Note that the number of entries of label 0 is much larger than that of label 1 for each document. This may bias the learning algorithm. We will discuss this in Section 5.5. Given such data, the parameters can be estimated using the following formula:

$$\vec{w}^*, b^* = \arg\max_{\vec{w},b}\sum_{j=1}^{N}\sum_{i=1}^{L_j}\left(\log\Pr(R(VE_i)\mid D_j)\right) \quad (5)$$

where L_j is the number of entries to be ranked for D_j, and *N* is the total number of training documents. We can use the Quasi-Newton algorithm for parameter estimation (Minka, 2003). In this paper, we used the WEKA[6] package to implement this model.

4.2 Features

We developed various novel features to build connections between an entry and the document text. When computing these features, both the entry's text (major terms, synonyms) and the document text (title and abstract) are tokenized and stemmed. To compute these features, we collected a set of 13,999 documents (each has title, abstract, and annotations) from PubMed.

Prior probability feature. We compute the appearance probability of a major term (*MT*), estimated on the 2 million documents. This prior probability reflects the prior quality of an entry.

Unigram overlap with the title. We count the number of unigrams overlapping between the *MT* of an entry and the title, dividing by the total number of unigrams in the *MT*.

Bigram overlap with the document. We first concatenate the title and abstract, then count the number of bigram overlaps between the *MT* and the concatenated string, dividing by the total number of bigrams in the *MT*.

Multinomial distribution feature. This feature assumes that the words in a major term appear in the document text with a multinomial distribution, as follows:

$$\Pr(MT\mid Text)=\mid MT\mid !*\prod_{w\in MT}\frac{\Pr(w\mid Text)^{\#(w,MT)}}{\#(w,MT)!} \quad (6)$$

$$\Pr(w\mid Text)=(1-\lambda)\frac{\#(w,Text)}{\sum_{w_i}\#(w_i,Text)}+\lambda\Pr_c(w) \quad (7)$$

where:

#(w,MT) - The number of times that *w* appears in *MT*; Similarly for *#(w,Text)*;

|MT| - The number of single words in *MT*;

Text - Either the title or abstract, thus we have two features of this type: *Pr(MT|Title)* and *Pr(MT|Abstract)*;

$Pr_c(w)$ - The probability of word *w* occurring in a background corpus. This is obtained from a unigram language model that was estimated on the 13,999 articles;

λ – A smoothing parameter that was empirically set to be 0.2.

Query-likelihood features. The major term of an entry is viewed as a query, and this class of features computes likelihood scores between the query (as Q) and the article *D* (either the title or the abstract). We used the very classic okapi model (Robertson et al, 1994), as follows:

$$Okapi(Q,D)=\sum_{q\in Q}\frac{tf(q,D)*\log\left(\frac{N-df(q)+0.5}{df(q)+0.5}\right)}{0.5+1.5*\left(\frac{\mid D\mid}{avg(\mid D\mid)}\right)+tf(q,D)} \quad (8)$$

[6] http://www.cs.waikato.ac.nz/ml/weka/ .

where:
tf(q,D) - The count of *q* occurring in document *D*;
|D| - The total word counts in document *D*;
df(q) - The number of documents containing word *q*;
avg(|D|) - The average length of documents in the collection;
N - The total number of documents (13,999).

We have two features: *okapi(MT, Title)* and *okapi(MT, Abstract)*. In other words, the title and abstract are processed separately. The advantage of using such query-likelihood scores is that they give a probability other than a binary judgment of whether a major term should be annotated to the article, as only indirect evidence exists for annotating a vocabulary entry to an article in most cases.

Neighborhood features. The first feature represents the number of neighboring documents that include the entry to be annotated for a document. The second feature, instead of counting documents, sums document similarity scores. The two features are formulated as follows, respectively:

$$freq(MT \mid D) = \left|\{D_i \mid MT \in D_i, D_i \in \Omega_k\}\right| \quad (9)$$

$$sim(MT \mid D) = \sum_{MT \in D_i;\, D_i \in \Omega_k} sim(D, D_i) \quad (10)$$

where Ω_k is the *k*-nearest neighbors for an input document *D* and $sim(D_i,D_j)$ is the similarity score between a target document and its neighboring document, given by the retrieval model.

Synonym Features. Each vocabulary entry has synonyms. We designed two binary features: one judges whether there exists a synonym that can be exactly matched to the article text (title and abstract); and the other measures whether there exists a synonym whose unigram words have all been observed in the article text.

5 Experiment

5.1 Datasets

To justify the effectiveness of our method, we collected two datasets. We randomly selected a set of 200 documents from PubMed to train the logistic regression model (named Small200). For testing, we used a benchmark dataset, NLM2007, which has been previously used in benchmarking biomedical document annotation[7] (Aronson et al., 2004; Vasuki and Cohen, 2009; Trieschnigg et al., 2009). The two datasets have no overlap with the aforementioned 13,999 documents. Each document in these two sets has only title and abstract (i.e., no full text). The statistics listed in Table 2 show that the two datasets are alike in terms of annotations. Note that we also evaluate our method on a larger dataset of 1000 documents, but due to the length limit, the results are not presented in this paper.

Dataset	Documents	Total annotations	Average annotations
Small200	200	2,736	13.7
NLM2007	200	2,737	13.7

Table 2. Statistics of the two datasets.

5.2 Evaluation Metrics

We use *precision*, *recall*, *F-score*, and *mean average precision* (MAP) to evaluate the ranking results. As can be seen from Section 3.2, the number of annotations per document is about 10. Thus we evaluated the performance with top 10 and top 15 items.

5.3 Comparison to Other Approaches

We compare our approach to three methods on the benchmark dataset - NLM2007. The first system is NLM's MTI system (Aronson et al., 2004). This is a knowledge-rich method that employs NLP techniques, biomedical thesauruses, and a *KNN* module. It also utilizes handcrafted filtering rules for refinement. The second and third methods rank entries according to Formula (9) and (10), respectively (Trieschnigg et al., 2009).

We trained our model on Small200. All feature values were normalized to [0,1] using the maximum values of each feature. The number of neighbors was set to be 20. Neighboring documents were retrieved from PubMed using the retrieval model described in (Lin and Wilbur, 2007). Existing document annotations were not used in retrieving similar documents as they should be treated as unavailable for new documents. As the average number of annotations per document is around 13 (see Table 2), we computed precision, recall, F-score, and MAP with top 10 and 15 entries, respectively.

Results in Table 3 demonstrate that our method outperforms all other methods. It has substantial improvements over MTI. To justify whether the improvement over using *neighbor-*

[7] http://ii.nlm.nih.gov/.

hood similarity is significant, we conducted the *Paired t-test* (Goulden, 1956). When comparing results of using *learning* vs. *neighborhood similarity* in Table 3, the p-value is 0.028 for top 10 and 0.001 for top 15 items. This shows that the improvement achieved by our approach is statistically significant (at significance level of 0.05).

	Methods	Pre.	Rec.	F.	MAP
Top 10	MTI	.468	.355	.404	.400
	Frequency	.635	.464	.536	.598
	Similarity	.643	.469	.542	.604
	Learning	**.657**	**.480**	**.555**	**.622**
Top 15	MTI	.404	.442	.422	.400
	Frequency	.512	.562	.536	.598
	Similarity	.524	.574	.548	.604
	Learning	**.539**	**.591**	**.563**	**.622**

Table 3. Comparative results on NLM2007.

5.4 Choosing Parameter *k*

We demonstrate here our search for the optimal number of neighboring documents in this task. As shown in Table 4, the more neighbors, the larger number of gold-standard annotations would be present in neighboring documents. With 20 neighbors a fairly high upper-bound recall (*UBR*) is observed (about 85% of gold-standard annotations of a target document were present in its 20 neighbors' annotations), and the average number of entries (*Avg_VE*) to be ranked is about 100.

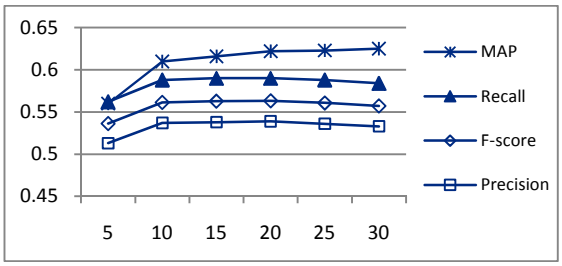

Figure 5. The performance (y-axis) varies with the number of neighbors (x-axis).

Measure	The number of neighboring documents					
	5	10	15	20	25	30
UBR	.704	.793	.832	.856	.871	.882
Avg_VE	38.8	64.1	83.6	102.2	119.7	136.4

Table 4. The upper-bound recall (*UBR*) and average number of entries (*Avg_VE*) with different number of neighboring documents.

To investigate whether the number of neighboring documents affects performance, we experimented with different numbers of neighboring documents. We trained a model on Small200, and tested it on NLM2007. The curves in Figure 5 show that the performance becomes very close when choosing no less than 10 neighbors. This infers that reliable performance can be obtained. The best performance (F-score of 0.563) is obtained with 20 neighbors. Thus, the parameter *k* is set to be 20.

5.5 Data Imbalance Issue

As mentioned in Section 4.1, there is a data imbalance issue in our task. For each document, we obtained an initial list of entries from 20 neighboring documents. The average number of gold-standard annotations is about 13, while the average number of entries to be ranked is around 100 (see Table 4). Thus the number of entries of label 0 (negative examples) is much larger than that of label 1 (positive examples). We did not apply any filtering strategy because the gold-standard annotations are not proportional to their occurring frequency in the neighboring documents. In fact, as shown in Figure 6, the majority of gold-standard annotations appear in only few documents among 20 neighbors. For example, there are about 250 gold-standard annotations appearing in only one of 20 neighboring documents and 964 appearing in less than 6 neighboring documents. Therefore, applying any filtering strategy based on their occurrence in neighboring documents may be harmful to the performance.

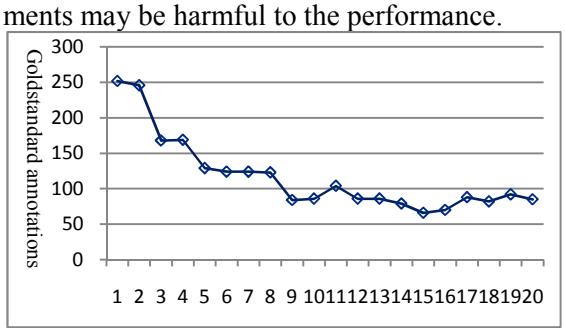

Figure 6. The distribution of annotations. X-axis is the number of neighboring documents in which gold-standard annotations are found.

5.6 Feature Analysis

To investigate the impact of different groups of features, we performed a feature ablation study. The features were divided into four groups. For each round of this study, we remove one group of features from the entire feature set, re-train the model on Small200, and then test the performance on NLM2007 with top 15 entries. We divided the features into four independent groups:

prior probability features, neighborhood features, synonym features, and other features (including unigram/bigram feature, query likelihood feature, etc., see Section 4.2). Results in Table 5 show that neighborhood features are dominant: removing such features leads to a remarkable decrease in performance. On the other hand, using only neighborhood features (the last row) yields significant worse results than using all features. This means that combining all features together indeed contributes to the optimal performance.

Feature Set	Pre.	Rec.	F.	MAP
All features	**.539**	**.591**	**.563**	**.622**
- Prior probability	.538	.590	.563	.622
- Neighborhood features	.419*	.459*	.438*	.467*
- Synonym features	.532	.583	.556	.611
- Other features	.529	.580	.553	.621
Only neighborhood features	.523*	.573*	.547*	.603*

Table 5. Feature analysis. Those marked by stars are significantly worse than the best results.

5.7 Discussions

All methods that rely on neighboring documents have performance ceilings. Specifically, for the NLM2007 dataset, the upper bound recall is around 85.6% with 20 neighboring documents, as shown in Table 5. Due to the same reason, this genre of methods is also limited to recommend entries that are recently added to the controlled vocabulary as such entries may have not been annotated to any document yet. This phenomenon has been demonstrated in the annotation behavior analysis: those latest entries have substantially fewer annotations than older ones.

6 Related Work

Our work is closely related to ontology-based or semantic-oriented document annotation (Corcho, 2006; Eriksson, 2007). This work is also related to *KNN*-based tag suggestion or recommendation systems (Mishne, 2006).

The task here is similar to keyword extraction (Nguyen and Kan, 2007; Jiang et al., 2009), but there is a major difference: keywords are always occurring in the document, while when an entry of a controlled vocabulary was annotated to a document, it may not appear in text at all.

As for the task tackled in this paper, i.e., annotating biomedical publications, three genres of approaches have been proposed: (1) *k-Nearest Neighbor* model: selecting annotations from neighboring documents, ranking and filtering those annotations (Vasuki and Cohen, 2009; Trieschnigg et al., 2009). (2) Classification model: learning the association between the document text and an entry (Ruch, 2006). (3) Based on knowledge resources: using domain thesauruses and NLP techniques to match an entry with concepts in the document text (Aronson, 2001; Aronson et al., 2004). (4) LDA-based topic model: (Mörchen et al., 2008).

7 Conclusion

This paper presents a novel study on service-centric annotation. Based on the analysis results of 2 million annotated scientific publications, we conclude that service-centric annotation exhibits the following unique characteristics: a) the number of annotation per document is significant smaller, but it conforms to a normal distribution; and b) entries of different granularity (general vs. specific) are used appropriately by the trained annotators. Service-centric and user-centric annotations have in common that the Zipf law holds and categorization imbalance exists.

Based on these observations, we introduced a logistic regression approach to annotate publications, with novel features. Significant improvements over other systems were obtained on a benchmark dataset. Although our features are tailored for this task in biomedicine, this approach may be generalized for similar tasks in other domains.

Abstract

In this paper, we explore a CLIR-based approach to construct large-scale Chinese-English comparable corpora, which is valuable for translation knowledge mining. The initial source and target document sets are crawled from news website and standardized uniformly. Keywords are extracted from the source document firstly, and then the extracted keywords are translated and combined as query words through certain criteria to retrieve against the index created using target document set. Meanwhile, the mapping correlations between source and target documents are developed according to the value of similarity calculated by the retrieval tool. Two methods are evaluated to filter the comparable document pairs so as to ensure the quality of the comparable corpora. Experimental results indicate that our approach is effective on the construction of Chinese-English comparable corpora.

1 Introduction

Parallel corpora are key resource for statistical machine translation, in which machine learning techniques are used to learn translation knowledge. Sufficient data is necessary for the data-driven approaches to estimate the model parameters reliably. However, as Munteanu (2006) stated, beyond a few resource-rich language pairs such as English-Chinese or English-French and a small number of contexts like parliamentary debates or legal texts, parallel corpora remain a scarce resource, despite the proposition of automated methods to collect parallel corpora from the Web. Researches on comparable corpora are motivated by the scarcity of parallel corpora. Compared with parallel corpora, comparable corpora are more abundant, up-to-date and accessible.

Comparable corpora are defined as pairs of monolingual corpora selected according to the same set of criteria, but in different languages or language varieties. When creating comparable corpora, the key process is to align the source document with relevant target documents. Early work by Braschler and Scäuble (1998) employed content descriptors and publication dates to align German and Italian news stories. Resnik (1999) mined comparable corpora on the assumption that the pages which are comparable of each other share a similar structure (headers, paragraphs, etc.) when text is presented in many languages in the Web. Tao and Zhai (2005) acquired comparable bilingual text corpora based on the observation that terms that are translations of each other or share the same topic tend to co-occur in the comparable corpora at the same/similar time periods. Recently, Talvensaari et al. (2007) introduced a CLIR-based approach to align two document collections with different languages. All the target documents were indexed with Lemur. Then appropriate keywords were extracted from the source language documents and translated into the target language as query words to retrieve similar target documents.

As we know, the problems may vary with the language of documents when using CLIR-based approach to construct comparable corpora, such as keyword extraction, out-of-vocabulary keyword translation and so on. This paper is a further endeavor to CLIR-based approach for com-

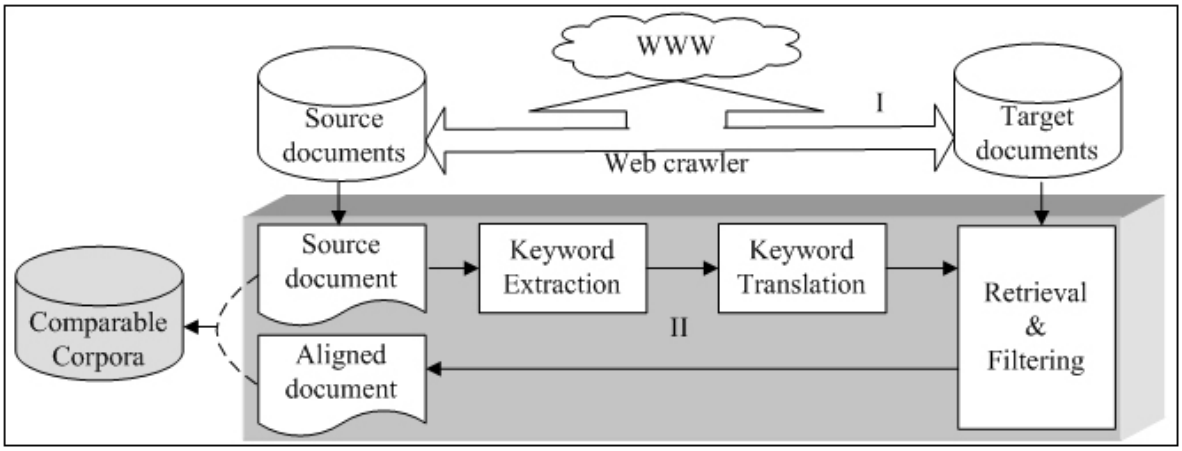

Figure 1. The general architecture of comparable corpora construction

parable corpora construction. We focus on the construction of Chinese-English comparable corpora, explore and address the issues during the construction. Experimental results show that our method is better through a rough comparison with Talvensaari et al. (2007) and it also outperforms our reconstruction of Tao and Zhai (2005) in respect to the quality of comparable corpora.

This paper is organized as follows. In section 2, the general architecture of our system is described, and each module is illuminated in detail. Section 3 reports and analyzes the experimental results followed by conclusions in section 4.

2 System Architecture

Figure 1 shows the general architecture of our comparable corpora construction system. It consists of two components: component I and component II. Component I is mainly composed by a web crawler, which is used to harvest source and target documents from selected web sites. We can get the final source and target document sets through content extraction and noise filtering. The core of the system is component II, which aligns a source document with target documents having comparable contents. It implements on the two document sets generated by component I. Component II is composed of three modules: keyword extraction, keyword translation, and retrieval & filtering. The methods for three modules are detailed respectively.

2.1 Keyword Extraction

A keyword is described as a meaningful and significant expression containing one or more words. Appropriate keywords briefly describe the theme of a document. In this paper, keywords are viewed as basic units of search indexes in order to retrieve closely related documents. Generally, phrases can capture the main idea of a document more effectively, inasmuch as they have more information than single words (an independent linguistic unit after word segmentation for Chinese).

Existing approaches for keyword extraction could be distinguished into two main categories: supervised or unsupervised methods. Supervised machine learning algorithms were widely used in keyword extraction such as Naïve Bayes (Frank et al., 1999; Witten et al., 1999), SVM (Zhang et al., 2006), CRF (Zhang et al., 2008), etc. These approaches had excellent stability. However, it was difficult for us to construct a big-enough golden annotated corpus to train a good classifier, especially for news web pages. Unsupervised methods hinged on evaluating various features to select keywords, such as word frequency (Luhn, 1957), word co-occurrence (Matsuo and Ishizuka, 2004), and TF*IDF (Li et al., 2007). The inherent problem in these methods was that most of their work came in the judgment whether a candidate was a keyword or not, but they had not paid sufficient attention to the identification of phrase candidates. Wan and Xiao (2008) proposed a method for keyphrase extraction from single document. However, it simply combined the adjacent candidate words to a multi-word phrase.

Based on the above observation, our approach for keyword extraction focuses more on the construction of phrasal candidates. It is mainly based on MWE (Multi-Word Expression) extraction together with relevant word ranking method.

MWE is a special lexical unit including compound terms, idioms and collocations, etc. The process of keyword extraction in this paper mainly depends on the following stages.

Stage 1: The generation of phrasal candidates

(1) The extraction of MWEs from the preprocessed document

Document preprocessing is a procedure of morphological analysis including segmentation and part of speech tagging for Chinese. The method based on the marginal probabilities detailed in (Luo and Huang, 2009) is adopted in this part.

We extract MWEs using LocalMaxs selection algorithm together with a relevance measure calculation method (FSCP) proposed by Silva et al. (1999). Suffix arrays and related structures in (Aires et al., 2008) are used to compute the FSCP value so as to raise efficiency. And the initial collection of MWEs named *G* for the document is generated after filtered by stopword list.

(2) The acquisition of new MWEs through the modification for segmentation

As a matter of fact, the results of segmentation for the document usually have some errors especially for out-of-vocabulary (OOV) words which are segmented to single Chinese characters in most cases. Inaccurate segmentation leads to some faults for keyword extraction. As stated in (Liu et al., 2007), OOV words can be identified by the method of MWEs extraction mentioned above. Therefore, we modify the segmentation like this: any MWE in *G* is merged to one word if it only consists of single Chinese characters and its frequency > *freq*. The changes before and after merging are shown in Table 1. Because the method of MWE extraction is based on statistical techniques, so low frequency of MWE will result in poor performance. But large value for *freq* means that very few MEWs can satisfy the frequency restriction. In our experiments, we set *freq*=2. The extraction process is called again to identify MWEs from the document with modified segmentation. Consequently, new collection of MWEs is acquired.

Additionally, some simple rules are defined according to language features to filter MWEs. In this paper, our method is tailored to extract keywords from news web pages which contain some special symmetric marks like "「, 」". The words in a specially marked area are usually important to the document. So we extract words within each paired marks and view them as a MWE on the condition that it contains two or more than two words. All of the MWEs are viewed as phrasal candidates and filtered by stopword list.

Stage 2: The generation of single words candidates

Our method also generates single word candidates with the account that both phrase and single word can be served as a keyword. The process of single word selection is independent of MWE extraction. The candidate words are restricted to nouns, verbs, strings (like WTO) and merged words as discussed in the previous stage. But the word will be removed if it only appears once in the document or is contained in the stopword list.

Stage 3: Keyword selection based on candidates ranking

As for MWE candidates, we calculate the weight for them using Formula 1 which refers to the formula used to sort NP phrases in (Bracewell et al., 2008). But the weight of *len* is reduced.

$$Weight(MWE) = \log(\sqrt{len} + f_{MWE} + \frac{1}{len} \times \sum_{i=1}^{len} tf(w_i)) \quad (1)$$

Where *len* is the length of MWE (in number of words); f_{MWE} is the frequency of the MWE within in the document; $tf(w_i)$ is the frequency of word w_i. The following rules are used to rank MWEs:

MWE	Segmentation before merging	Segmentation after merging	Pos before merging	Pos after merging
布 卡	鸟/ 人/ 布/ 卡/ 为/ 脚伤/ 所/ 苦/	鸟/ 人/ 布卡/ 为/ 脚伤/ 所/ 苦/	鸟/n 人/n 布/n 卡/n 为/vl 脚伤/n 所/us 苦/a	鸟/n 人/n 布卡/oov 为/vl 脚伤/n 所/us 苦/a
琼 丝	琼/ 丝/ 五金/ 梦/	琼丝/ 五金/ 梦/	琼/jb 丝/n 五金/b 梦/n	琼丝/oov 五金/b 梦/n

Table 1. Changes before and after merging

(a) more frequent MWEs are ranked higher; (b) MWEs with larger weight are ranked higher. In order to avoid redundancy, we remove the redundant MWEs with lower rank.

Single word candidates are ranked as follows: (a) the single word *w* with larger TF*IDF value is ranked higher; (b) the pos score for *w* in descending order is: named entity, merged words, nouns, strings, verbs. In the end, top-*a* MWEs and top-*b* single words are chosen to form the keyword set of the document.

Stage 4: Parameters evaluation and experimental results

The max number of keywords extracted from each document is limited to ten (a+b=10) and we run our approach on the dataset which include one hundred Chinese documents from the corpus of NTCIR-5 since they are also news articles. For evaluation of the results, the keywords extracted by our method are compared with the manually extracted keywords (at most ten keywords are assigned to each document). The F-measure is used as evaluation metric. It is defined like this: $F=(P+R)/2$; $P=num_{match}/num_{system}$; $R=num_{match}/num_{manual}$. Where num_{match} is the count of keywords extracted by our method matching with manually extracted keywords; num_{system} is the count of keywords extracted by our method; num_{manual} is the count of keywords assigned by human.

Figure 2 shows the performance curves for our extraction method. In this figure, *a* ranges from 0 to 10 while *b* is 10 to 0. It performs best when *a* = 4 and *b* = 6. So the two values are adopted in this paper.

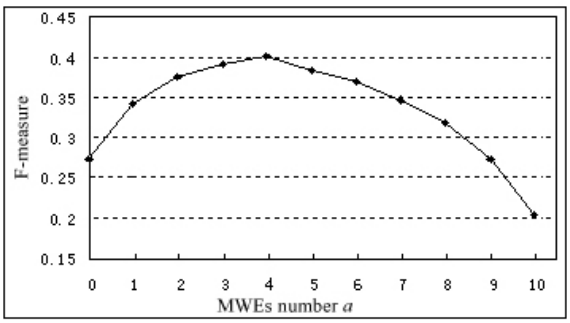

Figure 2. F-measure varies with the value of *a*

We test our approach on another dataset which also contains one hundred documents. In the experiments, the max number of keywords is set to ten. Table 2 shows the results of keyword extraction under three different conditions respectively. (A) Only extracts single words as keywords while just MWEs with (B). (C) The method presented in this paper which makes a proper combination of MWEs and single words.

	P	R	F
A (single words)	24.2%	28.5%	26.4%
B (MWEs)	18.1%	23.0%	20.6%
C (A+B)	34.2%	43.6%	38.9%

Table 2. Keyword extraction results

2.2 Keyword Translation

As for keyword translation, there are three main approaches: translation based on dictionary, parallel corpora and machine translation. Dictionary based approach is adopted in our system by taking the acquisition of translation resource into account.

Word Sense Disambiguation (WSD) and OOV problem are the main difficulties in CLIR (Cross Language Information Retrieval) task. A typical bilingual dictionary will provide a set of alternative translations for a given keyword, so how to choose the optimal translation is called Word Sense Disambiguation. Actually some keywords can not be found and translated due to the coverage limitation of a bilingual dictionary, which is called OOV problem.

In this paper, the keyword is given up if its size of translations gained from the bilingual dictionary is larger than two for the convenience of WSD. Additionally, both of the translations are treated as synonyms and equal weight is assigned to them when retrieval.

To address the OOV problem, researchers proposed methods using snippets returned by a search engine. For example, Wang et al. (2004) introduced a statistics-based approach called SCPCD to mine translations from the returned snippets. Different from (Wang et al., 2004), Zhou et al. (2007) used a pattern-based approach to analyze the mixed-languages snippets.

Leveraging on previous work, we analyze the co-occurrence mode of the OOV term and the corresponding translation in the returned snippets. Table 3 shows the typical co-occurrence modes collected during experiments, where the English words in bold are the corresponding translations of the underlined Chinese OOV terms. From Table 3, we can see the translations in number 1, 2 and 3 are included in the symmetric symbols, like bracket, quotation marks. However, the

Table 3. Chinese OOV and the corresponding translation in returned snippets

translations in number 4, 5, and 6 are embedded in the partial sentence while there are noise English words. In order to get the correct translation, the partial sentence needs to be segmented. By above analysis, we integrate the SCPCD method and the pattern-based method so as to extract more correct translations. The SCPCD method can be used to determine the boundaries for OOVs like number 4, 5, and 6; while pattern-based method makes use of the symmetric symbols like number 1, 2 and 3. Table 4 shows the experimental results for OOV translation methods. The average top-n inclusion rate is adopted as a metric. For a set of test OOV terms, its top-n inclusion rate is defined as the percentage of the OOVs whose translations can be found in the first n extracted translations.

	Pattern	SCPCD	Pattern + SCPCD
Top-1	40.0%	49.2%	68.1%
Top-3	41.5%	55.4%	70.2%

Table 4. The performance comparison of different OOV translation methods

The test dataset used is the Chinese topic terms in CLIR task of NTCIR-5. The search engine is Google. The bilingual dictionary used by us is LDC_CE_DICT 2.0. And we only adapt the pattern with symmetric symbols, which has the highest precision proposed by Cao et al. (2007).

2.3 Retrieval and Filtering

The process of retrieval is to construct the alignment relationship between source and target document pairs. It is a core module in our system since the quality of comparable corpora is greatly influenced by alignment level which depends on the relevance between document pairs. Our intention here is to retrieve high relevant target documents for the source documents. Open-source toolkit Indri is introduced to assist the retrieval process. Indri is a part of the Lemur project[1]. On the basis of Lemur, it combines inference networks with language modeling. And it's widely adopted by institution for scientific research since it is effective, flexible, usable and powerful. So it is employed by us to retrieve related documents. A query for each source document is formed by the translated keywords with Indri query language and then run against the target collection.

The essential of alignment is to compare the similarity between source and target document pairs. In order to reduce the workload of comparing, Pooling method is applied to assist the comparing process. We choose the top r documents returned by Indri retrieval system to build the related document pool. And g ($g<=r$) documents in the pool are selected to form the alignment document pairs together with the source document. In our experiments, we set r=10 and g=1.

In the process of alignment, three features are used to filter the alignment pairs for the sake of pruning the low relevant pairs. The first is publication date contained in documents. The second is similarity calculated by Indri between the query and the target document when retrieval. The last is KSD (Keyword similarity between document pairs) which is defined by our system. In this paper, we propose two methods to filter the alignment pairs by using various features.

(1) DSF filtering

This method depends on two features: date and similarity. At first, we give a priority to the target documents that have the closest date to the source document during the top-r documents searching. A date-window size d is defined to measure the date difference. We set d=1 in this paper. That is to say, the target documents with

[1] Lemur toolkit is developed by Carnegie Mellon University and University of Massachusetts. The open source code is available at http://www.lemurproject.org.

exactly the same date as the source document, and one day earlier or later are considered to be closest. Then, we select *g* documents with larger similarity from the related document pool. Finally, we rank all of the alignment pairs with the score of similarity and set a similarity threshold *s* to filter further. It should be noted that there are $n \cdot g$ alignment pairs, where *n* is the number of source documents having non-empty related document pool.

(2) DSKF filtering

This method utilizes all of the features: date, similarity and KSD. As for KSD, it integrates two factors. One is NTK, namely the number of translated keywords appeared in the target document, since the target document is more similar to the source document as increasing of NTK. The other is FIS, namely frequency information score. Inspired by paper (Tao and Zhai, 2005), we use the score of FIS to measure the correlations between the keywords in source document and translated keywords in target document which represent the matching for source and target document pair. We define d_s as the source document, d_t as the target document, *ks* as the set of keywords extracted from d_s, *kts* as the set of translated keywords. Formula 2 is used to compute the score of FIS:

$$Score_{FIS} = \sum_{i=1}^{ktsLen} (BM25(x_i, d_s) \cdot IDF(x_i) \cdot BM25(y_i, d_t) \cdot IDF(y_i) / norm(Dif(x_i, y_i))) \quad (2)$$

Where, *ktsLen* is the size of *kts*, y_i is an element in *kts*, x_i is the element in *ks* while y_i is the translation of x_i. Moreover, *BM25*(*w*, *d*) is the normalized frequency of word *w* in document *d*. It has been considered as one of the most effective matching functions for retrieval. *IDF* stands for Inverse Document Frequency which is also commonly used in information retrieval. *Dif*(*x, y*) is defined as the difference between *BM25*(*x*, d_s) and *BM25*(*y*, d_t). Formula 2 penalizes large difference due to the conditions like this: any keyword in source document appears many times while its translation appears rarely in target document. The process of its normalization is run by Formula 3 which makes the score less sensitive to the absolute value:

$$norm(score) = \begin{cases} 1, & score < 1 \\ \sqrt{score}, & else \end{cases} \quad (3)$$

Furthermore, the final KSD score is got by simply adding the normalized scores of NTK and FIS which are dealt with Formula 3. Actually, the two filtering methods differ principally in the last step. DSKF sorts all of the alignment pairs according to the KSD score while it is similarity in DSF. We also set a KSD threshold *k* for DSKF method to filter further. The values for *s* and *k* will be investigated in the following experiments.

3 Experiments

In this section, we first introduce how to acquire the source and target document sets. Then our system is tested on the two sets. The experimental results are reported and analyzed finally.

3.1 Experiment Setup

To test the effectiveness of the proposed system, large-scale of Chinese and English news web pages are crawled respectively from XinHuaNet and used as the document resource. The reasons for choosing news pages are:

(1) Many websites, like portal website, news agency, government and so on, provide large-scale news reports. At the same time, a large proportion of the reports can be crawled politely, so document acquisition is relatively easy.

(2) The news pages include various contents, such as politics, economy, sports, so the corpora made up of news pages can avoid the limitations of domain-specific corpora.

All the news pages are processed uniformly. The core content of each web page crawled is extracted and several tags describing the headline and publication date are added. Meanwhile, the original contents are kept with no change. Table 5 shows the basic information of document sets.

Year	Number of source documents	Number of target documents
2003	23747	3390
2004	25660	2943
2005	47333	11578
2006	28572	25320
2007	25036	25247
2008	14021	24292
2009	7476	10887
Total	171845	103657

Table 5. The composition of source document set and target document set

3.2 Results and Discussion

The quality of comparable corpora highly de-

pends on the alignment level between source and target document pairs. Braschler and Scäuble (1998) used five levels of relevance to assess the alignments as follows:

(1) Same story. The two documents deal with the same event.

(2) Related story. The two documents deal with the same event or topic from a slightly different viewpoint. Alternatively, the other document may concern the same event or topic, but the topic is only a part of a broader story or the article is comprised of multiple stories.

(3) Shared aspect. The documents deal with related events. They may share locations or persons.

(4) Common terminology. The events or topics are not directly related, but the documents share a considerable amount of terminology.

(5) Unrelated. The similarities between the documents are slight or nonexistent.

We randomly select 500 source documents published in 2009 as the test dataset. Experiments with different parameters are constructed based on this dataset. The quality of each alignment pair is manually assessed using the five-level relevance as discussed above. What should to be pointed out is that parameter s and k are not absolute values, but percentile rank level in our work. For instance, k = 10 means that we only choose the alignment pairs whose KSD score rank in top ten percent among all of the results.

Table 6 shows the results filtered by DSF method with different values of s ($s_1 < s_2 < s_3 < s_4$). Table 7 shows the results filtered by DSKF method with various values of k ($k_1 < k_2 < k_3 < k_4$). In order to evaluate the results conveniently, two standards are established: (a) the number of high relevant pairs created, which is the count of document pairs in Level 1 and 2; (b) the quality of the whole alignments, that is to say the percentage of alignment pairs with Level 1 and 2. Seen from Table 6 and 7, DSKF is better than DSF by considering the two standards. Compared with DSF, more high relevant pairs are left filtered by DSKF when they have the same total number of pairs. In other words, the DSKF method is more powerful to make high relevant pairs in higher rank so as to reduce alignment pairs which are rarely relevant. Therefore, DSKF is adopted in our system. Taking the first criterion into account, we give up the parameter k_1, k_2. Parameter k_4 is not the best considering the second criterion. Ultimately, k_3 is chosen as the final value for k. At this point, the number of alignment pairs in Level 1 and 2 is close to the maximum. Meanwhile, the percentage of high alignments reaches 68.5%.

Among the surveyed related work, Talvensaari et al. (2007) created Swedish-English comparable corpora based on CLIR techniques and its framework of construction is similar to ours. However, the two systems are different in the following aspects:

Level	s_1 = 10		s_2 = 30		s_3 =50		s_4 =70	
	Number	%	Number	%	Number	%	Number	%
Leve1 1	23	46.9%	54	36.5%	83	33.5%	96	27.7%
Level 2	18	36.7%	43	29.1%	62	25.0%	81	23.3%
Level 3	4	8.2%	21	14.2%	40	16.1%	57	16.4%
Level 4	4	8.2%	19	12.8%	41	16.5%	60	17.3%
Level 5	0	0.0%	11	7.4%	22	8.9%	53	15.3%
Total	49	100%	148	100%	248	100%	347	100%

Table 6. The distribution results filtered by DSF with different s parameters

Level	k_1 = 10		k_2 = 30		k_3 = 50		k_4 =70	
	Number	%	Number	%	Number	%	Number	%
Level 1	33	67.3%	78	52.7%	93	37.5%	98	28.2%
Level 2	15	30.6%	52	35.1%	77	31.0%	89	25.6%
Level 3	1	2.0%	9	6.1%	37	14.9%	62	17.9%
Level 4	0	0.0%	9	6.1%	34	13.7%	60	17.3%
Level 5	0	0.0%	0	0.0%	7	2.8%	38	11.0%
Total	49	100%	148	100%	248	100%	347	100%

Table 7. The distribution results filtered by DSKF with different k parameters

(1) The language is different. We focus on building comparable corpora of Chinese-English while they were Swedish-English.

(2) A series of sub problems are different due to language difference. As for keyword extraction, we propose a method to select both key phrases and single words, while they used RATF (Relative Average Term Frequency) method. For OOV problem, we combine the SCPCD method with the pattern-based method to extract OOV translations from snippets returned by a search engine. However, the classified s-gram matching technique was utilized by Talvensaari et al. (2007) to translate OOV words.

(3) Talvensaari et al. (2007) filtered their alignment pairs mainly depending on date and similarity, while we introduce new feature KSD to extend the original feature set.

Talvensaari et al. (2007) also randomly chose 500 source documents and assessed the quality of alignments using the same five-level relevance.

In addition to this, we implement the method of Tao and Zhai (2005) which is a purely statistical-based and language independent approach. The source and target documents published in 2009 are employed to test the method. The same sample as our system including 500 Chinese documents is chosen to make a further comparison with our work. We align each source document with one target document through the BM25Corr model in (Tao and Zhai, 2005). The alignment pairs are ranked according to mapping scores calculated by the BM25Corr model. And we select the top N (N = 248) alignment pairs for the benefit of comparison.

Table 8 shows the distribution results for the three systems. As illustrated in Table 8, we can roughly conclude that our approach creates more alignment pairs with the same number of source documents when compared with Talvensaari et al. (2007). Meanwhile, the percentage of high relevant document pairs is larger.

Likewise, our system outperforms BM25Corr in that it aligns more high relevant documents pairs when they use the same sample of test corpora and create the same total number of pairs. Obviously, the quality of comparable corpora gained by our system is better than BM25Corr.

All the experimental results and analysis mentioned above indicate that our method is effective to create alignment pairs. Up to now, both the source and target documents published in 2007-2009 years are used to build comparable corpora through our proposed system. It includes 23102 alignment pairs after filtered by DSKF.

Level	Talvensaari et al. (2007)		Our System (DSKF filtering)		BM25Corr (Top N = 248)	
	Number	%	Number	%	Number	%
Level 1	21	21.6%	93	37.5%	1	0.4%
Level 2	20	20.6%	77	31.0%	2	0.8%
Level 3	33	34.0%	37	14.9%	3	1.2%
Level 4	19	19.6%	34	13.7%	5	2.0%
Level 5	4	4.1%	7	2.8%	237	95.6%
Total	97	100%	248	100%	248	100%

4 Conclusions

In this paper, we propose a CLIR-based approach to create large-scale Chinese-English comparable corpora. Firstly, we harvest the original source and target document sets from news website using open-source crawler. Then the core content of each document is extracted through discriminating noise contents. Next, we delve into the approaches of problems such as keyword extraction and OOV translation followed by the process of retrieval to develop mapping correlations between source and target documents. Finally, three features as publication date, similarity score and KSD value are used to filter the aligned document pairs. Experimental results show that our approach is effective to mine Chinese-English document pairs with comparable contents. In the future, we will optimize the approach for every module in the construction of comparable corpora for the sake of improving the performance of the whole system. What's more, it will be worth consideration to mine mappings between terms which can be served as a feature for the process of developing mappings between document pairs in turn.

Abstract

Many existing methods for bilingual lexicon learning from comparable corpora are based on similarity of context vectors. These methods suffer from noisy vectors that greatly affect their accuracy. We introduce a method for filtering this noise allowing highly accurate learning of bilingual lexicons. Our method is based on the notion of *in-domain terms* which can be thought of as the most important contextually relevant words. We provide a method for identifying such terms. Our evaluation shows that the proposed method can learn highly accurate bilingual lexicons without using orthographic features or a large initial seed dictionary. In addition, we also introduce a method for measuring the similarity between two words in different languages without requiring any initial dictionary.

1 Introduction

In bilingual lexicon extraction, the context-based approach introduced by Rapp (1995) is widely used (Fung, 1995; Diab and Finch, 2000; among others). The focus has been on learning from comparable corpora since the late 1990s (Rapp, 1999; Koehn and Knight, 2002; among others). However, so far, the accuracy of bilingual lexicon extraction using comparable corpora is quite poor especially when orthographic features are not used. Moreover, when orthographic features are not used, a large initial seed dictionary is essential in order to acquire higher accuracy lexicon (Koehn and Knight, 2002). This means that current methods are not suitable when the language pairs are not closely related or when a large initial seed dictionary is unavailable.

When learning from comparable corpora, a large initial seed dictionary does not necessarily guarantee higher accuracy since the source and target texts are poorly correlated. Thus, inducing highly accurate bilingual lexicon from comparable corpora has so far been an open problem.

In this paper, we present a method that is able to improve the accuracy significantly without requiring a large initial bilingual dictionary. Our approach is based on utilising *highly associated terms* in the context vector of a source word. For example, the source word *powers* is highly associated with the context word *delegation*. We note that, firstly, both share context terms such as *parliament* and *affairs*. And, secondly, the translation equivalents of *powers* and *delegation* in the target language are not only highly associated but they also share context terms that are the translation equivalents of *parliament* and *affairs* (see Figure 1).

2 Related work

Most of the early work in bilingual lexicon extraction employ an initial seed dictionary. A large bilingual lexicon with 10k to 20k entries is necessary (Fung, 1995; Rapp, 1999).

Koehn and Knight (2002) introduce techniques for constructing the initial seed dictionary automatically. Their method is based on using identical spelling features. The accuracy of such initial bilingual lexicon is almost 90.0 percent and can be increased by restricting the word length (Koehn and Knight, 2002). Koehn and Knight found approximately 1000 identical words in their German

Coling 2008: Poster Volume, pages 481–489,
Beijing, August 2010

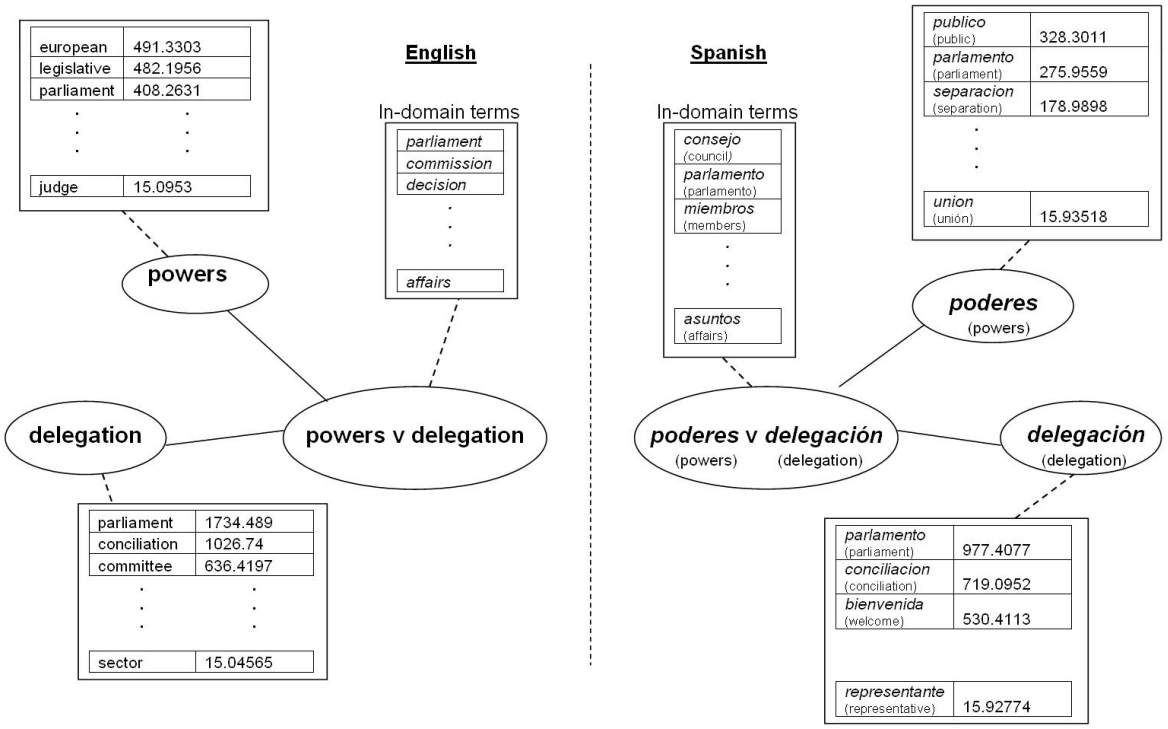

Figure 1: An example of in-domain terms that co-occur in English and Spanish. The source word is *powers* and the target word is *poderes*. The word *delegation* and *delegacion* are the highly associated words with the source word and the target word respectively. Their in-domain terms, as shown in the middle, can be used to map the source word in context of word *delegation* to its corresponding target word in context of *delegacion*.

and English monolingual corpora. They expanded the lexicon with the standard context-based approach and achieved about 25.0 percent accuracy (Koehn and Knight, 2002).

Similar techniques were used in Haghighi et al. (2008) who employ *dimension reduction* in the extraction method. They recorded 58.0 percent as their best F_1 score for the context vector approach on non-parallel comparable corpora containing *Wikipedia* articles. However, their method scores less on comparable corpora containing distinct sentences derived from the *Europarl English-Spanish* corpus.

3 Learning in-domain terms

In the standard context vector approach, we associate each source word and target word with their context vectors. The source and target context vectors are then compared using the initial seed dictionary and a similarity measure. Learning from comparable corpora is particularly problematic due to data sparsity, as important context terms may not occur in the training corpora while some may occur but with low frequency and can be missed. Some limitations may also be due to the size of the initial seed dictionary being small.

The initial seed dictionary can also contribute irrelevant or less relevant features that can mislead the similarity measure especially when the number of dimensions is large. The approach we adopt attempts to overcome this problem.

In Figure 1, for the source word *powers*, *delegation* is the highly associated word. Both *powers* and *delegation* share common contextual terms such as *parliament* and *affairs*. Now the translation equivalent of *delegation* is *delegacion*. For the potential translation equivalent *poderes*, we see that the common contextual terms shared by *powers* and *poderes* are terms *parlamento* (*parliament*) and *asuntos* (*affairs*).

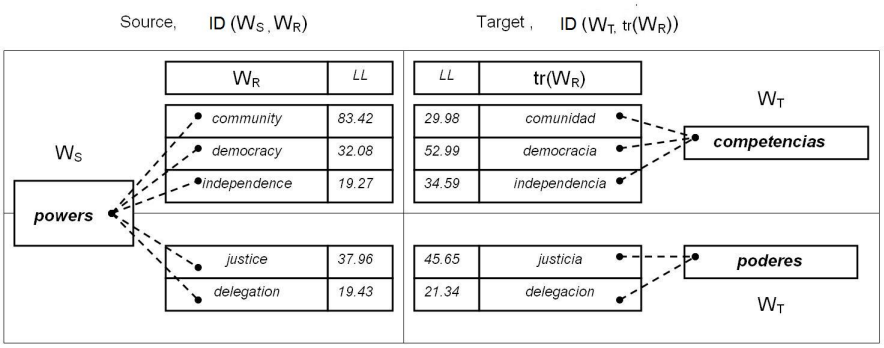

Figure 2: An example of English-Spanish lexicon learnt for the source word *powers*. On the top, the system suggested *competencias* and rejected *poderes* when *powers* is associated with *community*, *democracy* or *independence*. The word *poderes* is suggested when *powers* is associated with *justice* or *delegation*.

We observe that these common contextual terms are simultaneously the *first-order* and *second-order* context terms of the target word. They are the *shared* context terms of the target word and its highly associated context term. We define these terms as *in-domain terms*. These in-domain terms can be used to map words to their corresponding translations. The highly associated context terms can be thought of as sense discriminators that differentiate the different uses of the target word. In Figure 2, we show how *delegation* helps in selecting between the "control or influence" sense of *powers* while rejecting the "ability or skill" sense.

In this paper, our focus is not on sense disambiguation and we follow current evaluation methods for bilingual lexicon extraction. However, it is clear that our method can be adapted for building sense disambiguated bilingual lexicons.

3.1 Identifying highly associated words

To identify the context terms $CT(W_S)$ of a source word W_S, as in (Rapp, 1999), we use *log-likelihood ratio* (LL) Dunning (1993). We choose all words with $LL > t_1$ where t_1 is a threshold.

The *highly associated words* then are the top k highest ranked context terms. In our experiments, we only choose the top 100 highest ranked context terms as our highly associated terms.

In order to compute the log-likelihood ratio of target word a to co-occur with context word b, we create a contingency table. The contingency table contains the observed values taken from a given corpus. An example of the contingency table is shown in Table 1.

C[i,j]	***community***	***¬ community***		
powers	124	1831	**1955**	*C(powers)*
¬ powers	11779	460218	**471997**	*C(¬ powers)*
	11903	**462049**		
	C(community)	*C(¬ community)*		

Here $C[i, j]$ denotes the count of the number of sentences in which i co-occurs with j.
Total corpus size: N = 473952 in the above

Table 1: Contingency table for observed values of target word *powers* and context word *community*.

The LL value of a target word a and context word b is given by:

$$LL(a, b) =$$

$$\sum_{i \in \{a, \neg a\}, j \in \{b, \neg b\}} 2C(i, j) \log \frac{C(i, j)N}{C(i)\, C(j)}$$

3.1.1 Identifying in-domain terms

In our work, to find the translation equivalent of a source word W_S, we do not use the context terms $CT(W_S)$. Instead, we use the *in-domain terms* $IDT(W_S, W_R)$. For each highly associated term

W_R, we get different in-domain terms. Furthermore, $IDT(W_S, W_R)$ is a subset of $CT(W_S)$.

The in-domain terms of W_S given the context terms W_R is given by:

$$ID(W_S, W_R) = CT(W_S) \cap CT(W_R)$$

Programme and *public* are some of the examples of in-domain terms of *powers* given *community* as the highly associated term.

3.1.2 Finding translations pairs

Note that $ID(W_S, W_R)$ is an in-domain term vector in the source language. Let W_T be a potential translation equivalent for W_S. Let, $tr(W_R)$ be a translation equivalent for W_R. Let $ID(W_T, tr(W_R))$ be an in-domain term vector in the target language.

We use $tr(W_S|W_R)$ to denote the translation proposed for W_S given the highly associated term W_R. We compute $tr(W_S|W_R)$ using:

$$tr(W_S|W_R) = \underset{W_T}{\operatorname{argmax}}\, sim(ID(W_S, W_R), ID(W_T, tr(W_R)))$$

Our method learns translation pairs that are conditioned on highly associated words (W_R). Table 2 provides a sample of English-Spanish lexicon learnt for the word *power* with different W_R.

English		Spanish		Sim
W_S	W_R	$tr(W_R)$	W_T	
powers	community	comunidad	**competencias**	**0.9876**
			poderes	0.9744
			independiente	0.9501
	democracy	democracia	**competencias**	**0.9948**
			poderes	0.9915
			independiente	0.9483
	independence	independencia	**competencias**	**0.9939**
			poderes	0.9745
			independiente	0.9633
	justice	justicia	**poderes**	**0.9922**
			competencias	0.3450
			independiente	0.9296
	delegation	delegacion	**poderes**	**0.9568**
			competencias	0.9266
			independiente	0.8408

Table 2: A sample of translation equivalents learnt for *powers*.

In the next section, we introduce a similarity measure that operates on the context vectors in the source language and the target language without requiring a seed dictionary.

4 Rank-binning similarity measure

Most existing methods for computing similarity cannot be directly employed for measuring the similarity between in-domain term context vectors since each context vector is in a different language. A bilingual dictionary can be assumed but that greatly diminishes the practicality of the method.

We address this by making an assumption. We assume that the relative distributions of in-domain context terms of translation equivalent pairs are roughly comparable in the source language and in the target language. For example, consider the log-likelihood values of the in-domain terms for the translation pair *agreement-acuerdo* (conditioned on the highly associated term *association-associacion*) given in Figure 3. We note that the distribution of in-domain terms are comparable although not identical. Thus, the distribution can be used as a clue to derive translation pairs but we need a method to compute similarity of the vector of in-domain terms.

Rank-binning or rank histograms are usually used as a diagnostic tool to evaluate the spread of an ensemble rather than as a verification method. Wong (2009) use the method of rank-binning to roughly examine performance of a system on learning lightweight ontologies. We apply the rank-binning procedure for measuring the similarity of word pairs.

Pre-processing step:

1. Let W_S be a source language word and $x_1, x_2, ..., x_n$ be the set of n context terms ranked in descending log-likelihood values of W_S (see Table 3).

2. We transform the rank values of context terms x_k into the range [0,1] using:

$$z_k = \frac{rank(x_k) - 1}{n - 1}$$

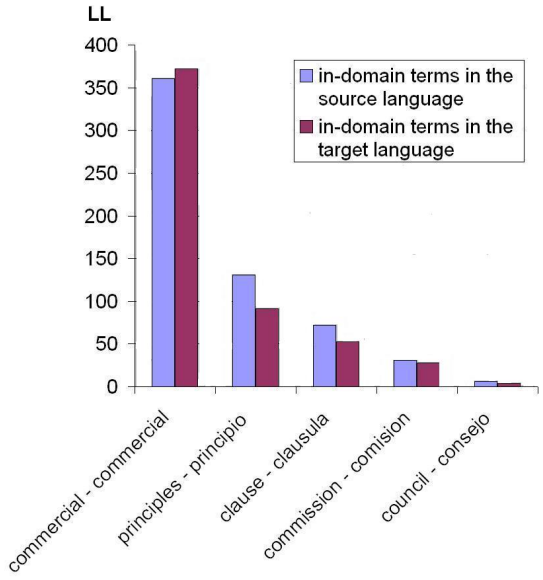

Figure 3: Similar distribution of in-domain terms for *agreement* with *association* and *acuerdo* with *asociacion*.

Binning procedure

We divide the interval $[0, 1]$ into g bins[1] of equal length. Let $b_1, \ldots, b_g$ denote the g bins. Then we map the in-domain terms vector $ID(W_S, W_R)$ into the binned vector $b_1, \ldots, b_g$. For each $x_k \in ID(W_S, W_R)$, this mapping is done by using the corresponding z_k from the pre-processing step. For each bin, we count the number of different in-domain terms that are mapped into this bin. Thus, if the range of the first bin b_1 is [0, 0.009] then *european, legislative, parliament* are mapped into b_1 i.e. $b_1 = 3$. The bins are normalised by dividing with $\mid ID(W_S, W_R) \mid$.

Rank binning similarity

We use Euclidean distance to compute similarity between bins. Given, bins $P = p_1, \ldots, p_g$ and $Q = q_1, \ldots, q_g$, the Euclidean distance is given by:

$$dist(P, Q) = \sqrt{\sum_{i=1}^{g} (p_i, q_i)^2}$$

[1]We used the following formula to estimate the number of bins:

$$g = 1 + 3.3 * log(\mid ID(W_S, W_R) \mid)$$

$CT(\textbf{\textit{powers}})$			
Context term	LL	$rank$	z_k
european	491.33	1	0.00000
legislative	482.19	2	0.00406
parliament	408.26	3	0.00813
:	:	:	:
:	:	:	:
:	:	:	:
public	16.96	245	0.99186
programme	15.40	246	0.99593
representatives	15.32	247	1.00000
$n = 247$			

Table 3: Some examples of transformed values of each term in $CT(powers)$.

In the next section, we describe the setup including the data, the lexicon and the evaluation used in our experiments.

5 Experimental setup

5.1 Data

For comparable text, we derive English and Spanish distinct sentences from the Europarl parallel corpora. We split the corpora into three parts according to year. We used about 500k sentences for each language in the experiments. This approach is further explained in Ismail and Manandhar (2009) and is similar to Koehn and Knight (2001) and Haghighi et al. (2008).

5.2 Pre-processing

For corpus pre-processing, we use sentence boundary detection and tokenization on the raw text before we clean the tags and filter stop words. We sort and rank words in the text according to their frequencies. For each of these words, we compute their context term log-likelihood values.

5.3 Lexicon

In the experiment, a bilingual lexicon is required for evaluation. We extract our evaluation lexicon from the `Word Reference`[2] free online dictionary. This extracted bilingual lexicon has low coverage.

[2]`http://wordreference.com`

5.4 Evaluation

In the experiments, we considered the task of building a bilingual English-Spanish lexicon between the 2000 high frequency source and target words, where we required each individual word to have at least a hundred highly associated context terms that are not part of the initial seed dictionary. Different highly associated W_R terms for a given W_T might derive similar (W_S, W_T) pairs. In this case, we only considered one of the (W_S, W_T) pairs. In future work, we would like to keep these for word sense discrimination purposes. Note that we only considered proposed translation pairs whose similarity values are above a threshold t_2.

We used the F_1 measure to evaluate the proposed lexicon against the evaluation lexicon. If either W_S or W_T in the proposed translation pairs is not in the evaluation lexicon, we considered the translation pairs as unknown, although the proposed translation pairs are correct. $Recall$ is defined as the proportion of the proposed lexicon divided by the size of the lexicon and $precision$ is given by the number of correct translation pairs at a certain recall value.

6 Experiments

In this section, we look into how the in-domain context vectors affect system performance. We also examine the potential of rank-binning similarity measure.

6.1 From standard context vector to in-domain context vector

Most research in bilingual lexicon extraction so far has employed the standard context vector approach. In order to explore the potential of the in-domain context vectors, we compare the systems that use in-domain approach against systems that use the standard approach. We also employ different sets of seed lexicon in each system to be used in the similarity measure:

- Lex_{700}: contains 700 cognate pairs from a few Learning Spanish Cognate websites[3].

- Lex_{100}: contains 100 bilingual entries of the most frequent words in the source corpus that have translation equivalents in the extracted evaluation lexicon. We select the top one hundred words in the source corpus, so that their translation equivalents is within the first 2000 high frequency words in the target corpus.

- Lex_{160}: contains words with similar spelling that occur in both corpora. We used 160 word pairs with an edit distance value less than 2, where each word is longer than 4 characters.

Models using the standard approach are denoted according to the size of the particular lexicon used in their context similarity measure, i.e. *CV-100* for using Lex_{100}, *CV-160* for using Lex_{160} and *CV-700* for using Lex_{700}. We use *IDT* to denote our model. We use lexicon sizes to distinguish the different variants, e.g. *IDT-CV100* for using Lex_{100}, *IDT-CV160* for using Lex_{160} and *IDT-CV700* for using Lex_{700}.

With *CV-700*, the system achieved 52.6 percent of the best F_1 score. Using the same seed dictionary, the best F_1 score has increased about 20 percent points with *IDT-CV700* recorded 73.1 percent. *IDT-CV100* recorded about 15.0 percent higher best F_1 score than *CV-100* with 80.9 and 66.4 percent respectively. Using an automatically derived seed dictionary, *IDT-CV160* yielded 70.0 percent of best F_1 score while *CV-160* achieved 62.4 percent. Results in Table 4 shows various precisions p_x at recall values *x*.

Model	$P_{0.10}$	$P_{0.25}$	$P_{0.33}$	$P_{0.50}$	$BestF_1score$
CV-700	58.3	61.2	64.8	55.2	52.6
CV-100	52.0	53.0	47.2	44.8	66.4
CV-160	68.5	56.8	48.8	48.8	62.4
IDT-CV700	83.3	90.2	82.0	66.7	73.1
IDT-CV100	80.0	75.8	66.7	69.4	80.9
IDT-CV160	90.0	80.6	73.9	69.2	70.0

Table 4: Performance of different models.

[3]such as `http://www.colorincolorado.org` and `http://www.language-learning-advisor.com`

6.2 Similarity measure using rank-binning

We use *RB* to denote our model based on the rank-binning approach. Running *RB* means that no seed dictionary is involved in the similarity measure. We also ran the similarity measure in the *IDT* (*IDT-RB160*) by employing the derived Lex_{160} for the in-domain steps.

We ran several tests using *IDT-RB160* with different numbers of bins. The results are illustrated in Figure 4. The *IDT-RB160* yielded 63.7 percent of best F_1 score with 4 bins. However, the F_1 score starts to drop from 61.1 to 53.0 percent with 6 and 8 bins respectively. With 3 and 2 bins the *IDT-RB160* yielded 63.7 and 62.0 percent of best F_1 score respectively. Using 1 bin is not be possible as all values fall under one bin. Thus, the rank-binning similarity measure for the rest of the experiments where *RB* is mentioned, refers to a 4 bins setting.

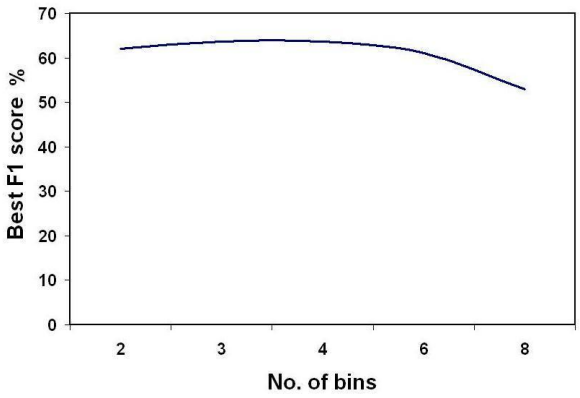

Figure 4: Performance of *IDT-RB160* with different numbers of bins.

While systems using the standard context similarity measure yielded scores higher than 50.0 percent of best F_1, the *RB* achieved only 39.2 percent. However, *RB* does not employ an initial dictionary and does not use orthographic features. As mentioned above, the system scored higher when the similarity measure was used in the *IDT* (i.e. *IDT-RB160*). Note that Lex_{160} is derived automatically so the approach can also be considered as unsupervised. The system performance is slightly lower compared to the conventional *CV-160*. However, *IDT-CV160* outperforms both of the systems (see Figure 5).

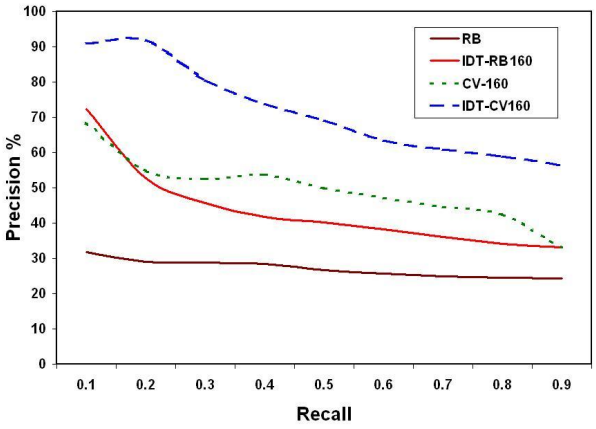

Figure 5: Performance of different unsupervised models.

Overall, systems that exploit in-domain terms yielded higher F_1 scores compared to the conventional context vector approach.

6.3 Comparison with CCA

Previous work in extracting bilingual lexicons from comparable corpora generally employ the conventional context vector approach. Haghighi et al. (2008) focused on applying *canonical correlation analysis* (*CCA*), a dimension reduction technique, to improve the method. They were using smaller comparable corpora, taken from the first 50k sentences of English Europarl and the second 50k of Spanish Europarl, and different initial seed dictionary. Hence, we tested *CCA* in our experimental setup. In *CV-700* setting, using *CCA* yields 57.5 percent of the best F_1 score compared to 73.1 percent of the best F_1 score with *IDT* that we reported in Section 6.2.

7 Discussion

7.1 Potential of in-domain terms

Our experiments clearly demonstrate that the use of in-domain terms achieves higher F_1 scores compared to conventional methods. It also shows that our method improves upon earlier reported dimension reduction methods. From our observation, the number of incorrect translation pairs

were further reduced when the context terms were filtered. Recall that the in-domain terms in the target language were actually the shared context terms of the target word and its highly associated context terms. Nevertheless, this approach actually depends on the initial bilingual lexicon in order to translate those highly associated context terms into the source language. Table 5 shows some examples of most confidence translation pairs proposed by the *IDT-CV100*.

English	Spanish	Sim score	Correct?
principle	principio	0.9999	Yes
government	estado	0.9999	No
government	gobierno	0.9999	Yes
resources	recursos	0.9999	Yes
difficult	dificil	0.9999	Yes
sector	competencia	0.9998	No
sector	sector	0.9998	Yes
programme	programa	0.9998	Yes
programme	comunidad	0.9998	No
agreement	acuerdo	0.9998	Yes

Table 5: Some examples of most confident translation pairs proposed by *IDT-CV100* ranked by similarity scores.

7.2 Seed dictionary variation

The initial seed dictionary plays a major role in extracting bilingual lexicon from comparable corpora. There are a few different ways for us to derive a seed dictionary. Recall that Lex_{700} and Lex_{100}, that are used in the experiments, are derived using different methods. The F_1 scores of the system using Lex_{100} were much higher compared to the system using Lex_{700}. Thus, extending Lex_{100} with additional high frequency words may provide higher accuracy.

One important reason is that all bilingual entries in Lex_{100} occur frequently in the corpora. Although the size of Lex_{700} is larger, it is not surprising that most of the words never occur in the corpora, such as *volleyball* and *romantic*. However, using Lex_{160} is more interesting since it is derived automatically from the corpora, though one should realize that the relationship between the language pair used in the respective monolingual corpora, English and Spanish, may have largely affect the results. Thus, for other systems involving unrelated language pairs, the rank-binning similarity measure might be a good option.

7.3 Word sense discrimination ability

As mentioned in Section 5.4, each source word may have more than one highly associated context term, W_R. Different W_R may suggest different target words for the same source word. For example, given the source word *powers* and the highly associated word *community*, *competencias* is proposed as the best translation equivalent. On the other hand, for same source word *powers*, when the highly associated word is *delegation*, the target word *poderes* is suggested.

8 Conclusion

We have developed a method to improve the F_1 score in extracting bilingual lexicon from comparable corpora by exploiting in-domain terms. This method also performs well without using an initial seed dictionary. More interestingly, our work reveals the potential of building word sense disambiguated lexicons.

A framework for representing lexical resources

Fabrice Issac
LDI
Université Paris 13

Abstract

Our goal is to propose a description model for the lexicon. We describe a software framework for representing the lexicon and its variations called Proteus. Various examples show the different possibilities offered by this tool. We conclude with a demonstration of the use of lexical resources in complex, real examples.

1 Introduction

Natural language processing relies as well on methods, algorithms, or formal models as on linguistic resources. Processing textual data involves a classic sequence of steps : it begins with the normalisation of data and ends with their lexical, syntactic and semantic analysis. Lexical resources are the first to be used and must be of excellent quality.

Traditionally, a lexical resource is represented as a list of inflected forms that are projected on a text. However, this type of resource can not take into account linguistic phenomena, as each unit of information is independent. This results in a number of problems regarding the improvement or review of the resource. On the other hand some languages such as Arabic, because of the potential large lexicon, lends itself less easily to this kind of manipulation.

Our goal is to propose a model for the description of the lexicon. After presenting the existing theory and software tools, we introduce a software framework called Proteus, capable of representing the lexicon and its variations. The different possibilities offered by this tool will be illustrated through various examples. We conclude with a demonstration of the use of lexical resources in different languages.

2 Context

Whatever the writing system of a language (logographic, syllabic or alphabetic), it seems that the word is a central concept. Nonetheless, the very definition of a word is subject to variation depending on the language studied. For some Asian languages such as Mandarin or Vietnamese, the notion of word delimiter does not exist ; for others, such as French or English, the space is a good indicator. Likewise, for some languages, prepositions are included in words, while for others they form a separate unit.

Languages can be classified according to their morphological mechanisms and their complexity ; for instance, the morphological systems of French or English are relatively simple compared to that of Arabic or Greek.

There are two main branches of morphology, inflectional or grammatical morphology and lexical morphology. The first one deals with context-related variations, as the rules of agreement in gender and number or the conjugation of verbs. The second one concerns word formation, generally involving the association of a lexeme to prefixes or suffixes.

3 Tagging

Text tagging consists in adding one or more information units to a group of characters : the token. This association is firstly performed in a context-free way, that is to say considering only the token, and secondly by increasing the context size : the tagging process is subsequently repeated in or-

Coling 2008: Poster Volume, pages 490–497,
Beijing, August 2010

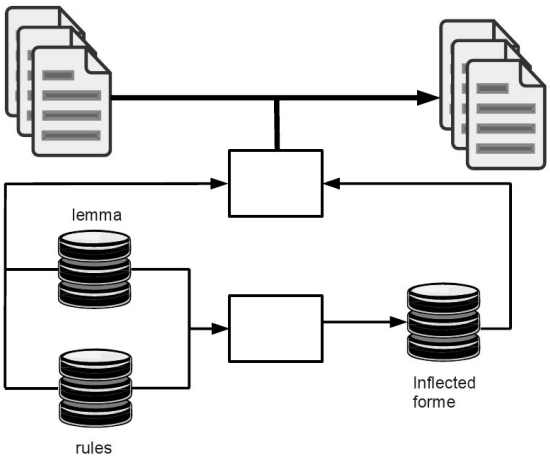

Figure 1: tagging schema

der to merge multiple tokens. Token merging applies to polylexical units, syntactic or para-textual structures.

We distinguish two main types of resources that can be projected on raw texts in order to enrich them. The first of these resources is a set of inflected forms associated with a number of information units (in the example below, the lemma and the morphosyntactic annotation of each form) :

```
abyssal   abyssal  A--ms
abysses   abysse   N-mp
```

The projection of this type of resources in textual corpora is quite simple. After identifying a token, the program only needs to check if the token is included in the resource and add the information units associated with it.

The second type of resources contains a set of rules and a set of canonical forms (usually the lemma but not necessarily). These sets are used jointly, to produce all the inflected forms or to analyse the tokens. Analysis consists in determining, for a given inflected form, which rule was used, on which canonical form, in order to generate it. Then the information to be associated with the inflected form is related to the rule found.

Diagram 1 presents the place of different resources in the tagging process.

4 Tools and resources

Several concepts are related to the use of lexical resources ; here we provide some examples of tools, theoretical as well as computational.

- resources in the form of a frozen list: Morphalou (Romary et al., 2004), Morfetik (Buvet et al., 2007), Lexique3 (New, 2006) ;
- lexical representation formalisms: DATR (Evans and Gazdar, 1996) ;
- inflections' parsers: Flemm (Namer, 2000) ;
- complete software platforms: Nooj (Silberztein, 2005), Unitex (Paumier, 2002) ;
- lexicon acquisition: lefff (Sagot et al., 2006).

4.1 Frozen resources

If this kind of resource is directly used in the tagging process, it raises many maintenance issues. Moreover, in the case of languages with rich morphology, the number of elements becomes too large. These lists are most often the result of inflection engines that use canonical forms and inflection rules to generate the inflected forms.

4.2 Hierarchical lexical representation formalisms

The goal of this type of formalisms is to represent the most general information at the top-level of a hierarchy. There is an inheritance mechanism to transmit, specify, and if necessary, delete information along the structure. It is possible to group under one tag a set of morphological phenomena and their exceptions. Multiple inheritance allows a node to inherit from several different hierarchies.

4.3 Inflections' parsers

They propose a morphological analysis for a given inflected form : they try to apply the derivation rules backwards and test whether the result obtained corresponds to an attested canonical form. The use of canonical forms is optional ; it provides an analysis for lexical neologisms but can cause incorrect results (*Hundred* is not the past participle of *hundre*).

4.4 Software platforms

Unitex / Intex / NooJ are complete environments for performing linguistic analysis on documents. They are able to project dictionaries on texts and to query them. They offer a set of tools for managing dictionaries, both lexical and inflectional. NooJ is the successor of Intex ; among the new features, is the redesign of the architecture of the dictionaries. It proposes handling simple and compound words in a single way. The method is a mix of manipulation of characters and use of morphological grammars.

The inflexion mechanism is based on classic character handling operators as well as on word manipulation operators. Here is the list of some operators:
<B> delete last character
<D> duplicate last character
<L> go left
<R> go right
<N> go to the end of next word form
<P> go to the end of previous word form
<S> delete next character

5 Representation and structuring of inflections: the Proteus model

We introduce a framework capable to represent and structure inflections efficiently, not only in terms of resource creation, but in terms of linguistic consistency too. At the inflection level we propose a simple multilingual mechanism for simple and compound forms. It is used both to generate simple forms and to analyse them. Regarding the lexicon, the model allows for clusters.

We distinguish three levels:

- the inflection level: determine how to produce a derived form from a base form ; the atomic processing unit here is the character (*i.e. local transformation*).
- the conjugation level: determine how to organise family rules effectively in order to avoid redundancy ; the atomic processing unit here is the transformation rule.
- the word level: once the derived form is produced, determine which operation is required to validate the form against non-morphological rules ; the processing unit here is the token (*i.e.* global transformation).

The model was developed to meet the following objectives:

1. A verbatim description of a language does not allow for the analysis of unknown words even if their inflection is regular. We must therefore develop a mechanism that we can use for both analysis and generation. Then we will be able to analyse not only known words but also neologisms.
2. In a lexical database, where, for French, the number of elements reaches one million, the presence of an error is always possible, even inevitable. We must therefore consider an effective maintenance procedure : a dictionary of lemmas linked to a dictionary of inflections and not a read-only resource containing all inflected forms.
3. The concept of word is so complex that we cannot limit a resource to simple words. The model must integrate the management of both simple and compound words. The only limit we set is syntax: the management of idioms, even if it is fundamental, requires the implementation of other tools.
4. The concept of inflection varies depending on the language. We must build a system capable of dealing with all types of affixation (prefixation, suffixation or infixation). The treatment of Arabic is from this point of view a good indicator since it uses all three types of affixation.
5. An inflection rule, applied to a canonical form, is never completely autonomous ; it is part of a group. For instance, we group together all the inflections of a verb type, for all tenses.
6. The transformation is not limited to morphological changes. For instance, phonological phenomena can occur too. More generally there are treatments that cannot be modelled on simple rules.

7. The proposed model is based on a set of simple tools, it is able to easily integrate third-party applications and allows use of dictionaries built in another environment.

5.1 Inflection description

Let f be the inflexion function and f^{-1} its inverse function, then

$$f(canonicalform, code) = inflectedform$$

$$f^{-1}(inflectedform, code) = canonicalform$$

By simplifying the model to the extreme, we use of a rule that generates an inflected form from its lemma. The form is represented as a list of caracters : (i) it shifts characters from the list to a stack or vice versa (ii) and deletes or inserts characters in the list. By default, the operations apply to characters placed at the end of the list of characters or, depending on the operator, at the top of the stack. Most operators allow for the application of the inverse function for the analysis of an inflection. Due to the operator based construction, the function has the following property:

let c_1, c_2 be valid code and x a character string, then

$$f(f(x, c_1), c_2) = f(x, c_1 \bullet c_2)$$

We now present the different operators. They must be sufficiently numerous, to offer the necessary expressive power to represent any kind of inflection, but small enough, not to make the task of creating the rule too difficult.

P (Push) : move a character from the list to the stack

D (Dump) : moves the character of the stack to the list

E (Erase) : deletes a character from the list

/x/ : adds the character x at the end of the list

To simplify code writing, it is possible to indicate the number of repetitions of an operator. Here is an example of code that generates an inflected form from its lemma.

Step	Mot	Pile	Code restant
1	céder		`3PE/è/3D/ais/`
2	cé	der	`E/è/3D/ais/`
3	c	der	`/è/3D/ais/`
4	cè	der	`3D/ais/`
5	cèder		`/ais/`
6	cèderais		

Steps:

1→2 : stack of three characters

2→3 : deleting of a character

3→4 : adding the character *è*

4→5 : dumping three characters from the stack

5→6 : addition of three characters *ais*

This code can inflect french verbs like *céder* (as *révéler*, *espérer*, ...). However, this kind of code does not allow reversing the operation, *i.e.* find the lemma from the inflection : the E (erase) operator, unlike other operators, is not reversible. Therefore we add another operator to erase this function or remove the characters to delete.

`\x\` : erase given character from the list (this rule cannot be applied if the character is not present)

The code of the previous example becomes `3P\é\/è/3D/ais/`.

Since consonant duplication is a common phenomenon, we introduce a specific operator :

C (Clone) : duplicates the last character of the list.

The code `C/ing/` generates the present participle of words such as *run*, *sit* or *stop*

The management of prefixes requires the addition of operators:

`]` (fill stack) : transfers all the characters from the list to the stack

`[` (empty stack) : transfers all the characters from the stack to the list

Operator] can prepare an addition at the beginning of a word since all characters are put in the stack. We are now able to describe the inflexion of the form: *move* → *unmovable*. The transformation "remove the character 'e' at the end of a word, add 'un' at the beginning and 'able' end of a word" is coded `\e\]/un/[/able/`. The same code can analyse verb constructions that end with the character *e*.

Processing compound words requires the addition, or rather the transformation, of an operator. The difficulty here is to distinguish the different components of an expression with respect to one or more separators (traditionally in French space, hyphen or apostrophe).

P|x| (Push): moves the character of the list to the stack to meet the character x

Changing the stacking operator allows us to access directly an element of an expression or a compound word. Please note that access to different elements of an expression is achieved by stacking and unstacking successively. The code `2P|-|/s/[` allows to form the plural of expressions such as *brother-in-law* : only the third word from the end is pluralized (*brothers-in-law*). To preserve the analysis function of the model, it would be necessary to add, symmetrically, a conditional popping operator (*e.g.* `D|x|`). However, compound words analysis is far more complex, and such an operator could not bring the solution.

5.2 Management of inflexion

We have defined an XML DTD to manage the inflections expressed in code.

```
<flex id="n-y-p" type="final">
    <name>Np</name>
    <info>Noun plural with
          a terminal y</info>
    <code>\y\/ies/</code>
<\flex>
```

The above definition associates n-y-p identifier with the code `\y\/ies/`. A typical inflexion is characterised by:

- an identifier (attribute `id`) is used by the description language ;
- a status (optional attribute `type`) ;
- a name (optional element `<name>`) which corresponds to the tag associated to the inflected form ;
- information (optional element `<info>`) about the inflection ;
- a Proteus inflection code (element `<code>`).

However it is often necessary to combine several transformations : masculine/feminine and singular/plural for nouns and adjectives, persons and tenses for verbs. Take for example the conjugation of a French verb in the first group in the present tense. The prototypical inflection may be given as follows:

```
<flex id="v1ip" type="term">
    <name>Vp</name>
    <info>verbes
        indicatif présent</info>
    <flex id="p1ns">
        <name>1s</name>
        <code>/e/</code>
    </flex>
    <flex id="p2ns">
        <name>2s</name>
        <code>/es/</code>
    </flex>
    <flex id="p3ns">
        <name>3s</name>
        <code>/e/</code>
    </flex>
    <flex id="p1np">
        <name>1p</name>
        <code>/ons/</code>
    </flex>
    <flex id="p2np">
        <name>2p</name>
        <code>/ez/</code>
    </flex>
    <flex id="p3np">
        <name>3p</name>
        <code>/ent/</code>
    </flex>
</flex>
```

In this structure we regroup all the inflections of a given tense. Each inflection is : associated to its own identifier, prefixed with the main identifier, separated with a point, and associated to a name which is also a concatenation. Note that it is the identifier that must be unique and not the name. This mechanism allows for the expression of variants in a paradigm (see below). The previous definition states that, for the first group of the present tense, French verbs require suffixes at the end of the canonical form. Note that this is

a generic definition that can take into account exceptions, and can be apllied to any tense or mood.

identifier	name	code
v1ip.p1ns	Vip1s	/e/
v1ip.p2ns	Vip2s	/es/
v1ip.p3ns	Vip3s	/e/
v1ip.p1np	Vip1p	/ons/
v1ip.p2np	Vip2p	/ez/
v1ip.p3np	Vip3p	/ent/

It is also possible to group inflections with a new element (<op> with the attribute type).

```
<flex id="vig1-1" type="nonterm">
    <name></name>
    <info>first group
      indicative</info>
    <op type="add">
        <item value="v1ip"/>
        <item value="v1ii"/>
        <item value="v1ips"/>
        <item value="v1ifs"/>
    </op>
</flex>
```

To the previous definitions we need to modify the code in order to add a prefix operation: *remove the 'er' at the end of the lemma*. So we added the possibility of code concatenation to a previously defined group. In the example bellow the pos attribute determines if the code to be added is a prefix (p) or a suffix (s). The value attribute indicates the identifier of the structure upon which the operation is applied.

```
<flex id="v1" type="final">
    <name></name>
    <info>"er" verb</info>
    <op type="conc" value="vig1-1">
        <item pos="p">\re\</item>
    </op>
</flex>
```

In some cases, modification has to be performed on a particular inflection. This is done via the application of a *mask* which operates on a group of inflections and changes, possibly selectively, codes of inflexion. A mask is a set of rules applied on code. A regular expression on the identifier (ervalue attribute) performs the selection. We use Proteus code to modify Proteus code. This *mise en abyme* seems inconsistent, since Proteus has been designed to apply on a language element. But it seemed inappropriate to introduce a new syntax.

The definition below allows to add the letter *e* to a form in order to maintain its pronunciation [ʒ].

```
<mask id="m-ge">
 <info>add e after a g</info>
  <item ervalue="v1ip\.p1np">
        ]5D/e/[</item>
  <item ervalue="v1ii\.p([123]ns|3np)">
        ]5D/e/[</item>
  <item ervalue="v1if\.p([12]n[ps]|3np)">
        ]5D/e/[</item>
</mask>
```

The previous definition transforms code as \er\/ons/ in \er\/eons/, \re\/ais/ in \re\/eais/, ... The mask is used in combination with the attribute mask in a inflection definition, as in the conc attribute.

```
  <flex id="v1" type="final">
      <name></name>
      <info>verbes en "er"</info>
      <op type="mask" value="vig1-1">
          <item value="m-ge"/>
      </op>
  </flex>
```

You can build a complex inflection by using a base and applying masks successively. The inflection of the French verb *neiger* (to snow) can be expressed using two masks. First a mask to take into account the pronunciation of the [ʒ] and a second one, the weather verb mask, which is only used in the third singular person.

5.3 Applications

The examples bellow show the different capabilities of the model.

5.3.1 Neologisms in French

The formation of French inflections should not create significant problems. For the most common languages, simple forms are less than 1 million. Therefore, most systems use this set of inflected forms and supply modules to guess unknown words, only when they arise. This experiment is used to validate the model and to analyse unknown forms.

The example below shows how we analyse an unknown form.

```
anticonservationnistes =(/s/)=>
anticonservationniste =(]/anti/[)=>
conservationniste =(/niste/)=>
conservation =(\e\/ation/)=>
conserve
```

The algorithm tries to apply a code and reiterates the process on the result until we obtain an

attested form. The set of rules provides a potential analysis of the unknown word. Note that the rules used allow to determine the part of speech. In the example, the analysed word can be a plural noun or an adjective.

5.3.2 Arabic verbs

Arabic is a Semitic language ; it uses a semitic root to derive all the words used. For example from the root كتب (which refers to the writing) it is possible to produce verb (write), noun (desk) or adjective (written).

With these lemmas it is possible to agglutinate prefixes and suffixes. The rules are very regular in morphology but also very productive. We build all inflexion from the semitic root. So we have the schema: root → radical → inflected form. We then define inflexion for prefix/suffix (identifier `pass1term`), a mask for the radical (identifier `pass1radical`) and a definition which combine both.

```
<mask id="pass1radical">
 <info>add radical past</info>
 <item ervalue=".">
   ]/2P\/´\/D\/´\/D/[+
 </item>
</mask>
```

```
<flex id="pass1" type="nonterm">
  <name>Vis</name>
  <info>passe</info>
  <op type="mask" value="pass1term">
    <item value="pass1radical"/>
  </op>
</flex>
```

The problem encounter with arab text is the possible non use of all vowels. In fact they are rarely used, generally in pedagogical or religious text. This mean that the context is fundamental to interpret a text, a vowel is added only to remove an ambiguity. However we decide to describe language fully vowelled and to manage this specificity in an earlier stage.

The objective is to provide a resource used during an lexical analysis. This can be done in two ways[1]:

[1]We used here a transliteration version of arab writing to be more clear.

5.3.3 Old French

We are developping (author reference) an Old French resource, as exhaustive as possible. One difficulty is to consider the various alternatives, dialectal or chronological. This *proto-morphological* problem complicates the development of the dictionary nomenclature. We solved this problem by introducing an arbitrary "language Phantom" and by adding one level to the composition of the nomenclature, in the form of a label named hyperlemma. All derivations are from this entity using Proteus rules. All variants are generated from this item by application of successive masks.

The example below shows the successive masks applied on the inflection rules to account for the variations of the imperfect tense. Each mask is named *modifxxx* and corresponds to the modification of the Proteus rule for each century *xxx*.

```
<flex id="vg1i-5" type="final">
      <name>Vii</name>
      <info>first group
            imparfait</info>
    <op type="mask" value="v1ii">
        <item value="modifXI"/>
        <item value="modifXII"/>
        <item value="modifXIII"/>
        <item value="modifXIIIa"/>
        <item value="vrber"/>
    </op>
</flex>
```

6 Implementation

This framework is not only a theoretical tool ; it is designed to be implemented in a tagging software as an autonomous module. Based on abstract descriptions (Proteus code and XML language), it allows the resource creator to focus on linguistic aspects. It is simple enough to be easily expressed in any computational language.

The platform described here is developed in Python, which allows a very compact coding and can be used for both generation and analysis.

7 Conclusion

Our work is part of a set of tools and resources dedicated to the analysis of natural language. We have presented a model for the representation of inflections coupled with a language to structure the transformation rules. Compound words are

handled in the same way as simple words. The proposed model also allows simple word identification in both analysis and resource generation functionality. We have presented three examples of the use of the model, each introducing a specificity: French, Old French and Arabic. In the near future we expect to begin work on the Korean, Polish and Greek.

The best way to improve the framework is to create real, *i.e.* exhaustive linguistic resources. The development of the framework can be considered from several ways.

The Proteus code and the XML language description need stability. In our opinion, addition of operations to take into account some language specificities would complicate the model without adding any significant improvement. These modifications will take place during the third stage, the word level, where post-treatments are applied. For instance, the tonic accent in Greek can move along the last three syllables of a word and affects the use of the diaeresis mark in diphthongs.

As far as the analysis functionnality is concerned, we are considering to develop specific heuristics for each language in order to guide the choice of rules.

Abstract

In this paper, we propose language-specific methods of sentiment analysis in morphologically rich languages. In contrast of previous works confined to statistical methods, we make use of various linguistic features effectively. In particular, we make chunk structures by using the dependence relations of morpheme sequences to restrain semantic scope of influence of opinionated terms. In conclusion, our linguistic structural methods using chunking improve the results of sentiment analysis in Korean news corpus. This approach will aid sentiment analysis of other morphologically rich languages like Japanese and Turkish.

1 Introduction

The Internet is a global forum where citizens of the world gather to express their opinions. Online services exist for users to share their personal thoughts while the use of blogs and Twitter substitutes for private diaries. For this reason, sentiment analysis which automatically extracts and analyzes the subjectivities and sentiments (or polarities) in written texts has recently been receiving attention in the field of NLP.

Sentiment analysis of English employs various statistical and linguistic methods referencing such linguistic resources as The Berkeley Parser and SentiWordNet. In the case of Korean, however, most previous works have been confined to statistical methods which focus either on the frequency of words or relevance of co-occurring words only. This is because it is hard to find proper resources due to the nature of Korean, exhibiting such features as rich functional morphemes, a relatively free word-order and frequent deletion of primary elements of sentences like the subject and object. The major drawbacks of statistical-based approaches are the facts that the 'real' meaning of the expressions which we feel when we read them cannot be reflected in the analysis, and that complex statistical measuring methods are computationally taxing.

In this paper, in order to overcome previous shortcomings, while making use of Korean case studies we propose a new approach for morphologically rich languages that makes effective use of linguistic information such as the semantic classes of words, semantic scope of negation terms like *not, no,* and the functional meaning of modal affixes. Especially, this approach makes chunk structures by using dependency relation of morpheme sequences to limit the semantic scope of influence of opinionated terms. This chunking method is simpler and more efficient than total syntactic parsing. In addition, we utilize subjectivity clues and contextual shifters whose effectiveness is established in previous references.

The contents of this paper are as follows: firstly, we review previous works related to our approaches. We follow up by introducing the framework and main processes of our approach are introduced. Finally, we describe our experiments and show how a linguistic approach is feasible in sentiment analysis of Korean as a morphologically rich language.

2 Related Work

Sentiment analysis research has been performed to distinguish the authors' polarity (sentiment orientation) on certain topics from document-level (Turney, 2002: Pang et al., 2002; Dave et al., 2003) to sentence-level (Hu and Liu, 2004;

Coling 2008: Poster Volume, pages 498–506,
Beijing, August 2010

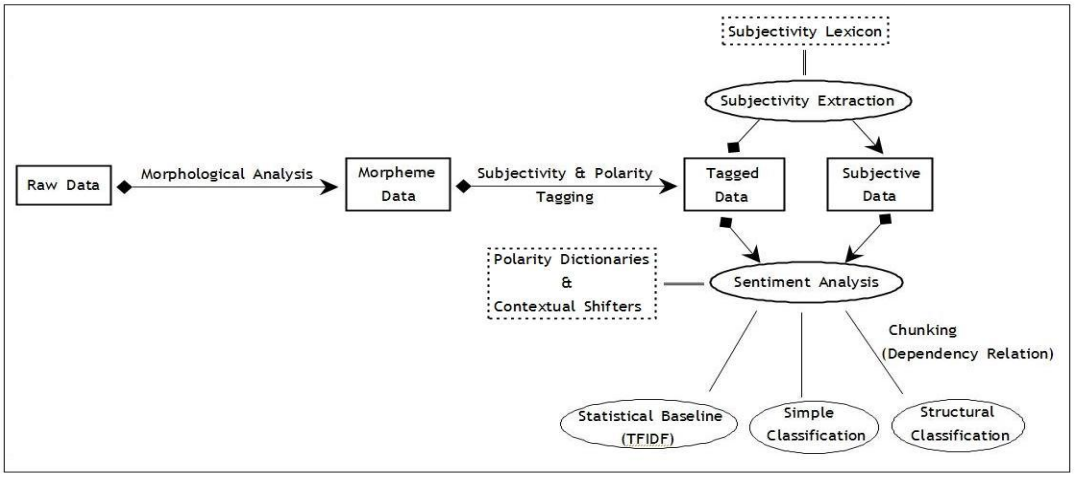

Figure 1. Sentiment Analysis Framework

Kim and Hovy, 2004). We will focus on sentence-level sentiment classification with our presupposition that the polarity of sentences in a single document can be diversified due to the inclusion of various subtopics.

Recently, much research has focused on subjectivity[1] extraction that divides objective facts from subjective opinions in data. Pang and Riloff (2005) and Yu and Hatzivassiloglou (2003) trained sentence-level subjectivity classifiers and proved that performing sentiment analysis targeting selected subjective sentences only gets higher results. We adopt a method of Wiebe and Riloff (2005)'s methods which classifies sentences containing more than two lexical items associated with subjectivity and compare the result of the experiments on full and extracted subjective corpora.

The core of the proposed new approach is the use of structural information in morphologically rich languages in the process of sentiment analysis. Choi et al. (2005) and Mao and Lebanon(2006) are representative of the structured sentiment analysis approach which takes advantage of Conditional Random Fields (CRF) to determine sentiment flow. McDonald et al. (2007) also dealt with sentiment analysis, via the global joint-structural approach. Furthermore, since there are a lot of good parsers for English data, Meena and Prabhakr (2007) and Liu and Seneff (2009) utilized sentiment structure information by such parsers such as Berkeley Parser.

In the case of Korean, much research applies dependency grammars for reducing the complexity of sentences to match the characteristics of Korean (Kim and Lee, 2005; Nam et al., 2008) but this still causes problems which prohibit wide use. Therefore we suggest a new morphological chunking method that binds semantically related concatenations of morphemes. This helps to define boundaries of semantic scopes of opinionated terms and is faster, simpler and more efficient on sentiment analysis than a general full parser.

Our approach focuses on the role of contextual shifters as well. In this paper, the term 'contextual shifter' covers both negation shifters and flow shifters: the former refers to the terms which can change semantic orientation of other terms from positive to negative and vise versa, the latter the terms which can control sentiment flow in sentences, for example, in English *not, nobody* (negation shifters), *however, but* (flow shifters). Kennedy and Inkpen (2006) did sentiment analysis of movie and product reviews by utilizing the contextual shifter information. Miyoshi and Nakagami (2007) also used this method to see the advancement of the result on sentimental analysis of electric product reviews in Japanese. In this work, we make use of the functions of each shifter to properly modify the value of the terms in the sentences and limit the number of the features which have to be observed in the analysis process to increase efficiency.

[1] The term 'subjectivity' is equivalent to Quick et al. (1985)'s private state which was defined as the words and phrases expressing individual mental and emotional states.

3 Sentiment Analysis Framework

The process of sentiment analysis in this paper is described in Figure 1. In this section, we explain each step of the process in detail.

3.1 Morphological Analysis

Korean is an agglutinative language where roots and affixes which have their own functional meaning combine to form complete words. Consequently, sufficient morphological analysis is very important to catch the precise and deep meaning of such expressions. If a certain sentence is misunderstood by wrong morphological analysis, there will be a strong possibility that opinionated terms in the sentence cannot be correctly analyzed.

We used the KTS [2] which is open-source probability based Korean morphological analyzer. Although the probabilistic rules established in KTS are elaborate, the main source of inaccuracy is rooted in the inadequacy of the lexicon. After categorizing all listed words in the sentence, the remaining words are mostly classified as general nouns. In this case, the terms which should play a role as important features in the process of sentiment analysis will be probably misunderstood.

(1) 너무 진부한 내용
nemu cinpuha-n nayyong
too stale-AD[3] content
'too stale contents'

(2) 너무/a 진부/ncs 하/xpa
nemu/a[4] cinpu/ncs ha/xpa
ㄴ/exm 내용/nc
n/exm nayyong/nc

(3) 너/npp 무진/nc 부/nc
ne/npp mucin/nc pu/nc
한/nc 내용/nc
han/nc nayyong/nc
'you Mujin(place name) wealth resentment contents'

For example, if sentence (1) which has to be analyzed as in (2) is incorrectly analyzed as in (3). This fault result ignores original spacing and randomly conjoins syllables in order to find the lexical items included in the dictionary because of the lack of lexicon. As the result, we cannot grasp the intended sentiment cinbu 'stale' in respect to the object nayyong 'contents' in the sentence. In order to solve such problems, we expanded the lexicon of KTS by adding 53,800 lexical items which are included in the Sejong[5] dictionary.

3.2 Subjectivity and Polarity Tagging

News corpora have no marks representing polarity of sentences as exist in the grading systems found in movie review corpora. In addition news data contain relatively more objective sentences which corpora tend to refer to as facts, as compared with reviews. Therefore in the case of news corpora there is a need to process the annotation of subjectivity and polarity tags for each sentence manually.

In our work, two native Korean annotators manually attached polarity labels to each sentence. Sentences are classified as subjective when they contain opinions pertaining to a certain object. Even if the opinion is not expressed on the surface using direct sentiment terms, the sentences are classified as subjective when the annotator can feel the subjectivity through the tone of voice. In the case of sentences containing common sense polarity value words such as donation, murder, etc, terms do not work as the judgment criterion, rather the annotator's judgment about the main theme of the sentence is applied. Only when the sentences are classified as subjective, the polarity tags are attached. The agreement rate of the two annotators in the manual annotation of polarity is 71%.

[2] http://kldp.net/projects/kts/

[3] Abbrebiates: AD(adnominal suffix), NM(nominative particle), IN(instrumental particle), SC(subordinative conjuctive suffix), CP(conjunctive particle), PST(past tense suffix), DC(declarative final suffix), RE(retrospective suffix), CN(conjectural suffix), PR(pronoun), PP(propositive suffix), AC(auxiliary conjunctive suffix), GE (genitive particle)

[4] POS tags of KTS: a(adverb), ncs(stative common noun), xpa(adjective-derived suffix), exm(adnominal suffix),nc (common noun), npp(personal pronoun)

[5] The 21st century Sejong Project is one of the Korean information policies run by the Ministry of Culture and Tourism of Korea. The project was named after King Sejong the Great who invented Hangeul. (http://www.sejong.or.kr/)

Label	Number of items	Lexical items
Positive	2,285 (1838 nouns, 133 verbs , 314 adjectives)	*Coh/pa* 'good', k*elcak/nc* 'masterpiece', *chincel/ncs* 'kind'
Negative	2,964 (2300 nouns, 359 verbs , 305 adjective)	*Nappu/pa* 'bad', *ssuleki/nc* 'trash', *koylophi/pv* 'harass'
Cynical	21 (adverbs)	*celday/a* 'Never', *kyeu/a* 'barely'
Intensifier	91 (80 adverbs, 10 nouns, 1 interjections)	*acu/a* 'very', *hancung/a* 'more', *tanyeonkho/a* 'decisively'
Conjectural	19 (13 final suffixes, 4 pre-final suffixes, 2 adnominal suffixes)	*keyss/efp* CN, *lthenteyo/ef* CN, *l/exm* CN
Obligative	6 (4 final suffixes, 2 auxiliary conjunctive suffixes)	*eya/ecx* 'must', *eyacyo/ef* PP
Quotative	5 (final suffixes)	*ntanunkun/ef* DC, *tayyo/ef* DC

Table 1. Polarity Dictionary

3.3 Subjectivity Extraction

The subjective lexicon used in subjectivity extraction contains 2,469 lexical items which includes 1,851 nouns, 201 verbs, 247 adjectives, 124 adverbs, 44 suffixes, and 2 conjunctive particles. The lemmas of Sejong dictionary are classified by a total of 581 semantic classes. Among them are 23 subjectivity-related semantic classes which include Abusive Language, External Mental State, Internal Mental State etc. Firstly, we have registered those lexical items –nouns, adjectives, verbs- under subjectivity-related semantic classes. Since they will be compared with morphologically analyzed data before subjectivity classification, all items were registered as tagged forms. Nouns took the biggest portion in the lexicon through this process, since adjectives and verbs which consist respectively of stative nouns (ncs) and active nouns (nca) plus derived suffixes (xpa, xpv) were all registered as nouns.

In Korean, sentiment can also be judged from particles and affixes having modal meaning.

(4) 정부가 무응답으로 대응한지 3 일이나 지났다.
*jengpwu-ka mwuungtap-ulo tayungha-nci 3il-**ina** cina-ss-ta.*
Government-NM no response-IN action-SC 3days-CP pass-PST-DC
'It already passed 3 days after government did not response'

(5) 그 배우가 안 나왔더라면 좋았을텐데.
*ku paywu-ka an-nao-ass-te-lamyen coh-ass-**ltheyntey***
the actor-NM not-star-PST-RE-if nice-PST-CN
'It were nice, if the actor would not have starred the main character'

(6) 그거 정말 맛있었겠다.
*ku-ke cengmal masiss-ess-**keyss**-ta*
that-PR really delicious-PST-CN-DC
'That must have been really delicious'

For example, conjunctive particle *-(i)na* in the sentence (4), final suffix *-ltheyntey* in (5), and pre-final suffix *-keyss* in (6) are very influential in judging the subjectivity of sentences. Therefore, we added those functional terms in the subjective lexicon.

We classified the sentences which contains more than two subjective items as subjective. When the sentence contained less than five morphemes, however, we manage to judge the sentence as subjective even when only one subjective item shows. The result of subjectivity extraction is confirmed by the widely used statistical method, TFIDF, in the following section.

3.4 Term Weighting

In our process of sentiment analysis, every term gets its own values by using polarity dictionaries and contextual shifters. In this section we introduce our polarity dictionary and contextual shif-

ters, and their lexical items. Also, the term-weighting methods of our approach is described.

Polarity dictionary: Table 1 shows our polarity dictionary used in sentiment classification. In the same way as a subjective lexicon, all lexical items are registered in the shape of a tagged morpheme. In addition, every item has labels with its own functional categories.

First, Positive and Negative refer to the basic polarity value of individual terms of sentences. The terms that are neither positive nor negative are classified as neutral. We registered nouns, adjectives and verbs included in Sejong dictionary's semantic class related with emotion or evaluation such as Positive Property Human, Negative Property Human, etc. After that, we selected the terms that are generally used to express polarity from other review corpora and added them to the dictionary. Since we deal with on-line texts, we also added acronyms, neologisms and new words which are frequently used to express opinion online.

Next we add various functional lexical items that are from other parts of speech to the polarity dictionary. Cynical items play a role of adding negative nuance to sentences. Intensifiers emphasize the meaning of following expressions. Conjectural, Obligative and Quotative items refer to something other than the author's opinion. Conjectural and Obligative means that the opinion included in the expressions is not actual but hypothetical. Quotative means that opinionated terms which are in same phrase express another person's opinions.

To determine the value of the terms, our approach uses a very simple measuring method. Every term initially gets +1 if Positive, -1 if Negative. All other words receive a value of 0. In the next step, the contexts of the sentences are examined and the values are modified. In the case of simple classification which does not go through the chunking process, we consider the distance of content words in Korean sentences which have various auxiliaries and affixes, and set a [-2, +2] window. In the case of structural classification, we take advantage of structures made by chunking. If Positives and Negatives are neighboring, we modify the values of the terms to reflect the fact that they influence each other. When Cynical items appear with Positives, we multiply by -1 to the value of Positives. When Cynicals appear with Negative items, we intensify the value of Negative by multiplying by 2. If Cynicals appear with neutral terms, we change the value of neutral terms to -1. The value of the terms which are affected by the Intensifier doubles, whereas the values of the terms which are in the scope of Conjectural, Obligative and Quotative items are reduced to half. In this way we control the importance of the terms in the sentence.

Contextual Shifters: contextual shifters in Korean consist of 13 negation shifters (adverbs such as *an/a* 'not'*, mos/a* 'cannot' and auxiliary verbs such as *anh/px* 'not'*, mal/px* 'stop') and 23 flow shifters (sentence-conjunctive adverbs such as *kulena/ajs, haciman/ajs* 'but, though', subordinative conjuctive suffixes *pnitaman/ecs, ntey/ecs* CN and conjunctive suffixes such as *eto/ecx* AC).

Since negation shifters play the role of shifting the polarity of the sentiment terms in our approach, we multiply them by -1. In the case of flow shifters, we limit the number of features to the terms after the shifter appears. We deemed it more important to understand an author's empathetic point, rather than to catch full sentiment flow in the sentences. Also such emphasized contents mostly exist after the flow shifters. Therefore we utilize this characteristic to reduce the work load and to prevent confusions which are caused by other minor sentiment terms.

(7) 음악도 좋고 영상도 좋았는데 스토리가 별로였다.
*umak-to coh-ko yengsang-to coh-ass-**nuntey** sutholi-ka pyello-yess-ta*
music-also good-CN image-also good-CN story-NM not so good-PST-DC
'music was good and image also good though, story is not so good,'

For example, in the sentence (7) *-nuntey* functions as a flow shifter. Dealing with the words after *–nuntey*, we can limit the object morphemes to 5 out of 14. Therefore, measuring load is significantly reduced, and furthermore, we can prevent the confusion from two positive terms *coh* 'good' before the flow shifter.

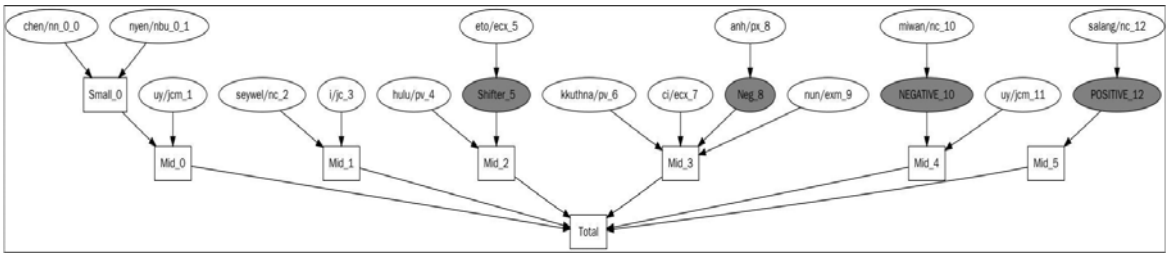

Figure 2. Chunking structure of the below sentence. (A short movie reviews)
천년의 세월이 흘러도 끝나지 않는 미완의 사랑
chen-nyen-uy seywel-i hulu-eto kkuthna-ci anh-nun miwan-uy salang
1000-year-GE time-NM flow-CN finish-CN not-AD incomplete-GE love
'an incomplete love that has not finished even after 1000 years'

3.5 Chunking using morphological dependency relation

In our approach, instead of complete syntactic parsing we use a chunking method based on the dependency relation of morpheme sequences in terms of the provision that it is important to limit the semantic influential scopes of main opinionated expressions.

Korean is a head-final language: in terms of dependency grammar, governors are always located after their dependents. We reflect upon this characteristic to form a relation if a certain morpheme acts as the governor of a previous morpheme. Chunks (small and mid nodes shown in figure 2.) are formed until an unrelated morpheme appears. The terms in a single chunk exert great semantic influence to control the value of each other. After determining the values of every morpheme in each chunk, this process is replicated at a higher level and finally the ultimate values of every term in the sentence are determined.

For example in Figure 2, the structure *[[chen+nyen]+uy] [seywel+i] [hulu+eto] [kkuthna+ci+anh+nun] [miwan+uy] [sarang]* is the result of the chunking process of the sentence *chen-nyen-uy seywel-i hulu-eto kkuthna-ci anh-nun miwan-uy salang* 1000-year-GE time-NM flow-CN finish-CN not-AD incomplete-GE love 'an incomplete love that has not finished even after 1000 years'. If we focus on the terms after the flow shifter *-eto*, the negation shifter *anh* 'not' in the first phrase only influences the verb *kkuthna-* 'finish' in the same chunk. This limitation of semantic scope of the negation shifter eliminates the possibility that it excessively modifies the values of other unrelated elements. Since the simple classification has a [-2, +2] window, *miwan* 'incomplete' is also influenced by *-anh*. Then the value of *miwan* becomes +1 which is classified as a positive term, and the whole expression *miwan-uy salang* 'an incomplete love' is misclassified as positive.

4 Experiment

4.1 Corpora

Since movie review data is commonly used for sentiment analysis, we primarily collected movie reviews. Following the comments of many previous works that it is hard to separate the sentences which mention the plot of movies from opinion sentences, especially short movie reviews which containing 1~2 sentences deliberately selected. The reason is that short reviews having limited space probably include opinions only. Movie review data of less than 20 characters was crawled from a representative movie site in Korea, Cine21[6]. It contains 185,405 reviews ranging from December 31, 2003 to December 28, 2009 (total 19.5MB).

Next, we collected 79,390 news articles from January 1, 2009 to April 7, 2010 (total 146.6MB) from the web site of the daily newspaper, The Hankyoreh[7]. The news data includes both objective and subjective sentences, and is categorized into 3 groups by the following characteristics: 71,612 general news articles, 3,743 opinionated news articles having subjective subtopics such as 'Yuna Kim, terrorism, etc.' and 3,432 editorial articles including columns and contributions. After randomly extracting 100 articles from each data group a Korean annotator attached subjectivity and polarity labels to each

Method	total		subjective	
	Accuracy (%)	F-measure[8] (%)	Accuracy	F-measure
TFIDF	87.67	93.431	90.02	94.748
NO chunking NO shifter	**87.676**	**93.432**	**90.034**	**94.757**
NO chunking YES shifters	**87.674**	**93.433**	90.018	94.745
YES chunking NO shifter	83.212	90.835	87.29	93.214
YES chunking YES shifters	83.212	90.835	87.29	93.214

Table 2. Sentiment analysis of short movie review corpora

Method	Data		Accuracy (%)	F-measure (%)
TFIDF	News articles	Total	63.032	28.532
		Subjective	82.00	89.919
	Subtopic News articles	Total	61.95	32.287
		Subjective	73.332	84.44
	Editorial articles	Total	57.53	73.04
		Subjective	87.23	93.18

Table 3. Subjectivity extraction of news corpora

sentence. The collection of sample sentences consists of 1,225 general news sentences, 1,185 subtopic news sentences and 2,592 sentences of editorial articles.

4.2 Experiment 1: Short Movie Reviews

Table 2 shows the result of a 5-fold cross variation experiment on the sentiment analysis of short movie review data using SVMlight. The numbers in bold face are the values being larger than the baseline, the results using TFIDF. A subjectivity extraction experiment was not carried out because of the presumption that all movie reviews used in this work are subjective. (There were a few reviews containing quotes from the movies or meaningless words only. Such cases, however, were ignored.) In the case of movie review data, selected subjective data is regarded as having stronger subjectivity.

When subjective data is compared with total data by the same experimental methods, there are consistent improvements in sentiment analysis for the subjective data. It is no surprise that the sentences that contain a more intense level of subjectivity can be easily classified as correct polarity.

In addition, contrary to our expectations, the application of the simple classification method (NO chunking) gets the higher results in comparison with the structural classification method (YES chunking) regardless of the use of contextual shifters. This phenomenon can be analyzed based on the limited length of reviews and the characteristics of online data. First, most sentences have a simple structure like the sequence of nouns or noun phrases due to restricted writing space. For this reason, the effect of chunking and contextual shifters on sentiment classification is insignificant. Second, the data includes various terms only seen on the Internet, vulgarisms and ungrammatical words. Furthermore, there are the problems of word spacing and spelling. Because of these drawbacks of online data, morphological analysis errors frequently occurred. The errors are further propagated to structures as a result of chunking. For this reason, when the chunking method is used, contextual shifters are ineffective at all as shown the results using the chunking method in Table 1.

4.3 Experiment 2: News articles

Subjectivity Extraction: The results of a 5-fold cross variation experiment of subjectivity extraction using SVMlight are described in Table 3. In this experiment, we use the commonly used statistical method TFIDF to compare total data with subjective data in the three groups in the subjectivity classification task. In conclusion, the chosen subjective data of all groups get higher results. Especially in the cases of news articles and subtopic news articles which are less subjective than editorial articles, F-measure value is greatly increased.

[8] F-measure = 2*precision*recall/(precision+recall)

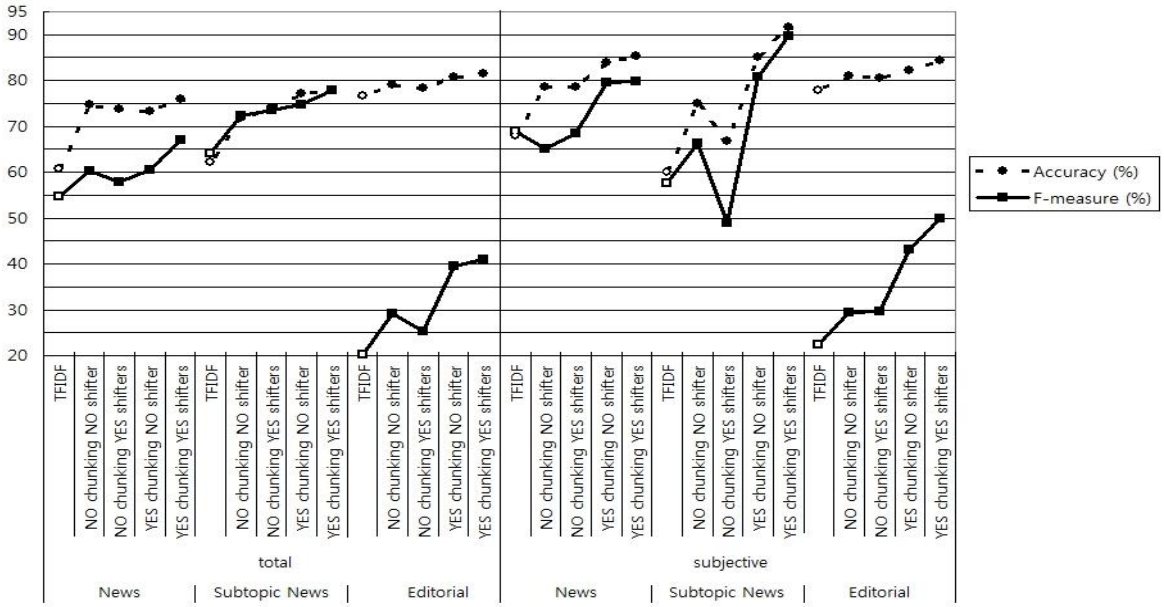

Figure 3. Sentiment analysis of news corpora

Sentiment Analysis: The results of sentiment analysis on the three groups of news data are summarized in Figure 3. The white points in Figure 3 are the values being larger than the baseline, the results using TFIDF.

First of all, all of our proposed classification methods get higher results than TFIDF, except in the case of F-measure of subjective News data. This shows that using language-specific features which inflect the target language's linguistic characteristics well, without complex mathematical measuring techniques, we could get better results than statistical methods in sentiment classification.

Secondly, similar to the result of movie review corpora, mostly subjective data shows greatly improved results in experimental methods overall. This means that our subjectivity extraction works successfully.

Finally, in contrast to the results of experiment 1, we get higher values of sentiment classification by using chunking and contextual shifters. This implies that the restriction on semantic scope of opinionated terms and the methods reducing features and properly modifying values of polarity terms by using contextual shifters also have merits in sentiment analysis of data such as news which has complex sentence structure like news. Furthermore, this tendency is noticeable particularly in the subjective data of all three groups. This confirms the effectiveness of utilizing linguistic methods in subjectivity extraction and sentiment analysis for news data which tries to maintain objectivity.

5 Discussion and Further Work

In this paper, we verified that simple measurements utilizing language-specific features can improve the results of sentiment analysis. Particularly the chunking method using morphological dependency relations and the lexicon which contains suffixes and particles having important functional meanings is expected to aid the sentiment analysis of other agglutinative languages such as Turkish and Japanese. In addition, this approach of sentiment analysis can be applied to various applications for extracting important information on the Internet to monitor a certain brand's reputations or to make social network for peoples who have similar opinions.

We have plans to confirm the results of this paper by experiments on corpora which are expanded in size and type in future work. We will also increase the number of lexical items of subjectivity lexicon and polarity dictionary. Furthermore, we will utilize other linguistic information such as synonym lists of Korean ontology and elaborate measuring methods using linguistic-specific features of morphologically rich languages effectively.

Challenges from Information Extraction to Information Fusion

Heng Ji
Computer Science Department
Queens College and Graduate Center
City University of New York
hengji@cs.qc.cuny.edu

Abstract

Information Extraction (IE) technology is facing new challenges of dealing with large-scale heterogeneous data sources from different documents, languages and modalities. Information fusion, a new emerging area derived from IE, aims to address these challenges. We specify the requirements and possible solutions to perform information fusion. The issues include redundancy removal, contradiction resolution and uncertainty reduction. We believe this is a critical step to advance IE to a higher level of performance and portability.

1 Introduction

Latest development of Information Extraction (IE) techniques has made it possible to extract 'facts' (entities, relations and events) from unstructured documents, and converting them into structured representations (e.g. databases). Once the collection grows beyond a certain size, an issue of critical importance is how a user can monitor a compact knowledge base or identify the interesting portions without having to (re) read large amounts of facts. In this situation users are often more concerned with the speed in which they obtain results, rather than obtaining the exact answers to their queries (Jagadish et al., 1999). The facts extracted from heterogeneous data sources (e.g. text, images, speech and videos) must then be integrated in a knowledge base, so that it can be queried in a uniform way. This provides unparalleled challenges and opportunities for improved decision making.

Data can be noisy, incorrect, or misleading. Unstructured data, mostly text, is difficult to interpret. In practice it is often the case that there are multiple sources which need to be extracted and compressed. In a large, diverse, and interconnected system, it is difficult to assure accuracy or even coherence among the data sources. In this environment, traditional IE would be of little value. Most current IE systems focus on processing a single document and language, and are customized for a single data modality. In addition, automatic IE systems are far from perfect and tend to produce errors.

Achieving really advances in IE requires that we take a broader view, one that looks outside a single source. We feel the time is now ripe to incorporate some information integration techniques in the database community (e.g. Seligman et al., 2010) to extend the IE paradigm to real-time information fusion and raise IE to a higher level of performance and portability. This requires us to work on a more challenging problem of *information fusion* - to remove redundancy, resolve contradictions and uncertainties by multiple information providers and design a general framework for the veracity analysis problem. The goal of this paper is to lay out the current status and potential challenges of information fusion, and suggest the following possible research avenues.

- **Cross-document:** We will discuss how to effectively aggregate facts across documents via entity and event coreference resolution.
- **Cross-lingual:** A shrinking fraction of the world's Web pages are written in English, and so the ability to access pages across a range of languages is becoming increasingly important for many applications. This need can be addressed in part by cross-lingual information fusion. We will discuss the chal-

Coling 2008: Poster Volume, pages 507–515,
Beijing, August 2010

lenges of extraction and translation respectively.

- **Cross-media:** Advances in speech and image processing make the application of IE possible on other data modalities, beyond traditional textual documents.

2 Cross-Document Information Fusion

Most current IE systems focus on processing one document at a time, and except for coreference resolution, operate one sentence at a time. The systems make only limited use of 'facts' already extracted in the current document. The output contains rich structures about entities, relations and events involving such entities. However, due to noise, uncertainty, volatility and unavailability of IE components, the collected facts may be incomplete, noisy and erroneous. Several recent studies have stressed the benefits of using information fusion across documents. These methods investigate quite different angles while follow a common research theme, namely to exploit global background knowledge.

2.1 Information Inference

Achieving really high performance (especially, recall) of IE requires deep semantic knowledge and large costly hand-labeled data. Many systems also exploited lexical gazetteers. However, such knowledge is relatively static (it is not updated during the extraction process), expensive to construct, and doesn't include any probabilistic information. Error analysis on relation extraction shows that a majority (about 78%) of errors occur on nominal mentions, and more than 90% missing errors occur due to the lack of enough patterns to capture the context between two entity mentions. For instance, to describe the "located" relation between a bomber and a bus, there are more than 50 different intervening strings (e.g. "killed many people on a", "'s attack on a", "blew apart a", "blew himself up on a", "drove his explosives-laden car into a", "had rigged the", "set off a bomb on a", etc.), but the ACE[1] training corpora only cover about 1/3 of these expressions.

Several recent studies have stressed the benefits of using information redundancy on estimating the correctness of the IE output (Downey et al., 2005), improving disease event extraction (Yangarber, 2006), Message Understanding Conference event extraction (Mann, 2007; Patwardhan and Riloff, 2009) and ACE event extraction (Ji and Grishman, 2008). This approach is based on the premise that many facts will be reported multiple times from different sources in different forms. This may occur both within the same document and within a cluster of topically related and successive documents. Therefore, by aggregating similar facts across documents and conducting statistical global inference by favoring interpretation consistency, enhanced extraction performance can be achieved with heterogeneous data than uniform data.

The underlying hypothesis of cross-document inference is that the salience of a fact should be calculated by taking into consideration both its confidence and the confidence of other facts connected to it, which is inspired by PageRank (Page et al., 1998) and LexRank (Erkan and Radev, 2004). For example, a vote by linked entities which are highly voted on by other entities is more valuable than a vote from unlinked entities. There are two major heuristics: (1) *an assertion that several information providers agree on is usually more trustable than that only one provider suggests*; and (2) *an information provider is* trustworthy *if it provides many pieces of true information, and a piece of information is likely to be true if it is provided by many trustworthy providers*. (Yin et al., 2008) used the above heuristics in a progressive, iterative enhancement process for information fusion.

The results from the previous work are promising, but the heuristic inferences are highly dependent on the order of applying rules, and the performance may have been limited by the thresholds which may overfit a small development corpus. One promising method might be using Markov Logic Networks (Richardson and Domingos, 2006), a statistical relational learning language, to model these global inference rules more declaratively. Markov Logic will make it possible to compactly specify probability distributions over the complex relational inferences. It can capture non-deterministic (soft) rules that tend to hold among facts but do not have to. Exploiting this approach will also provide greater flexibility to incorporate additional linguistic and world knowledge into inference.

[1] http://www.itl.nist.gov/iad/mig/tests/ace/

The information fused across documents can be represented as an information network (Ji, 2009) in which entities can be viewed as vertices on the graph and they can be connected by some type of static relationship (e.g. those attributes defined in NIST TAC-KBP task (McNamee and Dang, 2009)), or as a temporal chain linking dynamic events (e.g. Bethard and Martin, 2008; Chambers and Jurafsky, 2009; Ji et al., 2009a). The latter representation is more attractive because business or international affairs analysts often review many news reports to track people, companies, and government activities and trends. The query logs from the commercial search engines show that there is a fair number of news related queries (Mishne & de Rijke, 2006), suggesting that blog search users have an interest in the blogosphere response to news stories as they develop. For example, (Ji et al., 2009a) extracted centroid entities and then linked events centered around the same centroid entities on a time line.

Temporal ordering is a challenging task in particular because about half of the event mentions don't include explicit time arguments. The text order by itself is a poor predictor of chronological order (only 3% temporal correlation with the true order). Single-document IE technique can identify and normalize event time arguments from the texts, which results in a much better correlation score of 44% (Ji et al., 2009a). But this is still far from the ideal performance for real applications. In order to alleviate this bottleneck, a possible solution is to exploit global knowledge from the related documents and Wikipedia, and related events to recover and predict some implicit time arguments (Filatova and Hovy, 2001; Mani et al., 2003; Mann, 2007; Eidelman, 2008; Gupta and Ji, 2009).

2.2 Coreference Resolution

One of the key challenges for information fusion is cross-document entity coreference – precise clustering of mentions into correct entities. There are two principal challenges: the same entity can be referred to by more than one name string and the same name string can refer to more than one entity. The recent research has been mainly promoted in the web people search task (Artiles et al., 2007) such as (Balog et al., 2008), ACE2008 such as (Baron and Freedman, 2008) and NIST TAC KBP (McNamee and Dang, 2009) evaluations. Interestingly, the quality of information can often be improved by the fused fact network itself, which can be called as self-boosting of information fusion. For example, if two GPE entities are involved in a "conflict-attack" event, then they are unlikely to be connected by a "part-whole" relation; "Mahmoud Abbas" and "Abu Mazen" are likely to be coreferential if they get involved in the same "life-born" event. Some prior work (Ji et al., 2005; Jing et al., 2007) demonstrated the effectiveness of using semantic relations to improve entity coreference resolution; while (Downey et al., 2005; Sutton and McCallum, 2004; Finkel et al., 2005; Mann, 2007) experimented with information fusion of relations across multiple documents. The TextRunner system (Banko et al., 2007) can collapse and compress redundant facts extracted from multiple documents based on coreference resolution (Yates and Etzioni, 2009), semantic similarity computation and normalization.

Two relations are central for event fusion: *contradiction* – part of one event mention contradicts part of another, and *redundancy* – part of one event mention conveys the same content as (or is entailed by) part of another. Once these central relations are identified they will provide a basis for identifying more complex relations such as elaboration, presupposition or consequence. It is important to note that redundancy and contradiction among event mentions are *logical* relations that are not captured by traditional topic-based techniques for similarity detection (e.g. Brants and Stolle, 2002). Contradictions also arise from complex differences in the structure of assertions, discrepancies based on world-knowledge, and lexical contrasts. Ritter et al. (2009) described a contradiction detection method based on functional relations and pointed out that many contradictory fact pairs from the Web appear consistent, and that requires background knowledge to predict.

Assessing event coreference is essential: for texts to contradict, they must refer to the same event. Event coreference resolution is more challenging than entity coreference because each linking decision needs to be made based upon the overall similarity of the event trigger and multiple arguments. Hasler and Orasan (2009)

further found that in many cases even coreferential even arguments are not good indicators for event coreference.

Earlier work on event coreference resolution (e.g. Bagga and Baldwin, 1999) was limited to several MUC scenarios. Recent work (Chen et al., 2009) focus on much wider coverage of event types defined in ACE. The methods from the knowledge fusion community (e.g. Appriou et al., 2001; Gregoire, 2006) mostly focus on resolving conflicts rather than identifying them (i.e. inconsistency problem rather than ambiguity). These approaches allow the conflicts to be resolved in a straightforward way but they rely on the availability of meta-data (e.g., distribution of weights between attributes, probability assignment etc.). However, it is not always clear where to get this meta-data.

The event attributes such as Modality, Polarity, Genericity and Tense (Sauri et al., 2006) will play an important role in event coreference resolution because two event mentions cannot be coreferential if any of the attributes conflict with each other. Such attempts have been largely neglected in the prior research due to the low weights of attribute labeling in the ACE scoring metric. (Chen et al., 2009) demonstrated that simple automatic event attribute labeling can significantly improve event coreference resolution. In addition, some very recent work including (Nicolae and Nicolae, 2006; Ng, 2009; Chen et al., 2009) found that graph-cut based clustering can improve coreference resolution. The challenge lies in computing the affinity matrix.

3 Cross-Lingual Information Fusion

Cross-lingual comparable corpora are also prevalent now because almost all the influential events can be reported in multi-languages at the first time, but probably in different aspects. Therefore, linked fact networks can be constructed and lots of research tasks can benefit from such structures. Since the two networks are similar in structure but not homogeneous, we can do alignment and translation which may advance information fusion. Cross-lingual information fusion is concerned with technologies that fuse the information available in various languages and present the fused information in the user-preferred language. The following fundamental cross-lingual IE pipelines can be employed: (1) Translate source language texts into target language, and then run target language IE on the translated texts. (2) Run source language IE on the source language texts, and then use machine translation (MT) word alignments to translate (project) extracted information into target languages. Regardless of the different architectures, both pipelines are facing the following challenges from extraction and translation.

3.1 Extraction Challenges

Some recent fusion work focus on cross-lingual interaction and inference to improve both sides synchronously, beyond the parallel comparisons of cross-lingual IE pipelines in (e.g. Riloff et al., 2002). One of such examples is on cross-lingual co-training (e.g. Cao et al., 2003; Chen and Ji, 2009). In co-training (Blum and Mitchell, 1998), the uncertainty of a classifier is defined as the portion of instances on which it cannot make classification decisions. Exchanging tagged data in bootstrapping can help reduce the uncertainties of classifiers. The cross-lingual fusion process satisfies the co-training algorithm's assumptions about two views (in this case, two languages): (1) the two views are individually sufficient for classification (IE systems in both languages were learned from annotated corpora which are enough for reasonable extraction performance); (2) the two views are conditionally independent given the class (IE systems in different languages may use different features and resources).

(Cao et al., 2003) indicated that uncertainty reduction is an important factor for enhancing the performance of co-training. It's important to design new uncertainty measures for representing the degree of uncertainty correlation of the two classifiers in co-training. (Chen and Ji, 2009) proposed a new co-training framework using cross-lingual information projection. They demonstrated that this framework is particularly effective for a challenging IE task which is situated at the end of a pipeline and thus suffers from the errors propagated from upstream processing and has low-performance baseline.

3.2 Translation Challenges

Because the facts are aggregated from multiple languages, the translation errors will bring us great challenges. However, in order to extend

cross-lingual information fusion techniques to more language pairs, we can start from the much more scalable task of "information" translation (Etzioni et al., 2007). The additional processing may take the form of machine translation (MT) of extracted facts such as names and events. IE tasks performed notably worse on machine translated texts than on texts originally written in English, and error analysis indicated that a major cause was the low quality of name translation (Ji et al., 2009b). Traditional MT systems focus on the overall fluency and accuracy of the translation but fall short in their ability to translate certain informationally critical words. In particular, it appears that better entity name translation can substantially improve cross-lingual information fusion.

Some recent work (e.g. Klementiev and Roth, 2006; Ji, 2009) has exploited comparable corpora to enhance information translation. There are no document-level or sentence-level alignments across languages, but important facts such as names, relations and events in one language in such corpora tend to co-occur with their counterparts in the other. (Ji, 2009) used a bootstrapping approach to align the information networks from bilingual comparable corpora, and discover name translations and extract relations links simultaneously. The general idea is to start from a small seed set of common name pairs, and then rely on the link attributes to align their related names. Then the new name translations are added to the seed set for the next iteration. This bootstrapping procedure is repeated until no new translations are produced. This approach is based on graph traverses and doesn't need a name transliteration module to serve as baseline, or compute document-wise temporal distributions.

The novelty of using comparable corpora lies in constructing and mining multi-lingual information fusion framework which is capable of self-boosting. First, this approach can generate information translation pairs with high accuracy by using a small seed set. Second, the shortcomings of traditional approaches are due to their limited use of IE techniques, and this approach can effectively integrate extraction and translation based on reliable confidence estimation. Third, compared to bitexts this approach can take advantage of much less expensive comparable corpora. This approach can be extended to foster the research in other aspects for information fusion. For example, the aligned sub-graphs with names, relations and events can be used to reduce information redundancy; the outlier (misaligned) sub-graphs can be used to detect the novel or local information described in one language but not in the other after the fusion process. It does happen that the two persons have been explicitly reported as Father and Son relationship in one language, but in the other language, they are just reported as two common persons.

4 Cross-Media Information Fusion

The research challenges discussed so far concerned with textual data. Besides written texts, ever-increasing human generated data is available as speech recordings, microblogs, images and videos. We now discuss how to develop techniques for fusing a variety of media sources. State-of-the-art IE techniques have been developed primarily on newspaper articles and a few web texts, and it is not clear how systems would perform on other sources and how to integrate all available information.

4.1 Coreference Resolution

The main challenge is on designing a coherent information fusion framework that is able to exploit information across different parts of multimedia documents and link them via cross-media coreference resolution. The framework will handle multimedia information by considering not only the document's text and images data but also the layout structure which determines how a given text block is related to a particular image or video. For example, a Web news page about "Health Care Reform in America" is composed by text describing some event (e.g., Final Senate vote for the reform plans, Obama signs the reform agreement), images (e.g., images about various government involvements over decades) and videos (e.g. Obama's speech video about the decisions) containing additional information regarding the real extent of the event or providing evidence corroborating the text part.

Current state-of-the-art information fusion approaches can be divided into two groups: formal "top-down" methods from the generic knowledge fusion community and quantitative "bottom-up" techniques from the applied Semantic

Web community (Appriou et al., 2001; Gregoire, 2006). Both approaches have their limitations. It will be beneficial to combine both types of approaches so that the fusion decision can be made depending on the type of problem and the amount of domain information it possesses. Saggion et al. (2004) described a multimedia extraction approach to create composite index from multiple and multi-lingual sources. Magalhaes et al. (2008) described a semantic similarity metric based on key word vectors for multi-media fusion. Iria and Magalhaes (2009) exploited information across different parts of a multimedia document to improve document classification. It is important to go beyond key words and attempt representing the documents by the semantic facts identified by IE.

One possible solution is to exploit the linkage information. Specifically, coreference resolution methods should be applied to four types of cross-media data: (1) between the captions of images and context texts; (2) detecting HTML cross-media associations and quantifying the level of image and text block correlation (3) between the texts embedded in images and context texts; (4) between the transcribed texts from the speech in video clips (via automatic speech recognition) and context texts. We can apply a similarity graph to incorporate virtual linkages. For example, when we see images of two web documents containing the same object, we can raise our confidence that such documents are semantically correlated even if the two web documents are from different sources.

4.2 Uncertainty Reduction

When we combine information from images and their associated texts (e.g. meta-data, captions, surrounding text, transcription), one of the challenges lies in the uncertainty of text representation. Therefore it is important to study both how to learn good models from different sources with different kinds of associated uncertainty, and how to make use of these, along with their level of uncertainty in supporting coherent decisions, taking into account characteristics of the data as well as of its source.

The descriptions are usually generated by humans and thus are prone to error or subjectivity. The images, especially the web images, are typically labeled by different users in different languages and cultural backgrounds. It is unrealistic to expect descriptions to be consistent. In speech conversations, many facts are often embedded in questions such as "*It's OK to put Democratic career politicians at the Pentagon and the Justice Department if they're Democrats but not if they're Republicans, is that right?*" This challenge can be generally addressed by strengthening semantic attribute classification methods for Modality, Polarity and Genericity. And if the data sources are comparable, a more direct method of committee-based voting can also be exploited.

However, the fusion process may itself cause data uncertainties. We can follow the co-training framework as described in section 3.1 to reduce uncertainty in fusion. To handle the missing labels, a promising approach is to use graph-based label propagation (Deshpande et al., 2009), which can capture complex uncertainties and correlations in the data in a uniform manner. It's also worth importing the multi-dimensional uncertainty analysis framework described in data mining community (Aggarwal, 2010). The multi-dimensional uncertainty analysis method exactly suits the multi-media fusion needs: it allows us to combine first-order logic with probabilities, modeling inferential uncertainty about multiple aspects - both the context of facts and intended meanings.

4.3 Joint Modeling

IE is generally applied on top of machine generated transcription and automatic structuring that suffer from errors compared to the true content of relations and events. In the context of information fusion we can divide the problem of adaptation into two types: (1) radical adaptation such as from newswire to biomedical articles; (2) modest adaptation such as from newswire to wikipedia or automatic speech recognition (ASR) output. (1) requires a great deal of new development such as ontology definition and data annotation; while (2) can be partially addressed during the information fusion process.

For example, while dealing with speech input, IE systems need to be robust to the noise introduced by earlier speech processing tasks such as ASR, sentence segmentation, salience detection and and speaker identification. Some earlier work (Makhoul et al., 2005; Favre et al., 2008)

showed that using an IE system trained from newswire, the performance degrades notably when the system is tested on automatic speech recognition output. But no general solutions have been proposed to address the genre-specific challenges for speech data.

More specifically, pronoun resolution is one of the major challenges (Jing et al., 2007). For example, in wikipedia a lot of pronouns may refer to the entry entity; while in speech conversation we will need to resolve first and second person pronouns based on automatic speaker role identification; and improve cross-sentence third pronoun resolution by exploiting gender and animacy knowledge discovery methods.

The processing methods of text and other media are typically organized as a pipeline architecture of processing stages (e.g. from pattern recognition, to information fusion, and to summarization). Each of these stages has been studied separately and quite intensively over the past decade. It's critical to move away from approaches that make chains of independent local decisions, and instead toward methods that make multiple decisions jointly using global information. Joint inference techniques (Roth and Yih, 2004; Ji et al., 2005; McCallum, 2006) can transform the integration of multi-media into a benefit by reducing the errors in individual stages. In doing so, we can take advantage (among other properties) of the coherence of a discourse: that a correct analysis of a text discourse reveals a large number of connections from the image information in its context, and so (in general) a more tightly connected analysis is more likely to be correct. For example, prior work has demonstrated the benefit of jointly modeling name tagging and n-best hypotheses, ASR lattices or word confusion networks (Hakkani-Tür et al., 2006).

5 Conclusion

In the current information explosion era, IE technology is facing new challenges of dealing with heterogeneous data sources from different documents, languages and media which may contain a multiplicity of aspects on particular entities, relations and events. This new phenomena requires IE to perform both traditional lower level processing as well as information fusion of factual data based on implicit inferences. This paper investigated the issues of information fusion on a massive scale and the challenges have not been discussed in previous work. We specified the requirements and possible solutions for various dimensions to perform information fusion. We also overviewed some recent work to demonstrate how these goals can be achieved.

The field of information fusion is relatively new; and the nature of different data sources provides new ideas and challenges which are not present in other research. While much research has been performed in the area of data fusion, the context of automatic extraction provides a different perspective in which the fusion is performed in the context of a lot of uncertainty and noise. This new task will provide connections between NLP and other areas such as data mining and knowledge discovery. The progress on this task would save, anybody concerned with staying informed, an enormous amount of time. These are certainly ambitious goals and require long-term development of fusion and adaptation methods. But we hope that this outline of the research challenges will bring us closer to the goal.

Abstract

We describe an effective constituent projection strategy, where constituent projection is performed on the basis of dependency projection. Especially, a novel measurement is proposed to evaluate the candidate projected constituents for a target language sentence, and a PCFG-style parsing procedure is then used to search for the most probable projected constituent tree. Experiments show that, the parser trained on the projected treebank can significantly boost a state-of-the-art supervised parser. When integrated into a tree-based machine translation system, the projected parser leads to translation performance comparable with using a supervised parser trained on thousands of annotated trees.

1 Introduction

In recent years, supervised constituent parsing has been well studied and achieves the state-of-the-art for many resource-rich languages (Collins, 1999; Charniak, 2000; Petrov et al., 2006). Because of the cost and difficulty in treebank construction, researchers have also investigated the utilization of unannotated text, including the unsupervised parsing which totally uses unannotated data (Klein and Manning, 2002; Klein and Manning, 2004; Bod, 2006; Seginer, 2007), and the semi-supervised parsing which uses both annotated and unannotated data (Sarkar, 2001; Steedman et al., 2003; McClosky et al., 2006).

Because of the higher complexity and lower performance of unsupervised methods, as well as the need of reliable priori knowledge in semi-supervised methods, it seems promising to project the syntax structures from a resource-rich language to a resource-scarce one across a bilingual corpus. Lots of researches have so far been devoted to dependency projection (Hwa et al., 2002; Hwa et al., 2005; Ganchev et al., 2009; Smith and Eisner, 2009). While for constituent projection there is few progress. This is due to the fact that the constituent syntax describes the language structure in a more detailed way, and the degree of isomorphism between constituent structures appears much lower.

In this paper we propose for constituent projection a stepwise but totally automatic strategy, which performs constituent projection on the basis of dependency projection, and then use a constraint EM optimization algorithm to optimized the initially projected trees. Given a word-aligned bilingual corpus with source sentences parsed, we first project the dependency structures of these constituent trees to the target sentences using a dynamic programming algorithm, then we generate a set of candidate constituents for each target sentence and design a novel evaluation function to calculate the probability of each candidate constituent, finally, we develop a PCFG-style parsing procedure to search for the most probable projected constituent tree in the evaluated candidate constituent set. In addition, we design a constraint EM optimization procedure to decrease the noise in the initially projected constituent treebank.

Experimental results validate the effectiveness of our approach. On the Chinese-English FBIS corpus, we project the English parses produced by the Charniak parser across to the Chinese sen-

Coling 2008: Poster Volume, pages 516–524,
Beijing, August 2010

tences. A berkeley parser trained on this projected treebank can effectively boost the supervised parsers trained on bunches of CTB trees. Especially, the supervised parser trained on the smaller CTB 1.0 benefits a significant F-measure increment of more than 1 point from the projected parser. When using the projected parser in a tree-based translation model (Liu et al., 2006), we achieve translation performance comparable with using a state-of-the-art supervised parser trained on thousands of CTB trees. This surprising result gives us an inspiration that better translation would be achieved by combining both projected parsing and supervised parsing into a hybrid parsing schema.

2 Stepwise Constituent Projection

We first introduce the dynamic programming procedure for dependency projection, then describe the PCFG-style algorithm for constituent projection which is conducted on projected dependent structures, and finally show the constraint EM procedure for constituent optimization.

2.1 Dependency Projection

For dependency projection we adopt a dynamic programming algorithm, which searches the most probable projected target dependency structure according to the source dependency structure and the word alignment.

In order to mitigate the effect of word alignment errors, multiple GIZA++ (Och and Ney, 2000) results are combined into a compact representation called alignment matrix. Given a source sentence with m words, represented as $E_{1:m}$, and a target sentence with n words, represented as $F_{1:n}$, their word alignment matrix A is an $m \times n$ matrix, where each element $A_{i,j}$ denotes the probability of the source word E_i aligned to the target word F_j.

Using $P(D_F|D_E, A)$ to denote the probability of the projected target dependency structure D_F conditioned on the source dependency structure D_E and the alignment matrix A, the projection algorithm aims to find

$$\tilde{D_F} = \underset{D_F}{\operatorname{argmax}} P(D_F|D_E, A) \quad (1)$$

Algorithm 1 Dependency projection.

1: **Input**: F, and P_e for all word pairs in F
2: **for** $\langle i, j\rangle \subseteq \langle 1, |F|\rangle$ in topological order **do**
3: $\quad \mathbf{buf} \leftarrow \emptyset$
4: $\quad$ **for** $k \leftarrow i..j-1$ **do** ▷ all partitions
5: $\quad\quad$ **for** $l \in \mathbf{V}[i,k]$ and $r \in \mathbf{V}[k+1,j]$ **do**
6: $\quad\quad\quad$ insert DERIV(l, r, P_e) into $\mathbf{buf}$
7: $\quad\quad\quad$ insert DERIV(r, l, P_e) into $\mathbf{buf}$
8: $\quad \mathbf{V}[i,j] \leftarrow$ top K derivations of $\mathbf{buf}$
9: **Output:** the best derivation of $\mathbf{V}[1, |F|]$
10: **function** DERIV(p, c, P_e)
11: $\quad d \leftarrow p \cup c \cup \{p \cdot root \curvearrowright c \cdot root\}$ ▷ new derivation
12: $\quad d \cdot evl \leftarrow$ EVAL(d, P_e) ▷ evaluation function
13: $\quad$ **return** d

$P(D_F|D_E, A)$ can be factorized into each dependency edge $x \curvearrowright y$ in D_F

$$P(D_F|D_E, A) = \prod_{x \curvearrowright y \in D_F} P_e(x \curvearrowright y|D_E, A)$$

P_e can then be obtained by simple accumulation across all possible situations of correspondence

$$P_e(x \curvearrowright y|D_E, A) = \sum_{1 \le x', y' \le |E|} A_{x,x'} \times A_{y,y'} \times \delta(x', y'|D_E)$$

where $\delta(x', y'|D_E)$ is a 0-1 function that equals 1 only if the dependent relation $x' \curvearrowright y'$ holds in D_E.

The search procedure needed by the argmax operation in equation 1 can be effectively solved by the Chu-Liu-Edmonds algorithm used in (McDonald et al., 2005). In this work, however, we adopt a more general and simple dynamic programming algorithm as shown in Algorithm 1, in order to facilitate the possible expansions. In practice, the cube-pruning strategy (Huang and Chiang, 2005) is used to speed up the enumeration of derivations (loops started by line 4 and 5).

2.2 Constituent Projection

The PCFG-style parsing procedure searches for the most probable projected constituent tree in a shrunken search space determined by the projected dependency structure and the target constituent tree. The shrunken search space can be built as following. First, we generates the candidate constituents of the source tree and the candidate spans of the target sentence, so as to enumerate the candidate constituents of the target sentence. Then we compute the consistent degree for

each pair of candidate constituent and span, and further estimate the probability of each candidate constituent for the target sentence.

2.2.1 Candidate Constituents and Spans

For the candidate constituents of the source tree, using only the original constituents imposes a strong hypothesis of isomorphism on the constituent projection between two languages, since it requires that each couple of constituent and span must be strictly matched. While for the candidate spans of the target sentences, using all subsequences makes the search procedure suffer from more perplexity. Therefore, we expand the candidate constituent set and restrict the candidate span set:

- Candidate Constituent: Suppose a production in the source constituent tree, denoted as $p \rightarrow c_1 c_2 .. c_h .. c_{|p|}$, and c_h is the head child of the parent p. Each constituent, p or c, is a triple $\langle lb, rb, nt \rangle$, where nt denotes its non-terminal, while lb and rb represent its left- and right bounds of the sub-sequence that the constituent covers. The candidate constituent set of this production consists the head of the production itself, and a set of incomplete constituents,

$$\{\langle l, r, p \cdot nt* \rangle | c_1 \cdot lb \leq l \leq c_h \cdot lb \wedge \\ c_h \cdot rb \leq r \leq c_{|p|} \cdot rb \wedge \\ (l < c_h \cdot lb \vee r > c_h \cdot rb)\}$$

  where the symbol $*$ indicates an incomplete non-terminal. The candidate constituent set of the entire source tree is the unification of the sets extracted from all productions of the tree.

- Candidate Span: A candidate span of the target sentence is a tuple $\langle lb, rb \rangle$, where lb and rb indicate the same as in a constituent. We define the candidate span set as the spans of all *regular dependent segment*s in the corresponding projected dependency structure. A regular dependency segment is a dependent segment that every modifier of the root is a complete dependency structure. Suppose a dependency structure rooted at word p, denoted as $c_{lL} .. c_{l2} c_{l1} \curvearrowleft p \curvearrowright c_{r1} c_{r2} .. c_{rR}$, it has L ($L \geq 0$) modifiers on its left and R ($R \geq 0$) modifiers on its right, each of them is a smaller complete dependency structure. Then the word p itself is a regular dependency segment without any modifier, and

$$\{c_{li} .. c_{l1} \curvearrowleft p \curvearrowright c_{r1} .. c_{rj} | 0 \leq i \leq L \wedge \\ 0 \leq j \leq R \wedge \\ (i > 0 \vee j > 0)\}$$

  is a set of regular dependency structures with at least one modifier. The regular dependency segments of the entire projected dependency structure can simply be accumulated across all dependency nodes.

2.2.2 Span-to-Constituent Correspondence

After determining the candidate constituent set of the source tree, denoted as Φ_E, and the candidate span set of the target sentence, denoted as Ψ_F, we then calculate the consistent degree for each pair of candidate constituent and candidate span.

Given a candidate constituent $\phi \in \Phi_E$ and a candidate span $\psi \in \Psi_F$, their consistent degree $\mathcal{C}(\psi, \phi | A)$ is the probability that they are aligned to each other according to A.

We display the derivations from bottom to up. First, we define the alignment probability from a word i in the span ψ to the constituent ϕ as

$$P(i \mapsto \phi | A) = \frac{\sum_{\phi \cdot lb \leq j \leq \phi \cdot rb} A_{i,j}}{\sum_j A_{i,j}}$$

Then we define the alignment probability from the span ψ to the constituent ϕ as

$$P(\psi \mapsto \phi | A) = \prod_{\psi \cdot lb \leq i \leq \psi \cdot rb} P(i \mapsto \phi | A)$$

Note that we use i to denote both a word and its index for simplicity without causing confusion. Finally, we define $\mathcal{C}(\phi, \psi | A)$ as

$$\mathcal{C}(\psi, \phi | A) = P(\psi \mapsto \phi | A) \times P(\phi \mapsto \psi | A^T) \quad (2)$$

Where $P(\phi \mapsto \psi | A^T)$ denotes the alignment probability from the constituent ϕ to the span ψ, it can be calculated in the same manner.

2.2.3 Constituent Projection Algorithm

The purpose of constituent projection is to find the most probable projected constituent tree for the target sentence conditioned on the source constituent tree and the word alignment

$$\tilde{T_F} = \underset{T_F \subseteq \Phi_F}{\operatorname{argmax}} P(T_F|T_E, A) \quad (3)$$

Here, we use Φ_F to denote the set of candidate constituents of the target sentence

$$\begin{aligned}\Phi_F &= \Psi_F \otimes NT(\Phi_E) \\ &= \{\phi_F | \psi(\phi_F) \in \Psi_F \wedge nt(\phi_F) \in NT(\Phi_E)\}\end{aligned}$$

where $\psi(\cdot)$ and $nt(\cdot)$ represent the span and the non-terminal of a constituent respectively, and $NT(\cdot)$ represents the set of non-terminals extracted from a constituent set. Note that T_F is a subset of Φ_F if we treat a tree as a set of constituents.

The probability of the projected tree T_F can be factorized into the probabilities of the projected constituents that composes the tree

$$P(T_F|T_E, A) = \prod_{\phi_F \in T_F} P_\phi(\phi_F|T_E, A)$$

while the probability of the projected source constituent can be defined as a statistics of span-to-constituent- and constituent-to-constituent consistent degrees

$$P_\phi(\phi_F|T_E, A) = \frac{\sum_{\phi_E \in \Phi_E} \mathcal{C}(\phi_F, \phi_E|A)}{\sum_{\phi_E \in \Phi_E} \mathcal{C}(\psi(\phi_F), \phi_E|A)}$$

where $\mathcal{C}(\phi_F, \phi_E|A)$ in the numerator denotes the consistent degree for each pair of constituents, which can be calculated based on that of span and constituent described in Formula 2

$$\mathcal{C}(\phi_F, \phi_E) = \begin{cases} 0 & \textbf{if } \phi_F \cdot nt \neq \phi_E \cdot nt \\ \mathcal{C}(\psi(\phi_F), \phi_E) & \textbf{else} \end{cases}$$

Algorithm 2 shows the pseudocode for constituent projection. A PCFG-style parsing procedure searches for the best projected constituent tree in the constrained space determined by Ψ_F. Note that the projected trees are binarized, and can be easily recovered according to the asterisks at the tails of non-terminals.

Algorithm 2 Constituent projection.

Input: Ψ_F, Φ_F, and P_ϕ for all spans in Ψ_F
for $\langle i, j \rangle \in \Psi$ in topological order **do**
  $\mathbf{buf} \leftarrow \emptyset$
  for $p \in \Phi_F$ s.t. $\psi(p) = \langle i, j \rangle$ **do**
    for $k \leftarrow i..j-1$ **do** ▷ all partitions
      for $l \in \mathbf{V}[i, k]$ and $r \in \mathbf{V}[k+1, j]$ **do**
        insert DERIV(l, r, p, P_ϕ) into $\mathbf{buf}$
  $\mathbf{V}[i, j] \leftarrow$ top K derivations of $\mathbf{buf}$
Output: the best derivation of $\mathbf{V}[1, |F|]$
function DERIV(l, r, p, P_ϕ)
  $d \leftarrow l \cup r \cup \{p\}$ ▷ new derivation
  $d \cdot evl \leftarrow$ EVAL(d, P_ϕ) ▷ evaluation function
  return d

2.3 EM Optimization

Since the constituent projection is conducted on each sentence pair separately, the projected treebank is apt to suffer from more noise caused by free translation and word alignment error. It can be expected that an EM iteration over the whole projected treebank will lead to trees with higher consistence.

We adopt the inside-outside algorithm to improve the quality of the initially projected treebank. Different from previous works, all expectation and maximization operations for a single tree are performed in a constrained space determined by the candidate span set of the projected target dependency structure. That is to say, all the summation operations, both for calculating α/β values and for re-estimating the rule probabilities, only consider the spans in the candidate span set. This means that the projected dependency structures are supposed believable, and the noise is mainly introduced in the following constituent projection procedure.

Here we give an overall description of the treebank optimization procedure. First, an initial PCFG grammar G_F^0 is estimated from the original projected treebank. Then several iterations of α/β calculation and rule probability re-estimation are performed. For example in the i-the iteration, α/β values are calculated based on the current grammar G_F^{i-1}, afterwards the optimized grammar G_F^i is obtained based on these α/β values. The iterative procedure terminates when the likelihood of whole treebank increases slowly. Finally, with the optimized grammar, a constrained PCFG parsing procedure is conducted on each of the initial pro-

jected trees, so as to obtain an optimized treebank.

3 Applications of Constituent Projection

The most direct contribution of constituent projection is pushing an initial step for the statistical constituent parsing of resource-scarce languages. It also has some meaningful applications even for the resource-rich languages. For instances, the projected treebank, due to its large scale and high coverage, can used to boost an traditional supervised-trained parser. And, the parser trained on the projected treebank can adopted to conduct tree-to-string machine translation, since it give parsing results with larger isomorphism with the target language than a supervised-trained parser dose.

3.1 Boost an Traditional Parser

We first establish a unified framework for the enhanced parser where a projected parser is adopted to guide the parsing procedure of the baseline parser.

For a given target sentence S, the enhanced parser selected the best parse $\tilde{T}$ among the set of candidates $\Omega(S)$ according to two evaluation functions, given by the baseline parser $\mathbb{B}$ and the projected guide parser $\mathbb{G}$, respectively.

$$\tilde{T} = \underset{T \in \Omega(S)}{\operatorname{argmax}} P(T|\mathbb{B}) \times P(T|\mathbb{G})^{\lambda} \quad (4)$$

These two evaluation functions can be integrated deeply into the decoding procedure (Carreras et al., 2008; Zhang and Clark, 2008; Huang, 2008), or can be integrated at a shallow level in a reranking manner (Collins, 2000; Charniak and Johnson, 2005). For simplicity and generability, we adopt the reranking strategy. In k-best reranking, $\Omega(S)$ is simply a set of candidate parses, denoted as $\{T_1, T_2, ..., T_k\}$, and we use the single parse of the guide parser, $T_{\mathbb{G}}$, to re-evaluate these candidates. Formula 4 can be redefined as

$$\tilde{T}(T_{\mathbb{G}}) = \underset{T \in \Omega(S)}{\operatorname{argmax}} \mathbf{w} \cdot \mathbf{f}(T, T_{\mathbb{G}}) \quad (5)$$

Here, $\mathbf{f}(T, T_{\mathbb{G}})$ and $\mathbf{w}$ represent a high dimensional feature representation and a corresponding weight vector, respectively. The first feature $f_1(T, T_{\mathbb{G}}) = logP(T|\mathbb{B})$ is the log probability of the baseline parser, while the remaining features are integer-valued guide features, and each of them represents the guider parser's predication result for a particular configuration in candidate parse T, so as to utilize the projected parser's knowledge to guide the parsing procedure of the traditional parser.

In our work a guide feature is composed of two parts, the non-terminal of a certain constituent ϕ in the candidate parse T,[1] and the non-terminal at the corresponding span $\psi(\phi)$ in the projected parse $T_{\mathbb{G}}$. Note that in the projected parse this span does not necessarily correspond to a constituent. In such situations, we simply use the non-terminal of the constituent that just be able to cover this span, and attach a asterisk at the tail of this non-terminal. Here is an example of the guide features

$$f_{100}(T, T_{\mathbb{G}}) = VP \in T \circ PP* \in T_{\mathbb{G}}$$

It represents that a VP in the candidate parse corresponds to a segment of a PP in the projected parse. The quantity of its weight w_{100} indicates how probably a span can be predicated as VP if the span corresponds to a partial PP in the projected parse.

We adopt the perceptron algorithm to train the reranker. To reduce overfitting and produce a more stable weight vector, we also use a refinement strategy called averaged parameters (Collins, 2002).

3.2 Using in Machine Translation

Researchers have achieved promising improvements in tree-based machine translation (Liu et al., 2006; Huang et al., 2006). Such models use a parsed tree as input and converts it into a target tree or string. Given a source language sentence, first we use a traditional source language parser to parse the sentence to obtain the syntax tree T, and then use the translation decoder to search for the best derivation $\tilde{d}$, where a derivation d is a sequence of transformations that converts the source tree into the target language string

$$\tilde{d} = \underset{d \in D}{\operatorname{argmax}} P(d|T) \quad (6)$$

[1] Using non-terminals as features brings no improvement in the reranking experiments, so as to examine the impact of the projected parser.

Here D is the candidate set of d, and it is determined by the source tree T and the transformation rules.

Since the tree-based models are based on the synchronous transformational grammars, they suffer much from the isomerism between the source syntax and the target sentence structure. Considering that the parsed tree produced by a projected parser may have larger isomorphism with the target language, it would be a promising idea to adopt the projected parser to parse the input sentence for the subsequent translation decoding procedure.

4 Experiments

In this section, we first invalidate the effect of constituent projection by evaluating a parser trained on the projected treebank. Then we investigate two applications of the projected parser: boosting an traditional supervised-trained parser, and integration in a tree-based machine translation system. Following the previous works, we depict the parsing performance by F-score on sentences with no more than 40 words, and evaluate the translation quality by the case-sensitive BLEU-4 metric (Papineni et al., 2002) with 4 references.

4.1 Constituent Projection

We perform constituent projection from English to Chinese on the FBIS corpus, which contains 239K sentence pairs with about 6.9M/8.9M words in Chinese/English. The English sentences are parsed by the Charniak Parser and the dependency structures are extracted from these parses according to the head-finding rules of (Yamada and Matsumoto, 2003). The word alignment matrixes are obtained by combining the 10-best results of GIZA++ according to (Liu et al., 2009).

We first project the dependency structures from English to Chinese according to section 2.1, and then project the constituent structures according to section 2.2. We define an assessment criteria to evaluate the confidence of the final projected constituent tree

$$c = \sqrt[n]{P(D_F|D_E, A) \times P(T_F|T_E, A)}$$

where n is the word count of a Chinese sentence in our experiments. A series of projected Chinese treebanks with different scales are obtained by specifying different c as the filtering threshold. The state-of-the-art Berkeley Parser is adopted to train on these treebanks because of its high performance and independence of head word information.

Thres c	**#Resrv**	**Cons-**F_1	**Span-**F_1
0.5	12.6K	23.9	32.7
0.4	17.8K	23.9	33.4
0.3	27.2K	25.4	35.7
0.2	45.1K	26.6	38.0
0.1	87.0K	27.8	40.4

Table 1: Performances of the projected parsers on the CTB test set. #Resrv denotes the amount of reserved trees within threshold c. Cons-F_1 is the traditional F-measure, while Span-F_1 is the F-measure without consideration of non-terminals.

Table 1 shows the performances of these projected parsers on the standard CTB test set, which is composed of sentences in chapters 271-300. We find that along with the decrease of the filtering threshold c, more projected trees are reserved and the performance of the projected parser constantly increases. We also find that the traditional F-value, Cons-F_1, is obviously lower than the one without considering non-terminals, Span-F_1. This indicates that the constituent projection procedure introduces more noise because of the higher complexity of constituent correspondence. In all the rest experiments, however, we simply use the projected treebank filtered by threshold $c = 0.1$ and do not try any smaller thresholds, since it already takes more than one weak to train the Berkeley Parser on the 87 thousands trees resulted by this threshold.

The constrained EM optimization procedure described in section 2.3 is used to alleviate the noise in the projected treebank, which may be caused by free translation, word alignment errors, and projection on each single sentence pair. Figure 1 shows the log-likelihood on the projected treebank after each EM iteration. It is obvious that the log-likelihood increases very slowly after 10 iterations. We terminate the EM procedure after 40 iterations.

Finally we train the Berkeley Parser on the optimized projected treebank, and test its perfor-

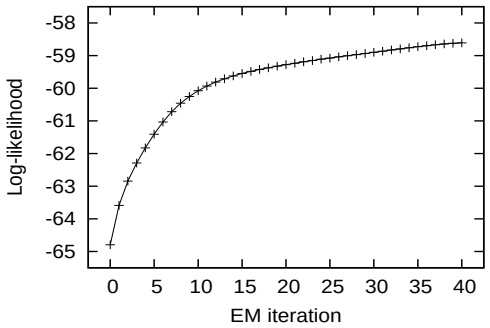

Figure 1: Log-likelihood of the 87K-projected treebank after each EM interation.

Train Set	Cons-F_1	Span-F_1
Original 87K	27.8	40.4
Optimized 87K	22.8	40.2

Table 2: Performance of the parser trained on the optimized projected treebank, compared with that of the original projected parser.

Train Set	Baseline	Bst-Ini	Bst-Opt
CTB 1.0	75.6	76.4	76.9
CTB 5.0	85.2	85.5	85.7

Table 3: Performance improvement brought by the projected parser to the baseline parsers trained on CTB 1.0 and CTB 5.0, respectively. Bst-Ini/Bst-Opt: boosted by the parser trained on the initial/optimized projected treebank.
