When we compare *n*-gram counts estimated from the *web* with counts taken from a well-formed standard corpus, we notice that *web* counts are "estimated" or "approximated" as page counts, whereas standard corpus counts are the exact number of occurrences of the *n*-gram. In this way, *web* counts are dependent on the particular search engine's algorithms and representations, and these may perform approximations to handle the large size of their indexing structures and procedures, such as ignoring punctuation and using stopword lists (Kilgarriff, 2007). This assumption, as well as the following discussion, are not valid for for controlled data sets derived from Web data, such

as the Google 1 trillion n-grams[1]. Thus, our results cannot be compared to those using this kind of data (Bergsma et al., 2009).

In data-driven techniques, some statistical measures are based on contingency tables, and the counts for each of the table cells can be straightforwardly computed from a standard corpus. However, this is not the case for the *web*, where the occurrences of an n-gram are not precisely calculated in relation to the occurrences of the $(n-1)$-grams composing it. For instance, the n-gram *the man* may appear in 200,000 pages, while the words *the* and *man* appear in respectively 1,000,000 and 200,000 pages, implying that the word *man* occurs with no other word than *the*[2].

In addition, the distribution of words in a standard corpus follows the well known Zipfian distribution (Baayen, 2001) while, in the *web*, it is very difficult to distinguish frequent words or n-grams as they are often estimated as the size of the *web*. For instance, the Yahoo! frequencies plotted in figure 1(a) are flattened in the upper part, giving the same page counts for more than 700 of the most frequent words. Another issue is the size of the corpus, which is an important information, often needed to compute frequencies from counts or to estimate probabilities in n-gram models. Unlike the size of a standard corpus, which is easily obtained, it is very difficult to estimate how many pages exist on the *web*, especially as this number is always increasing.

But perhaps the biggest advantage of the *web* is its availability, even for resource-poor languages and domains. It is a free, expanding and easily accessible resource that is representative of language use, in the sense that it contains a great variability of writing styles, text genres, language levels and knowledge domains.

4 Analysing n-gram frequencies

In this section, we describe an experiment to compare the probability distribution of the vocabulary of two corpora, Europarl (Koehn, 2005) and Genia (Ohta et al., 2002), that represent a sample of general-purpose and specialised English. In addition to both corpora, we also considered the counts from the *web* as a corpus, using Google and Yahoo! APIs, and these four corpora act as *n-gram count sources*. To do that, we preprocessed the data (§ 4.1), extracted the vocabularies from each corpus and calculated their counts in our four n-gram count sources (§ 4.2), analysing their rank plots to compare how each of these sources models general-purpose and specialised language (§ 4.3). The experiments described in this section were implemented in the `mwetoolkit` and are available at `http://sf.net/projects/mwetoolkit/`.

	V_{ep}	V_{genia}	V_{inter}
types	104,144	20,876	6,798
hapax	41,377	9,410	–
tokens	39,595,352	486,823	–

Table 1: Some characteristics of general vs domain-specific corpora.

4.1 Preprocessing

The Europarl corpus v3.0 (*ep*) contains transcriptions of the speeches held at the European Parliament, with more than 1.4M sentences and 39,595,352 words. The Genia corpus (*genia*) contains abstracts of scientific articles in biomedicine, with around 1.8K sentences and 486,823 words. These standard corpora were preprocessed in the following way:

1. conversion to XML, lemmatisation and POS tagging[3];
2. case homogenisation, based on the following criteria:
   - all-uppercase and mixed case words were normalised to their predominant form, if it accounts for at least 80% of the occurrences;
   - uppercase words at the beginning of sentences were lowercased;
   - other words were not modified.

[1] This dataset is released through LDC and is not freely available. Therefore, we do not consider it in our evaluation.

[2] In practice, this procedure can lead to negative counts.

[3] Genia contains manual POS tag annotation. Europarl was tagged using the TreeTagger (`www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger`).

This lowercasing algorithm helps to deal with the massive use of abbreviations, acronyms, named entities, and formulae found in specialised corpora, such as those containing biomedical (and other specialised) scientific articles.

For calculating arbitrary-sized n-grams in large textual corpora efficiently, we implemented a structure based on suffix arrays (Yamamoto and Church, 2001). While suffix trees are often used in LM tools, where n-grams have a fixed size, they are not fit for arbitrary length n-gram searches and can consume quite large amounts of memory to store all the node pointers. Suffix arrays, on the other hand, allow for arbitrary length n-grams to be counted in a time that is proportional to $\log(N)$, where N is the number of words (which is equivalent to the number of suffixes) in the corpus. Suffix arrays use a constant amount of memory proportional to N. In our implementation, where every word and every word position in the corpus are encoded as a 4-byte integer, it corresponds precisely to $4 \times 2 \times N$ plus the size of the vocabulary, which is generally very small if compared to N, given a typical token/type ratio. The construction of the suffix array takes $O(N \log_2 N)$ operations, due to a sorting step at the end of the process.

4.2 Vocabulary creation

After preprocessing, we extracted all the unigram surface forms (i.e. all words) from *ep* and from *genia*, generating two vocabularies, V_{ep} and V_{genia}, where the words are ranked in descending frequency order with respect to the corpus itself seen as a n-gram count source. Formally, we can model a *vocabulary* as a set V of words $v_i \in V$ taken from a corpus. A word *count* is the value $c(v_i) = n$ of a function that goes from words to natural numbers, $c : V \to \mathbb{N}$. Therefore, there is always an implicit word order relation $\leq_r$ in a vocabulary, that can be generated from V and c by using the order relation $\geq$ in $\mathbb{N}$[4]. Thus, a *rank* is defined as a partially-ordered set formed by a vocabulary–word order pair relation: $\langle V, \leq_r \rangle$.

Table 1 summarises some measures of the extracted vocabularies, where V_{inter} denotes the intersection of V_{ep} and V_{genia}. Notice that V_{inter} contains considerably less entries than the smallest vocabulary (V_{genia}). This shows to what extent both types of text differ and how important it is to use the correct techniques when working with domain-specific data in empirical approaches. The table also shows the number of hapax legomena (i.e. words that occur only once) in each corpus, and in this aspect both corpora are similar[5]. It also shows how sparseness affects language, since a vocabulary that is 400% bigger has only 5% less hapax legomena.

n-gram	genia	ep	google	yahoo
642	1	4	8090K	220M
African	2	2028	15400K	916M
fatty	16	22	2550K	59700K
medicine	4	643	21900K	934M
Mac	15	3	34500K	1910M
SH2	27	1	113K	3270K
advances	4	646	6200K	173M
thereby	29	2370	8210K	145M

Table 2: Distribution of some words in V_{inter}.

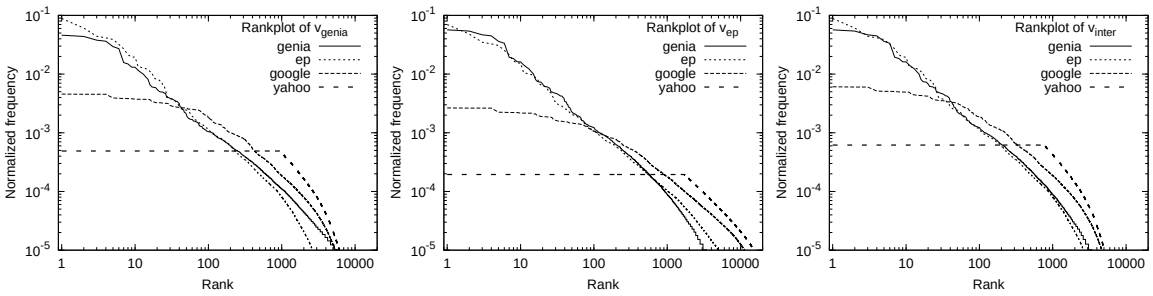
For each entry in each vocabulary, we obtained a count estimated from four different n-gram count sources: *ep*, *genia*, Google as a corpus (*google*) and Yahoo! as a corpus (*yahoo*). The latter were configured to return only results for pages in English. Table 2 shows an example of entries extracted from V_{inter}. Notice that there are no zeroes in columns *genia* and *ep*, since this vocabulary only contains words that occur at least once in these corpora. Also, some words like *Mac* and *SH2*, that are probably specialised terms, occur more in *genia* than in *ep* even if the latter is more than 80 times larger than the former.

4.3 Rank analyses

For each vocabulary, we want to estimate how similar the ranks generated by each of the four count sources are. Figure 1 shows the rank position (x) against the frequency (y) of words in V_{genia}, V_{ep} and V_{inter}, where each plotted point represents a rank position according to corpus fre-

[4] That is, $\forall v_1, v_2 \in V$, suppose $c(v_1) = n_1$ and $c(v_2) = n_2$, then $v_1 \leq_r v_2$ if and only if $n_1 \geq n_2$.

[5] The percentual difference in the proportion of hapax legomena can be explained by the fact that *genia* is much smaller than *ep*.



(a) Rank plot of V_{genia}. (b) Rank plot of V_{ep}. (c) Rank plot of V_{inter}.

Figure 1: Plot of normalised frequencies of vocabularies according to rank positions, log-log scale.

quencies and may correspond to several different words.[6] The four sources have similar shaped curves for each of the three vocabularies: *ep* and *genia* could be reasonably approximated by a linear regression curve (in the log-log domain). *google* and *yahoo* present Zipfian curves for low frequency ranges but have a flat line for higher frequencies, and the phenomenon seems consistent in all vocabularies and more intense on *yahoo*. This is related to the problem discussed in section 3 which is that *web*-based frequencies are not accurate to model common words because *web* counts correspond to page counts and not to word counts, and that a common word will probably appear dozens of times in a single page. Nonetheless, *google* seems more robust to this effect, and indeed *yahoo* returns exactly the same value (roughly 2 billion pages) for a large number of common words, producing the perfectly straight line in the rank plots. Moreover, the problem seems less serious in V_{inter}, but this could be due to its much smaller size. These results show that *google* is incapable of distinguishing among the top-100 words while *yahoo* is incapable of distinguishing among the top-1000 words, and this can be a serious drawback for *web*-based counts both in general-purpose and specialised NLP tasks.

The curves agree in a large portion of the frequency range, and the only interval in which *genia* and *ep* disagree is in lower frequencies (shown in the bottom right corner). This happens because general-purpose *ep* frequencies are much less accurate to model the specialised *genia* vocabulary, specially in low frequency ranges when sparseness becomes more marked (figure 1(a)), and vice-versa (figure 1(b)). This effect is minimised in figure 1(c), corresponding to V_{inter}.

Although both vocabularies present the same word frequency distributions, it does not mean that their ranks are similar for the four count sources. Tables 3 and 4 show the correlation scores for the compared count sources and for the two vocabularies, using Kendall's τ. The τ correlation index estimates the probability that a word pair in a given rank has the same *respective* position in another rank, in spite of the distance between the words[7].

In the two vocabularies, correlation is low, which indicates that the ranks tend to order words differently even if there are some similarities in terms of the shape of the frequency distribution. When we compare *genia* with *google* and with *yahoo*, we observe that *yahoo* is slightly less correlated with *genia* than *google*, probably because of its uniform count estimates for frequent words. However, both seem to be more similar to *genia* than *ep*.

A comparison of *ep* with *google* and with *yahoo* shows that *web* frequencies are much more similar to a general-purpose count source like *ep* than to a specialised source like *genia*. Additionally, both *yahoo* and *google* seem equally correlated to *ep*.

[6] Given the Zipfian behaviour of word probability distributions, a log-log scale was used to plot the curves.

[7] For all correlation values, $p < 0.001$ for the alternative hypothesis that τ is greater than 0.

	V_{genia}	V_{genia} top	V_{genia} middle	V_{genia} bottom
genia-ep	0.26	0.24	0.13	0.06
genia-google	0.28	0.24	0.18	0.09
genia-yahoo	0.27	0.22	0.17	0.09
ep-google	0.57	0.68	0.53	0.49
ep-yahoo	0.57	0.68	0.53	0.49
google-yahoo	0.90	0.90	0.89	0.89

Table 3: Kendall's τ for count sources in V_{genia}.

	V_{ep}	V_{ep} top	V_{ep} middle	V_{ep} bottom
genia-ep	0.26	0.36	0.07	0.04
genia-google	0.27	0.39	0.15	0.12
genia-yahoo	0.24	0.35	0.12	0.10
ep-google	0.40	0.45	0.22	0.09
ep-yahoo	0.38	0.44	0.20	0.08
google-yahoo	0.86	0.89	0.84	0.83

Table 4: Kendall's τ for count sources in V_{ep}.

Surprisingly, this correlation is higher for V_{genia} than for V_{ep}, as *web* frequencies and *ep* frequencies are more similar for a specialised vocabulary than for a general-purpose vocabulary. This could mean that the three perform similarly (poorly) at estimating frequencies for the biomedical vocabulary (V_{genia}) whereas they differ considerably at estimating general-purpose frequencies.

The correlation of the rank (first column) is also decomposed into the correlation for *top* words (more than 10 occurrences), *middle* words (10 to 3 occurrences) and *bottom* words (2 and 1 occurrences). Except for the pair *google-yahoo*, the correlation is much higher in the top portion of the vocabulary and is close to zero in the long tail. In spite of the logarithmic scale of the graphics in figure 1, that show the largest difference in the top part, the bottom part is actually the most irregular. The only exception is *ep* compared with the *web* count sources in V_{genia}: these two pairs do not present the high variability of the other compared pairs, and this means that using *ep* counts (general-purpose) to estimate *genia* counts (specialised) is similar to using *web* counts, independently of the position of the word in the rank. Counts from *google* and from *yahoo* are also very similar, specially if we also consider Spearman's ρ, that is very close to total correlation. Web ranks are also more similar for a specialised vocabulary than for a general-purpose one, providing further evidence for the hypothesis that the higher correlation is a consequence of both sources being poor frequency estimators. That is, for a given vocabulary, when *web* count sources are good estimators, they will be more distinct (e.g. having less zero frequencies).

5 Combining corpora frequencies

In our second experiment, the goal is to propose and to evaluate techniques for the combination of *n*-gram counts from heterogeneous sources. Therefore, we will use the insights about the vocabulary differences presented in the previous section. In this evaluation, we measure the impact of the suggested techniques in the identification of noun–noun compounds in corpora. Noun compounds are very frequent in general-purpose and specialised texts (e.g. *bus stop*, *European Union* and *gene activation*). We extract them automatically from *ep* and from *genia* using a standard method based on POS patterns and association measures (Evert and Krenn, 2005; Pecina, 2008; Ramisch et al., 2010).

5.1 Experimental setup

The evaluation task consists of, given a corpus of N words, extract all occurrences of adjacent pairs of nouns[8] and then rank them using a standard statistical measure that estimates the association strength between the two nouns. Analogously to the formalism adopted in section 4.2, we assume that, for each corpus, we generate a set NN containing n-grams $v_{1\ldots n} \in NN$[9] for which we obtain n-gram counts from four sources. The elements in NN are generated by comparing the POS pattern *noun–noun* against all the bigrams in the corpus and keeping only those pairs of adjacent words that match the pattern. The calculation of the association measure, considering a bigram $v_1 v_2$, is based on a contingency table which cells

[8] We ignore other types of compounds, e.g. adjective–noun pairs.

[9] We abbreviate a sequence $v_1 \ldots v_n$ as $v_{1\ldots n}$.

contain all possible outcomes $a_1a_2, a_i \in \{v_i, \neg v_i\}$. For *web*-based counts, we corrected up to 2% of them by forcing the frequency of a unigram to be at least equal to the frequency of the bigram in which it occurs. Such inconsistencies are incompatible with statistical approaches based on contingency table, as discussed in section 2.

The log-likelihood association measure (*LL*, alternatively called *expected mutual information*), estimates the difference between the observed table and the expected table under the assumption of independent events, where $E(a_1 \ldots a_n) = \frac{\prod_{i=1}^{n} c(a_i)}{N^{n-1}}$ is calculated using maximum likelihood:

$$LL(v_1v_2) = \sum_{a_1a_2} c(a_1a_2) \times \log_2 \frac{c(a_1a_2)}{E(a_1a_2)}$$

The evaluation of the *NN* lists is performed automatically with the help of existing noun compound dictionaries. The general-purpose gold standard, used to evaluate NN_{ep}, is composed of bigram noun compounds extracted from several resources: 6,212 entries from the Cambridge International Dictionary of English, 22,981 from Wordnet and 2,849 from the data sets of MWE 2008[10]. Those were merged into a single general-purpose gold standard that contains 28,622 bigram noun compounds. The specialised gold standard, used to evaluate NN_{genia}, is composed of 7,441 bigrams extracted from constituent annotation of the *genia* corpus with respect to concepts in the Genia ontology (Kim et al., 2006).

True positives (TPs) are the *n*-grams of *NN* that are contained in the respective gold standard, while *n*-grams that do not appear in the gold standard are considered false positives[11]. While this is a simplification that underestimates the performance of the method, it is appropriate for the purpose of this evaluation because we compare only the *mean average precision* (MAP) between two *NN* ranks, in order to verify whether improvements obtained by the combined frequencies are significant. Additionaly, MWEs are complex linguistic phenomena, and their annotation, specially in a domain corpus, is a difficult task that reaches low agreement rates, sometimes even for expert native speakers. Therefore, not only for theoretical reasons but also for practical reasons, we adopted an automatic evaluation procedure rathern than annotating the top candidates in the lists by hand.

Since the log-likelihood measure is a function that assigns a real value to each *n*-gram, there is a rank relation $\leq_r$ that will be used to calculate MAP as follows:

$$MAP(NN, \leq_r) = \frac{\sum_{v_{1\ldots n} \in NN} P(v_{1\ldots n}) \times p(v_{1\ldots n})}{|\text{TPs in } NN|},$$

where $p = 1$ if $v_{1\ldots n}$ is a TP, 0 else, and the precision $P(v_{1\ldots n})$ of a given *n*-gram corresponds to the number of TPs before $v_{1\ldots n}$ in $\langle NN, \leq_r \rangle$ over the total number of *n*-grams before $v_{1\ldots n}$ in $\langle NN, \leq_r \rangle$.

5.2 Combination heuristics

From the initial list of 176,552 lemmatised *n*-grams in NN_{ep} and 14,594 in NN_{genia}, we filtered out all hapax legomena in order to remove noise and avoid useless computations. Then, we counted the occurrences of v_1, v_2 and v_1v_2 in our four sources, and those were used to calculate the four *LL* values of *n*-grams in both lists. We also propose three heuristics to combine a set of m count sources c_1 through c_m into a single count source c_{comb}:

$$c_{comb}(v_{1\ldots n}) = \sum_{i=1}^{m} w_i(v_{1\ldots n}) \times c_i(v_{1\ldots n}),$$

where $w(v_{1\ldots n})$ is a function that assigns a weight between 0 and 1 for each count source according to the *n*-gram $v_{1\ldots n}$. Three different functions were used in our experiments: *uniform* linear interpolation assumes a constant and uniform weight $w(v_{1\ldots n}) = 1/m$ for all *n*-grams; *proportional* linear interpolation assumes a constant weight $w_i(v_{1\ldots n}) = ((\sum_{j=1}^{m} N_j) - N_i)/\sum_{j=1}^{m} N_j$ that is proportional to the inverse size of the corpus; and *back-off* uses the uniform interpolation of *web* frequencies whenever the *n*-gram count in the original corpus falls below a threshold (empirically defined as $\log_2(N/100,000)$).

[10] 420 entries provided by Timothy Baldwin, 2,169 entries provided by Su Nam Kim and 250 entries provided by Preslav Nakov, freely available at `http://multiword.sf.net/`

[11] In fact, nothing can be said about an *n*-gram that is not in a (limited-coverage) dictionary, further manual annotation would be necessary to asses its relevance.

MAP of rank	NN_{genia}	NN_{ep}
LL_{genia}	0.4400	0.0462
LL_{ep}	0.4351	0.0371
LL_{google}	0.4297	0.0532
LL_{yahoo}	0.4209	0.0508
$LL_{uniform}$	0.4254	0.0508
$LL_{proportional}$	0.4262	0.0520
$LL_{backoff}$	0.3719	0.0370

Table 5: Performance of compound extraction.

Table 5 shows that the performance of *backoff* is below all other techniques for both vocabularies, thus excluding it as a successful combination heuristic. The large difference between MAP scores for NN_{ep} and for NN_{genia} is explained by the relative size of the gold standards: while the general-purpose reference accounts for 16% of the size of the NN_{ep} set, the specialised reference has as many entries as 50% of NN_{genia}. Moreover, the former was created by joining heterogeneous resources while the latter was compiled by human annotators from the Genia corpus itself. The goal of our evaluation, however, is not to compare the difficulty of each task, but to compare the combination heuristics presented in each row of the table.

The best MAP for NN_{genia} was obtained with *genia*, that significantly outperforms all other sources except *ep*[12]. On the other hand, the use of *web*-based or interpolated counts in extracting specialised noun–noun compounds does not improve the performance of results based on sparse but reliable counts drawn from well-formed corpora. Nonetheless, the performance of *ep* in specialised extraction is surprising and could only be explained by some overlap between the corpora. Moreover, the interpolated counts are not significantly different from *google* counts, even if this corpus should have the weakest weight in *proportional* interpolation.

General-purpose compound extraction, however, benefits from the counts drawn from large corpora as *google* and *yahoo*. Indeed, the former significantly outperforms all other count sources, closely followed by *proportional* counts. In both vocabularies, *proportional* interpolation performs very similar to the best count source, but, strangely enough, it still does not outperform *google*. Further data inspection would be needed to explain these results for the interpolated combination and to try to shed some light on the reason why the *backoff* method performs so poorly.

[12]Significance was assessed through a standard one-tailed t test for equal sample sizes and variances, $\alpha = 0.005$.

6 Future perspectives

In this work, we presented a detailed evaluation of the use of *web* frequencies as estimators of corpus frequencies in general-purpose and specialised tasks, discussing some important aspects of corpus-based versus *web*-based *n*-gram frequencies. The results indicate that they are not only very distinct but they are so in different ways. The importance of domain-specific data for modelling a specialised vocabulary is discussed in terms of using *ep* to get V_{genia} counts. Furthermore, the *web* corpora were more similar to *genia* than to *ep*, which can be explained by the fact that "similar" is different from "good", i.e. they might be equally bad in modelling *genia* while they are distinctly better for *ep*.

We also proposed heuristics to combine count sources inspired by standard interpolation and back-off techniques. Results show that we cannot use *web*-based or combined counts to identify specialised noun compounds, since they do not help minimise data sparseness. However, general-purpose extraction is improved with the use of *web* counts instead of counts drawn from standard corpora.

Future work includes extending this research to other languages and domains in order to estimate how much of these results depend on the corpora sizes. Moreover, as current interpolation techniques usually combine two corpora, weights are estimated in a more or less ad hoc procedure (Lapata and Keller, 2005). Interpolating several corpora would need a more controlled learning technique to obtain optimal weights for each frequency function. Additionally, the evaluation shows that corpora perform differently according to the frequency range. This insight could be used to define weight functions for interpolation.

Abstract

Previous research in cross-document entity coreference has generally been restricted to the offline scenario where the set of documents is provided in advance. As a consequence, the dominant approach is based on greedy agglomerative clustering techniques that utilize pairwise vector comparisons and thus require $O(n^2)$ space and time. In this paper we explore identifying coreferent entity mentions across documents in high-volume streaming text, including methods for utilizing orthographic and contextual information. We test our methods using several corpora to quantitatively measure both the efficacy and scalability of our streaming approach. We show that our approach scales to at least an order of magnitude larger data than previous reported methods.

1 Introduction

A key capability for successful information extraction, topic detection and tracking, and question answering is the ability to identify equivalence classes of entity mentions. An entity is a real-world person, place, organization, or object, such as the person who serves as the 44th president of the United States. An entity mention is a string which refers to such an entity, such as "Barack Hussein Obama", "Senator Obama" or "President Obama". The goal of coreference resolution is to identify and connect all textual entity mentions that refer to the same entity.

The first step towards this goal is to identify all references within the same document, or *within document coreference resolution*. A document often has a leading canonical reference to the entity ("Barack Obama") followed by additional expressions for the same entity ("President Obama.") An intra-document coreference system must first identify each reference, often relying on named entity recognition, and then decide if these references refer to a single individual or multiple entities, creating a *coreference chain* for each unique entity. Feature representations include surface form similarity, lexical context of mentions, position in the document and distance between references. A variety of statistical learning methods have been applied to this problem, including use of decision trees (Soon et al., 2001; Ng and Cardie, 2002), graph partitioning (Nicolae and Nicolae, 2006), maximum-entropy models (Luo et al., 2004), and conditional random fields (Choi and Cardie, 2007).

Given pre-processed documents, in which entities have been identified and entity mentions have been linked into chains, we seek to identify across an entire document collection all chains that refer to the same entity. This task is called cross document coreference resolution (CDCR). Several of the challenges associated with CDCR differ from the within document task. For example, it is unlikely that the same document will discuss John Phillips the American football player and John Phillips the musician, but it is quite probable that documents discussing each will appear in the same collection. Therefore, while matching entities with the same mention string can work well for within document coreference, more sophisticated approaches are necessary for the cross document scenario where a *one-entity-per-name* assumption is unreasonable.

One of the most common approaches to both within document and cross document coreference resolution has been based on agglomerative clustering, where vectors might be bag-of-word contexts (Bagga and Baldwin, 1998; Mann and

Coling 2008: Poster Volume, pages 1050–1058,
Beijing, August 2010

Yarowsky, 2003; Gooi and Allan, 2004; Chen and Martin, 2007). These algorithms creates a $O(n^2)$ dependence in the number of *mentions* – for within document – and *documents* – for cross document. This is a reasonable limitation for within document, since the number of references will certainly be small; we are unlikely to encounter a document with millions of references. In contrast to the small n encountered within a document, we fully expect to run a CDCR system on hundreds of thousands or millions of documents. Most previous approaches cannot handle collections of this size.

In this work, we present a new method for cross document coreference resolution that scales to very large corpora. Our algorithm operates in a *streaming* setting, in which documents are processed one at a time and only a single time. This creates a linear ($O(n)$) dependence on the number of documents in the collection, allowing us to scale to millions of documents and millions of unique entities. Our algorithm uses streaming clustering with common coreference similarity computations to achieve large scale. Furthermore, our method is designed to support both name disambiguation and name variation.

In the next section, we give a survey of related work. In Section 3 we detail our streaming setup, giving a description of the streaming algorithm and presenting efficient techniques for representing clusters over streams and for computing similarity. Section 4 describes the data sets on which we evaluate our methods and presents results. We conclude with a discussion and description of ongoing work.

2 Related Work

Traditional approaches to cross document coreference resolution have first constructed a vector space representation derived from local (or global) contexts of entity mentions in documents and then performed some form of clustering on these vectors. This is a simple extension of Firth's distributional hypothesis applied to entities (Firth, 1957). We describe some of the seminal work in this area.

Some of the earliest work in CDCR was by Bagga and Baldwin (1998). Key contributions of their research include: promotion of a set-theoretic evaluation measure, *B-CUBED*; introduction of a data set based on 197 New York Times articles which mention a person named *John Smith*; and, use of TF/IDF weighted vectors and cosine similarity in single-link greedy agglomerative clustering.

Mann and Yarowsky (2003) extended Bagga and Baldwin's work and contributed several innovations, including: use of biographical attributes (*e.g.,* year of birth, occupation), and evaluation using *pseudonames*. Pseudonames are sets of artificially conflated names that are used as an efficient method for producing a set of gold-standard disambiguations.[1] Mann and Yarowsky used 4 pairs of conflated names in their evaluation. Their system did not perform as well on named entities with little available biographic information.

Gooi and Allan (2004) expanded on the use of pseudonames by semi-automatically creating a much larger evaluation set, which they called the 'Person-X' corpus. They relied on automated named-entity tagging and domain-focused text retrieval. This data consisted of 34,404 documents where a single person mention in each document was rewritten as 'Person X'. Besides their novel construction of a large-scale resource, they investigated several minor variations in clustering, namely (a) use of Kullback-Leibler divergence as a distance measure, (b) use of 55-word snippets around entity mentions (vs. entire documents or extracted sentences), and (c) scoring clusters using average-link instead of single- or complete-link.

Finally, in more recent work, Chen and Martin (2007) explore the CDCR task in both English and Chinese. Their work focuses on use of both local, and document-level noun-phrases as features in their vector-space representation.

There have been a number of open evaluations of CDCR systems. For example, the Web People Search (WePS) workshops (Artiles et al., 2008) have created a task for disambiguating personal names from HTML pages. A set of ambiguous names is chosen and each is submitted to a popular web search engine. The top 100 pages are then manually clustered.We discuss several other data

[1] See Sanderson (2000) for use of this technique in word sense disambiguation.

sets in Section 4.[2]

All of the papers mentioned above focus on disambiguating personal names. In contrast, our system can also handle organizations and locations. Also, as was mentioned earlier, we are committed to a scenario where documents are presented in sequence and entities must be disambiguated instantly, without the benefit of observing the entire corpus. We believe that such a system is better suited to highly dynamic environments such as daily news feeds, blogs, and tweets. Additionally, a streaming system exposes a set of known entity clusters after each document is processed instead of waiting until the end of the stream.

3 Approach

Our cross document coreference resolution system relies on a streaming clustering algorithm and efficient calculation of similarity scores. We assume that we receive a stream of coreference chains, along with entity types, as they are extracted from documents. We use SERIF (Ramshaw and Weischedel, 2005), a state of the art document analysis system which performs intra-document coreference resolution. BBN developed SERIF to address information extraction tasks in the ACE program and it is further described in Pradhan et al. (2007).

Each unique entity is represented by an entity cluster c, comprised of entity chains from many documents that refer to the same entity. Given an entity coreference chain e, we identify the best known entity cluster c. If a suitable entity cluster is not found, a new entity cluster is formed.

An entity cluster is selected for a given coreference chain using several similarity scores, including document context, predicted entity type, and orthographic similarity between the entity mention and previously discovered references in the entity cluster. An efficient implementation of the similarity score allows the system to identify the top k most likely mentions without considering all m entity clusters. The final output of our system is a collection of entity clusters, each containing a list of coreference chains and their documents. Additionally, due to its streaming nature, the system can be examined at any time to produce this information based on only the documents that have been processed thus far.

In the next sections, we describe both the clustering algorithm and efficient computation of the entity similarity scores.

3.1 Clustering Algorithm

We use a streaming clustering algorithm to create entity clusters as follows. We observe a set of points from a potentially infinite set $\mathcal{X}$, one at a time, and would like to maintain a fixed number of clusters while minimizing the maximum *cluster radius*, defined as the radius of the smallest ball containing all points of the cluster. This setup is well known in the theory and information retrieval community and is referred to as the dynamic clustering problem (Can and Ozkarahan, 1987).

Others have attempted to use an incremental clustering approach, such as Gooi and Allan (2004) (who eventually prefer a hierarchical clustering approach), and Luo et al. (2004), who use a Bell tree approach for incrementally clustering within document entity mentions. Our work closely follows the *Doubling Algorithm* of Charikar et al. (1997), which has better performance guarantees for streaming data. Streaming clustering means potentially linear performance in the number of observations since each document need only be examined a single time, as opposed to the quadratic cost of agglomerative clustering.[3]

The Doubling Algorithm consists of two stages: update and merge. Update adds points to existing clusters or creates new clusters while merge combines clusters to prevent the clusters from exceeding a fixed limit. New clusters are created according to a threshold set using development data. We selected a threshold of 0.5 since it worked well in preliminary experiments. Since the number of entities grows with time, we have skipped the merge step in our initial experiments so as not to limit cluster growth.

We use a dynamic caching scheme which backs the actual clusters in a disk based index, but re-

[2]We preferred other data sets to the WePS data in our evaluation because it is not easily placed in temporal order.

[3]It is possible to implement hierarchical agglomerative clustering in $O(n \log m)$ time where n is the number of points and m in the number of clusters. However this is still superlinear and expensive in situations where m continually increases like in streaming coreference resolution.

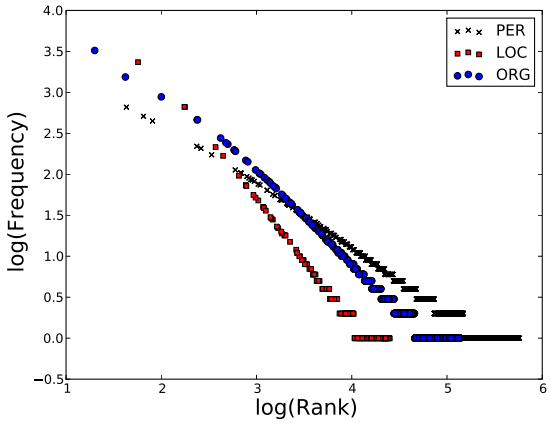

Figure 1: Frequency vs. rank for 567k people, 136k organizations, and 25k locations in the New York Times Annotated Corpus (Sandhaus, 2008).

tains basic cluster information in memory (see below). Doing so improves paging performance as observed in Omiecinski and Scheuermann (1984). Motivated by the Zipfian distribution of named entities in news sources (Figure 1), we organize our cluster store using an LRU policy, which facilitates easy access to named entities that were observed in the recent past. We obtain additional performance gains by hashing the clusters based on the constituent mention string (details below). This allows us to quickly retrieve a small but related number of clusters, k. It is always the case that $k << m$, the current number of clusters.

3.2 Candidate Cluster Selection

As part of any clustering algorithm, each new item must be compared against current clusters. As we see more documents, the number of unique clusters (entities) grows. Therefore, we need efficient methods to select candidate clusters.

To select the top candidate clusters, we obtain those that have high orthographic similarity with the head name mention in the coreference chain e. We compute this similarity using the dice score on either word unigrams or character skip bigrams. For each entity mention string associated with a cluster c, we generate all possible n-grams using one of the above two policies. We then index the cluster by each of its n-grams in a hash maintained in memory. In addition, we keep the number of n-grams generated for each cluster.

When given a new head mention e for a coreference chain, we generate all of the n-grams and look up clusters that contain these n-grams using the hash. We then compute the dice score:

$$\text{dice}(e, c) = \frac{|\{\text{ngram}(e)\} \cap \{\text{ngram}(c)\}|}{|\{\text{ngram}(e)\} \cup \{\text{ngram}(c)\}|},$$

where $\{\text{ngram}(e)\}$ are the set of n-grams in entity mention e and $\{\text{ngram}(c)\}$ are the set of n-grams for all entity mentions in cluster c. Note that we can calculate the numerator (the intersection) by looking up the n-grams of e in the hash and counting matches with c. The denominator is equivalent to the number of n-grams unique to e and to c plus the number that are shared. The number that are shared is the intersection. The number unique to e is the total number of n-grams in e minus the intersection. The final term, the number unique to c, is computed by taking the total number of n-grams in c (a single integer stored in memory) minus the intersection.

Through this strategy, we can select only those clusters that have the highest orthographic similarity to e without requiring the cluster contents, which may not be stored in memory. In our experiments, we evaluate settings where we select all candidates with non-zero score and a pruned set of the top k dice score candidates. We also include in the n-gram list known aliases to facilitate orthographically dissimilar, but reasonable matches (*e.g.,* IBM or 'Big Blue' for 'International Business Machines, Inc.').[4]

For further efficiency, we keep separate caches for each named entity type.[5] We then select the appropriate cache based on the automatically determined type of the named entity provided by the named entity tagger, which also prevents spurious matches of non-matching entity types.

3.3 Similarity Metric

After filtering by orthographic information to quickly obtain a small set of candidate clusters, a full similarity score is computed for the current

[4]We generated alias lists for entities from Freebase.

[5]Persons (PER), organizations (ORG), and locations (LOC).

entity coreference chain and each retrieved candidate cluster. These computations require information about each cluster, so the cluster's sufficient statistics are loaded using the LRU cache described above.

We define several similarity metrics between coreference chains and clusters to deal with both name variation and disambiguation. For name variation, we define an orthographic similarity metric to match similar entity mention strings. As before, we use word unigrams and character skip bigrams. For each of these methods, we compute a similarity score as dice(e, c) and select the highest scoring cluster.

To address name disambiguation, we use two types of context from the document. First, we use *lexical* features represented as TF/IDF weighted vectors. Second, we consider *topic* features, in which each word in a document is replaced with the topic inferred from a topic model. This yields a distribution over topics for a given document. We use an LDA (Blei et al., 2003) model trained on the New York Times Annotated Corpus (Sandhaus, 2008). We note that LDA can be computed over streams (Yao et al., 2009).

To compare context vectors we use cosine similarity, where the cluster vector is the average of all document vectors assigned to the cluster. Note that the filtering step in Section 3.2 returns only those candidates with some orthographic similarity with the coreference chain, so a similarity metric that uses context only is still restricted to orthographically similar entities.

Finally, we consider a combination of orthographic and context similarity as a linear combination of the two metrics as:

$$\text{score}(e, c) = \alpha \, \text{dice}(e, c) + (1 - \alpha)\text{cosine}(e, c) \; .$$

We set $\alpha = 0.8$ based on initial experiments.

4 Evaluation

We used several corpora to evaluate our methods, including two data sets commonly used in the coreference community. We also created a new test set using artificially conflated names. And finally to test scalability, we ran our algorithm over a large text collection that, while it did not have ground truth entity clusters, was useful for computing other performance statistics. Properties for each data set are given in Table 1.

Attribute	*smith*	*nytac*	*ace08*	*kbp09*
Total Documents	197	1.85M	10k	1.2M
Annotated Docs	197	19,360	415	**
Annotated Entities	35	200	3,943	**

Table 1: Data sets used in our experiments. For the *kbp09* data we did not have annotations.

4.1 John Smith corpus

Bagga and Baldwin (1998) evaluated their disambiguation system on a set of 197 articles from the New York Times that mention a person named 'John Smith'. This data exhibits no name variants and is strictly a disambiguation task. We include this data (*smith*) to allow comparison to previous work.

4.2 NYTAC Pseudo-name corpus

To study the effects of word sense ambiguity and disambiguation several researchers have artificially conflated dissimilar words together and then attempted to disambiguate them (Sanderson, 2000). The obvious advantage is cheaply obtained ground truth for disambiguation.

The same trick has also been employed in person name disambiguation (Mann and Yarowsky, 2003; Gooi and Allan, 2004). We adopt the same method on a somewhat larger scale using annotations from the New York Times Annotated Corpus (*NYTAC*) (Sandhaus, 2008), which annotates documents based on whether or not they mention an entity. The NYTAC data contains documents from 20 years of the New York Times and contains rich metadata and document-level annotations that indicate when an entity is mentioned in the document using a standard lexicon of entities. (Note that mention strings are not tagged.) Using these annotations we created a set of 100 pairs of conflated person names.

The names were selected to be medium frequency (*i.e.,* occurring in between 50 and 200 articles) and each pair matches in gender. The first 50 pairs are for names that are topically similar, for example, Tim Robbins and Tom Hanks (both actors); Barbara Boxer and Olympia Snowe (both

US politicians). We imagined that this would be a more challenging subset because of presumed lexical overlap. The second set of 50 name pairs were arbitrarily conflated. We sub-selected the data to ensure that no two entities in our collection co-occur in the same document and this left us with 19,360 documents for which ground-truth was known. In each document we rewrote the conflated name mentions using a single gender-neutral name; any middle initials or names were discarded.

4.3 ACE 2008 corpus

The NIST ACE 2008 (*ace08*) evaluation studied several related technologies for information extraction, including named-entity recognition, relation extraction, and cross-document coreference for person names in both English and Arabic. Approximately 10,000 documents from several genres (predominantly newswire) were given to participants, who were expected to cluster person and organization entities across the entire collection. However, only a selected set of about 400 documents were annotated and used to evaluate system performance. Baron and Freedman (2008) describe their work in this evaluation, which included a separate task for within-document coreference.

4.4 TAC-KBP 2009 corpus

The NIST TAC 2009 Knowledge Base Population track (*kbp09*) (McNamee and Dang, 2009) conducted an evaluation of a system's ability to link entity mentions to corresponding Wikipedia-derived knowledge base nodes. The TAC-KBP task focused on ambiguous person, organization, and geo-political entities mentioned in newswire, and required systems to cope with name variation (*e.g.,* "Osama Bin Laden" / "Usama Bin Laden" or "Mark Twain" / "Samuel Clemens") as well as name disambiguation. Furthermore, the task required detection of when no appropriate KB entry exists, which is a departure from the conventional disambiguation problem. The collection contains over 1.2 million documents, primarily newswire. Wikipedia was used as a surrogate knowledge base, and it has been used in several previous studies (*e.g.,* Cucerzan (2007)). This task is closely related to CDCR, as mentions that are aligned to the same knowledge base entry create a coreference cluster. However, there are no actual CDCR annotations for this corpus, though we used it nonetheles as a benchmark corpus to evaluate speed and to demonstrate scalability.

5 Discussion

5.1 Accuracy

In Table 2 we report cross document coreference resolution performance for a variety of experimental conditions using the B^3 method, which includes precision, recall, and calculated $F_{\beta=1}$ values. For each of the three evaluation corpora (*smith*, *nytac*, and *ace08*) we report values for two baseline methods and for similarity metrics using different types of features. The first baseline, called *Baseline*, places each coreference chain in its own cluster while the second baseline, called *ExactMatch*, merges all mentions that match exactly orthographically into the same cluster.

Use of name similarity scores as features (in addition to their use for candidate cluster selection) is indicated by rows labeled *Ortho*. Use of lexical features is indicated by *BoW* and use of topic model features by *Topic*.

Using topic models as features was more helpful than lexical contexts on the *smith* corpus.

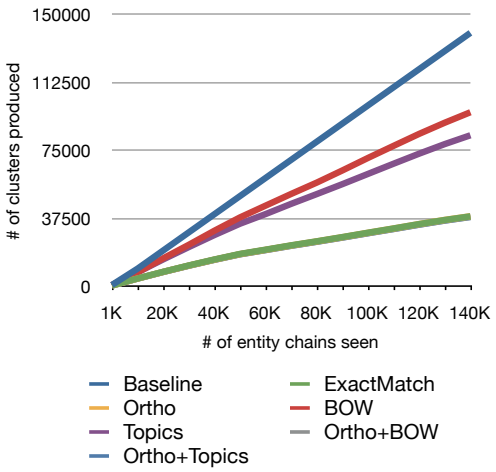

Figure 2: Number of clusters produced vs. number of entity chains observed in the stream. Number of entity chains is proportional to the number of documents.

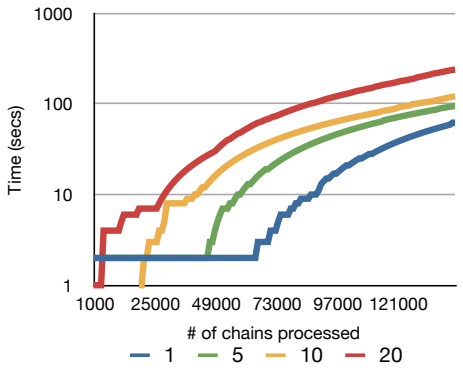

Figure 3: Elapsed processing time as a function of bounding the number of candidate clusters considered for an entity. When fewer candidates are considered, clustering decisions can be made much faster.

When used alone *topic* beats *BoW*, but in combination with the *ortho* features performance is equivalent. For both *nytac* and *ace08* heavy reliance on orthographic similarity proved hard to beat. On the *ace08* corpus Baron and Freedman (2008) report B^3 F-scores of 83.2 for persons and 67.8 for organizations, and our streaming results appear to be comparable to their offline method.

The cluster growth induced by the various measures can be seen in Figure 2. The two baseline methods, *Baseline* and *ExactMatch*, provide bounds on the cluster growth with all other methods falling in between.

5.2 Hashing Strategies for Candidate Selection

Table 3 contains B^3 F-scores when different hashing strategies are employed for candidate selection. The trend appears to be that stricter matching outperforms fuzzier matching; full mentions tended to beat words, which beat use of the character bigrams. This agrees with the results described in the previous section, which show heavy reliance on orthographic similarity.

5.3 Timing Results

Figure 3 shows how processing time increases with the number of entities observed in the *ace08* document stream. We experimented with using an upper bound on the number of candidate clusters to consider for an entity.

Figure 4 compares the efficiency of using three different methods for candidate cluster identification. The most restrictive hashing strategy, using exact mention strings, is the most efficient, followed by the use of words, then the use of character skip bigrams. This makes intuitive sense – the strictest matching reduces the number of candidate clusters that have to be considered when processing an entity.[6]

The *ace08* corpus contained over 10,000 documents and is one of the largest CDCR test sets. In Figure 5 we show how processing time grows when processing the *kbp09* corpus. Doubling the number of entities processed increases the runtime by about a factor of 5. The curve is not linear due to the increasing number of entity cluster's that must be considered. Future work will examine how to keep the number of clusters considered constant over time, such as ignoring older entities.

6 Conclusion

We have presented a new streaming cross document coreference resolution system. Our approach is substantially faster than previous sys-

[6]In the limit, if names were unique, hashing on strings would completely solve the CDCR problem and processing an entity would be O(1)

Table 3: B^3 F-scores using different hashing strategies for candidate selection. Name/cluster similarity could be based on character skip bigrams, words appear in names, or exact matching of mention.

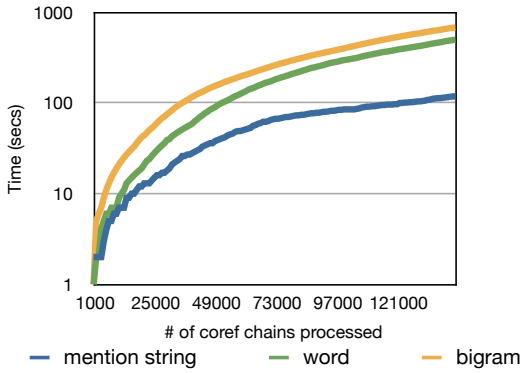

Figure 4: Comparison of three hashing strategies for identifying candidate clusters for a given entity. The more restrictive strategies lead to faster processing as fewer candidates are considered.

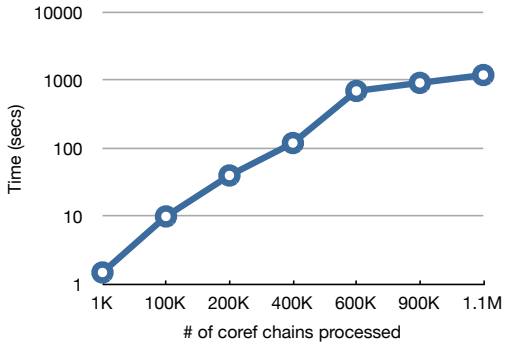

Figure 5: The number of coreference chains processed over time in the *kbp09* corpus. The processing of over 1 million coreference chains is at least an order of magnitude larger than previous systems reported.

tems, and our experiments have demonstrated scalability to an order of magnitude larger data than previously published evaluations. Despite its speed and simplicity, we still obtain competitive results on a variety of data sets as compared with batch systems. In future work, we plan to investigate additional similarity metrics that can be computed efficiently, as well as experiments on web scale corpora.

Abstract

We study correlation of rankings of text summarization systems using evaluation methods with and without human models. We apply our comparison framework to various well-established content-based evaluation measures in text summarization such as coverage, Responsiveness, Pyramids and ROUGE studying their associations in various text summarization tasks including generic and focus-based multi-document summarization in English and generic single-document summarization in French and Spanish. The research is carried out using a new content-based evaluation framework called FRESA to compute a variety of divergences among probability distributions.

1 Introduction

Text summarization evaluation has always been a complex and controversial issue in computational linguistics. In the last decade, significant advances have been made in the summarization evaluation field. Various evaluation frameworks have been established and evaluation measures developed. SUMMAC (Mani et al., 2002), in 1998, provided the first system independent framework for summary evaluation; the Document Understanding Conference (DUC) (Over et al., 2007) was the main evaluation forum from 2000 until 2007; nowadays, the Text Analysis Conference (TAC)[1] provides a forum for assessment of different information access technologies including text summarization.

Evaluation in text summarization can be extrinsic or intrinsic (Spärck-Jones and Galliers, 1996). In an extrinsic evaluation, the summaries are assessed in the context of an specific task a human or machine has to carry out; in an intrinsic evaluation, the summaries are evaluated in reference to some ideal model. SUMMAC was mainly extrinsic while DUC and TAC followed an intrinsic evaluation paradigm. In order to intrinsically evaluate summaries, the automatic summary (*peer*) has to be compared to a *model* summary or summaries. DUC used an interface called SEE to allow human judges compare a peer summary to a model summary. Using SEE, human judges give a *coverage* score to the peer summary representing the degree of overlap with the model summary. Summarization systems obtain a final coverage score which is the average of the coverage's scores associated to their summaries. The system's coverage score can then be used to rank summarization systems. In the case of query-focused summarization (e.g. when the summary has to respond to a question or set of questions) a *Responsiveness* score is also assigned to each summary which indicates how responsive the summary is to the question(s).

Because manual comparison of peer summaries with model summaries is an arduous and costly

[1] http://www.nist.gov/tac

Coling 2008: Poster Volume, pages 1059–1067,
Beijing, August 2010

process, a body of research has been produced in the last decade on automatic content-based evaluation procedures. Early studies used text similarity measures such as cosine similarity (with or without weighting schema) to compare peer and model summaries (Donaway et al., 2000), various vocabulary overlap measures such as set of n-grams overlap or longest common subsequence between peer and model have also been proposed (Saggion et al., 2002; Radev et al., 2003). The *Bleu* machine translation evaluation measure (Papineni et al., 2002) has also been tested in summarization (Pastra and Saggion, 2003). The DUC conferences adopted the ROUGE package for content-based evaluation (Lin, 2004). It implements a series of recall measures based on n-gram co-occurrence statistics between a peer summary and a set of model summaries. ROUGE measures can be used to produce systems ranks. It has been shown that system rankings produced by some ROUGE measures (e.g., ROUGE-2 which uses bi-grams) correlate with rankings produced using coverage. In recent years the Pyramids evaluation method (Nenkova and Passonneau, 2004) was introduced. It is based on the distribution of "content" in a set of model summaries. Summary Content Units (SCUs) are first identified in the model summaries, then each SCU receives a weight which is the number of models containing or expressing the same unit. Peer SCUs are identified in the peer, matched against model SCUs, and weighted accordingly. The Pyramids score given to the peer is the ratio of the sum of the weights of its units and the sum of the weights of the best possible ideal summary with the same number of SCUs as the peer. The Pyramids scores can be used for ranking summarization systems. Nenkova and Passonneau (2004) showed that Pyramids scores produced reliable system rankings when multiple (4 or more) models were used and that Pyramids rankings correlate with rankings produced by ROUGE-2 and ROUGE-SU2 (i.e. ROUGE with skip bi-grams). Still this method requires the creation of models and the identification, matching, and weighting of SCUs in both models and peers.

Donaway et al. (2000) put forward the idea of using directly the full document for comparison purposes, and argued that content-based measures which compare the document to the summary may be acceptable substitutes for those using model summaries. A method for evaluation of summarization systems without models has been recently proposed (Louis and Nenkova, 2009). It is based on the direct content-based comparison between summaries and their corresponding source documents. Louis and Nenkova (2009) evaluated the effectiveness of the Jensen-Shannon (Lin, 1991b) theoretic measure in predicting systems ranks in two summarization tasks query-focused and update summarization. They have shown that ranks produced by Pyramids and ranks produced by the Jensen-Shannon measure correlate. However, they did not investigate the effect of the measure in past summarization tasks such as generic multi-document summarization (DUC 2004 Task 2), biographical summarization (DUC 2004 Task 5), opinion summarization (TAC 2008 OS), and summarization in languages other than English.

We think that, in order to have a better understanding of document-summary evaluation measures, more research is needed. In this paper we present a series of experiments aimed at a better understanding of the value of the Jensen-Shannon divergence for ranking summarization systems.

We have carried out experimentation with the proposed measure and have verified that in certain tasks (such as those studied by (Louis and Nenkova, 2009)) there is a strong correlation among Pyramids and Responsiveness and the Jensen-Shannon divergence, but as we will show in this paper, there are datasets in which the correlation is not so strong. We also present experiments in Spanish and French showing positive correlation between the Jensen-Shannon measure and ROUGE.

The rest of the paper is organized in the following way: First in Section 2 we introduce related work in the area of content-based evaluation identifying the departing point for our inquiry; then in Section 3 we explain the methodology adopted in our work and the tools and resources used for experimentation. In Section 4 we present the experiments carried out together with the results. Section 5 discusses the results and Section 6 concludes the paper.

2 Related Work

One of the first works to use content-based measures in text summarization evaluation is due to (Donaway et al., 2000) who presented an evaluation framework to compare rankings of summarization systems produced by recall and cosine-based measures. They showed that there was weak correlation between rankings produced by recall, but that content-based measures produce rankings which were strongly correlated, thus paving the way for content-based measures in text summarization evaluation.

Radev et al. (2003) also compared various evaluation measures based on vocabulary overlap. Although these measures were able to separate random from non-random systems, no clear conclusion was reached on the value of each of the measures studied.

Nowadays, a widespread summarization evaluation framework is ROUGE (Lin and Hovy, 2003) which, as we have mentioned before, offers a set of statistics that compare peer summaries with models. Various statistics exist depending on the used n-gram and on the type of text processing applied to the input texts (e.g., lemmatization, stopword removal).

Lin et al. (2006) proposed a method of evaluation based on the use of "distances" or divergences between two probability distributions (the distribution of units in the automatic summary and the distribution of units in the model summary). They studied two different Information Theoretic measures of divergence: the Kullback-Leibler ($\mathcal{KL}$) (Kullback and Leibler, 1951) and Jensen-Shannon ($\mathcal{JS}$) (Lin, 1991a) divergences. In this work we use the Jensen-Shannon ($\mathcal{JS}$) divergence that is defined as follows:

$$\begin{aligned} D_{\mathcal{JS}}(P||Q) &= \frac{1}{2}\sum_w P_w \log_2 \frac{2P_w}{P_w+Q_w} \\ &+ Q_w \log_2 \frac{2Q_w}{P_w+Q_w} \end{aligned} \quad (1)$$

This measure can be applied to the distribution of units in system summaries P and reference summaries Q and the value obtained used as a score for the system summary. The method has been tested by (Lin et al., 2006) over the DUC 2002 corpus for single and multi document summarization tasks showing good correlation among divergence measures and both coverage and ROUGE rankings.

Louis and Nenkova (2009) went even further and, as in (Donaway et al., 2000), proposed to directly compare the distribution of words in full documents with the distribution of words in automatic summaries to derive a content-based evaluation measure. They found high correlation among rankings produced using models and rankings produced without models. This work is the departing point for our inquiry into the value of measures that do not rely on human models.

3 Methodology

The methodology of this paper mirrors the one adopted in past work (Donaway et al., 2000; Louis and Nenkova, 2009). Given a particular summarization task T, p data points to be summarized with input material $\{I_i\}_{i=0}^{p-1}$ (e.g. document(s), questions, topics), s peer summaries $\{\text{SUM}_{i,k}\}_{k=0}^{s-1}$ for input i, and m model summaries $\{\text{MODEL}_{i,j}\}_{j=0}^{m-1}$ for input i, we will compare rankings of the s peer summaries produced by various evaluation measures. Some measures we use compare summaries with n out of the m models:

$$\text{MEASURE}_M(\text{SUM}_{i,k}, \{\text{MODEL}_{i,j}\}_{j=0}^{n}) \quad (2)$$

while other measures compare peers with all or some of the input material:

$$\text{MEASURE}_M(\text{SUM}_{i,k}, I_i') \quad (3)$$

where I_i' is some subset of input I_i. The values produced by the measures for each summary $\text{SUM}_{i,k}$ are averaged for each system $k = 0, \ldots, s-1$ and these averages are used to produce a ranking. Rankings are compared using Spearman Rank correlation (Spiegel and Castellan, 1998) used to measure the degree of association between two variables whose values are used to rank objects. We use this correlation to directly compare results to those presented in (Louis and Nenkova, 2009). Computation of correlations is

done using the CPAN Statistics-RankCorrelation-0.12 package[2], which computes the rank correlation between two vectors.

3.1 Tools

We carry out experimentation using a new summarization evaluation framework: FRESA –FRamework for Evaluating Summaries Automatically– which includes document-based summary evaluation measures based on probabilities distribution. As in the ROUGE package, FRESA supports different n-grams and skip n-grams probability distributions. The FRESA environment can be used in the evaluation of summaries in English, French, Spanish and Catalan, and it integrates filtering and lemmatization in the treatment of summaries and documents. It is developed in Perl and will be made publicly available. We also use the ROUGE package to compute various ROUGE statistics in new datasets.

3.2 Summarization Tasks and Data Sets

We have conducted our experimentation with the following summarization tasks and data sets:

Generic multi-document-summarization in English (i.e. production a short summary of a cluster of related documents) using data from DUC 2004[3] corpus task 2: 50 clusters (10 documents each) – 294,636 words.

Focused-based summarization in English (i.e. production a short focused multi-document summary focused on the question "who is X?", where X is a person's name) using data from the DUC 2004 task 5: 50 clusters (10 documents each plus a target person name) – 284,440 words.

Update-summarization task that consists of creating a summary out of a cluster of documents and a topic. Two sub-tasks are considered here: A) an initial summary has to be produced based on an initial set of documents and topic; B) an update summary has to be produced from a different (but related) cluster assuming documents used in A) are known. The English TAC 2008 Update Summarization dataset is used which consists of 48 topics with 20 documents each – 36,911 words.

Opinion summarization where systems have to analyze a set of blog articles and summarize the opinions about a target in the articles. The TAC 2008 Opinion Summarization in English[4] data set (taken from the Blogs06 Text Collection) is used: 25 clusters and targets (i.e., target entity and questions) were used – 1,167,735 words.

Generic single-document summarization in Spanish using the "Spanish *Medicina Clínica*"[5] corpus which is composed of 50 biomedical articles in Spanish, each one with its corresponding author abstract – 124,929 words.

Generic single document summarization in French using the "Canadien French Sociological Articles" corpus from the journal *Perspectives interdisciplinaires sur le travail et la santé* (PISTES)[6]. It contains 50 sociological articles in French with their corresponding author abstracts – 381,039 words.

3.3 Summarization Systems

For experimentation in the TAC and the DUC datasets we directly use the peer summaries produced by systems participating in the evaluations. For experimentation in Spanish and French (single-document summarization) we have created summaries at the compression rates of the model summaries using the following summarization systems:

- *CORTEX* (Torres-Moreno et al., 2002), a single-document sentence extraction system for Spanish and French that combines various statistical measures of relevance (angle between sentence and topic, various Hamming weights for sentences, etc.) and applies an optimal decision algorithm for sentence selection;
- *ENERTEX* (Fernandez et al., 2007), a summarizer based on a theory of textual energy;

[5] http://www.elsevier.es/revistas/ctl_servlet?_f=7032&revistaid=2

[6] http://www.pistes.uqam.ca/

- *SUMMTERM* (Vivaldi et al., 2010), a terminology-based summarizer that is used for summarization of medical articles and uses specialized terminology for scoring and ranking sentences;
- *JS* summarizer, a summarization system that scores and ranks sentences according to their Jensen-Shannon divergence to the source document;
- a *lead-based* summarization system that selects the lead sentences of the document;
- a *random-based* summarization system that selects sentences at random;
- the multilingual word-frequency *Open Text Summarizer* (Yatsko and Vishnyakov, 2007);
- the *AutoSummarize* program of Microsoft Word;
- the commercial SSSummarizer[7];
- the *Pertinence* summarizer[8];
- the *Copernic* summarizer[9].

3.4 Evaluation Measures

The following measures derived from human assessment of the content of the summaries are used in our experiments:

- *Coverage* is understood as the degree to which one peer summary conveys the same information as a model summary (Over et al., 2007). Coverage was used in DUC evaluations.
- *Responsiveness* ranks summaries in a 5-point scale indicating how well the summary satisfied a given information need (Over et al., 2007). It is used in focused-based summarization tasks. Responsiveness was used in DUC-TAC evaluations.
- *Pyramids* (briefly introduced in Section 1) (Nenkova and Passonneau, 2004) is a content assessment measure which compares content units in a peer summary to weighted content units in a set of model summaries. Pyramids is the adopted metric for content-based evaluation in the TAC evaluations.

For DUC and TAC datasets the values of these measures are available and we used them directly.

We used the following automatic evaluation measures in our experiments:

- We use the *Rouge* package (Lin, 2004) to compute various statistics. For the experiments presented here we used uni-grams, bi-grams, and the skip bi-grams with maximum skip distance of 4 (ROUGE-1, ROUGE-2 and ROUGE-SU4). ROUGE is used to compare a peer summary to a set of model summaries in our framework.
- Jensen-Shannon divergence formula given in Equation 1 is implemented in our FRESA package with the following specification for the probability distribution of words w.

$$P_w = \frac{C_w^T}{N} \tag{4}$$

$$Q_w = \begin{cases} \frac{C_w^S}{N_S} & \text{if } w \in S \\ \frac{C_w^T + \delta}{N + \delta * B} & \text{elsewhere} \end{cases} \tag{5}$$

Where P is the probability distribution of words w in text T and Q is the probability distribution of words w in summary S; N is the number of words in text and summary $N = N_T + N_S$, $B = 1.5|V|$, C_w^T is the number of words in the text and C_w^S is the number of words in the summary. For smoothing the summary's probabilities we have used $\delta = 0.005$.

4 Experiments and Results

We first replicated the experiments presented in (Louis and Nenkova, 2009) to verify that our implementation of JS produced correlation results compatible with that work. We used the TAC 2008 Update Summarization data set and computed JS and ROUGE measures for each peer

[7] http://www.kryltech.com/summarizer.htm

[8] http://www.pertinence.net

[9] http://www.copernic.com/en/products/summarizer

summary. We produced two system rankings (one for each measure), which were compared to rankings produced using the manual Pyramids and Responsiveness scores. Spearman correlations were computed among the different rankings. The results are presented in Table 1. These results confirm a high correlation among Pyramids, Responsiveness, and JS. We also verified high correlation between JS and ROUGE-2 (0.83 Spearman correlation, not shown in the table) in this task and dataset.

Measure	Pyr.	p-value	Resp.	p-value
ROUGE-2	0.96	$p < 0.005$	0.92	$p < 0.005$
JS	0.85	$p < 0.005$	0.74	$p < 0.005$

Table 1: Spearman system rank correlation of content-based measures in TAC 2008 Update Summarization task

Then, we experimented with data from DUC 2004, TAC 2008 Opinion Summarization pilot and with single document summarization in Spanish and French. In spite of the fact that the experiments for French and Spanish corpora use less data points (i.e., less summarizers per task) than for English, results are still quite significant.

For DUC 2004, we computed the JS measure for each peer summary in tasks 2 and 5 and we used JS and the official ROUGE, coverage, and Responsiveness scores to produce systems' rankings. The various Spearman's rank correlation values for DUC 2004 are presented in Tables 2 (for task 2) and 3 (for task 5). For task 2, we have verified a strong correlation between JS and coverage. For task 5, the correlation between JS and coverage is weak, and the correlation between JS and Responsiveness weak and negative.

Measure	Cov.	p-value
ROUGE-2	0.79	$p < 0.0050$
JS	0.68	$p < 0.0025$

Table 2: Spearman system rank correlation of content-based measures with coverage in DUC 2004 Task 2

Although the Opinion Summarization task is a new type of summarization task and its evaluation is a complicated issue, we have decided to compare JS rankings with those obtained using Pyramids and Responsiveness in TAC 2008. Spearman's correlation values are listed in Table 4. As can be seen, there is weak and negative correlation of JS with both Pyramids and Responsiveness. Correlation between Pyramids and Responsiveness rankings is high for this task (0.71 Spearman's correlation value).

Measure	Cov.	p-value	Resp.	p-value
ROUGE-2	0.78	$p < 0.001$	0.44	$p < 0.05$
JS	0.40	$p < 0.050$	-0.18	$p < 0.25$

Table 3: Spearman system rank correlation of content-based measures in DUC 2004 Task 5

Measure	Pyr.	p-value	Resp.	p-value
JS	-0.13	$p < 0.25$	-0.14	$p < 0.25$

Table 4: Spearman system rank correlation of content-based measures in TAC 2008 Opinion Summarization task

For experimentation in Spanish and French, we have run 11 multi-lingual summarization systems over each of the documents in the two corpora, producing summaries at a compression rate close to the compression rate of the provided authors' abstracts. We have computed JS and ROUGE measures for each summary and we have averaged the measure's values for each system. These averages were used to produce rankings per each measure. We computed Spearman's correlations for all pairs of rankings. Results are presented in Tables 5-6. All results show medium to strong correlation between JS and ROUGE measures. However the JS measure based on uni-grams has lower correlation than JSs which use n-grams of higher order.

5 Discussion

The departing point for our inquiry into text summarization evaluation has been recent work on the use of content-based evaluation metrics that do not rely on human models but that compare summary content to input content directly (Louis and Nenkova, 2009). We have some positive and some negative results regarding the direct use of the full document in content-based evaluation. We have verified that in both generic muti-document sum-

Measure	ROUGE-1	p-value	ROUGE-2	p-value	ROUGE-SU4	p-value
JS	0.56	$p < 0.100$	0.46	$p < 0.100$	0.45	$p < 0.200$
JS_2	0.88	$p < 0.001$	0.80	$p < 0.002$	0.81	$p < 0.005$
JS_4	0.88	$p < 0.001$	0.80	$p < 0.002$	0.81	$p < 0.005$
JS_M	0.82	$p < 0.005$	0.71	$p < 0.020$	0.71	$p < 0.010$

Table 5: Spearman system rank correlation of content-based measures with ROUGE in the *Medicina Clinica* Corpus (Spanish)

Measure	ROUGE-1	p-value	ROUGE-2	p-value	ROUGE-2	p-value
JS	0.70	$p < 0.050$	0.73	$p < 0.05$	0.73	$p < 0.500$
JS_2	0.93	$p < 0.002$	0.86	$p < 0.01$	0.86	$p < 0.005$
JS_4	0.83	$p < 0.020$	0.76	$p < 0.05$	0.76	$p < 0.050$
JS_M	0.88	$p < 0.010$	0.83	$p < 0.02$	0.83	$p < 0.010$

Table 6: Spearman system rank correlation of content-based measures with ROUGE in the PISTES Sociological Articles Corpus (French)

marization and in topic-based multi-document summarization in English correlation among measures that use human models (Pyramids, Responsiveness, and ROUGE) and a measure that does not use models (the Jensen Shannon divergence) is strong. We have found that correlation among the same measures is weak for summarization of biographical information and summarization of opinions in blogs. We believe that in these cases content-based measures should consider in addition to the input document, the summarization task (i.e. its text-based representation) to better assess the content of the peers, the task being a determinant factor in the selection of content for the summary. Our multi-lingual experiments in generic single-document summarization confirm a strong correlation among the Jensen-Shannon divergence and ROUGE measures. It is worth noting that ROUGE is in general the chosen framework for presenting content-based evaluation results in non-English summarization. For the experiments in Spanish, we are conscious that we only have one model summary to compare with the peers. Nevertheless, these models are the corresponding abstracts written by the authors of the articles and this is in fact the reason for choosing this corpus. As the experiments in (da Cunha et al., 2007) show, the professionals of a specialized domain (as, for example, the medical domain) adopt similar strategies to summarize their texts and they tend to choose roughly the same content chunks for their summaries. Because of this, the summary of the author of a medical article can be taken as reference for summaries evaluation. It is worth noting that there is still debate on the number of models to be used in summarization evaluation (Owkzarzak and Dang, 2009). In the French corpus PISTES, we suspect the situation is similar to the Spanish case.

6 Conclusions and Future Work

This paper has presented a series of experiments in content evaluation in text summarization to assess the value of content-based measures that do not rely on the use of model summaries for comparison purposes. We have carried out extensive experimentation with different summarization tasks drawing a clearer picture of tasks where the measures could be applied. This paper makes the following contributions:

- We have shown that if we are only interested in ranking summarization systems according to the content of their automatic summaries, there are tasks where models could be substituted by the full document in the computation of the Jensen-Shannon divergence measure obtaining reliable rankings. However, we have also found that the substitution of models by full-documents is not always advisable. We have found weak correlation among different rankings in complex summarization tasks such as the summarization of biographical information and the summa-

Measure	ROUGE-1	p-value	ROUGE-2	p-value	ROUGE-2	p-value
JS	0.83	$p < 0.002$	0.66	$p < 0.05$	0.741	$p < 0.01$
JS_2	0.80	$p < 0.005$	0.59	$p < 0.05$	0.68	$p < 0.02$
JS_4	0.75	$p < 0.010$	0.52	$p < 0.10$	0.62	$p < 0.05$
JS_M	0.85	$p < 0.002$	0.64	$p < 0.05$	0.74	$p < 0.01$

Table 7: Spearman system rank correlation of content-based measures with ROUGE in the RPM2 Corpus (French)

rization of opinions about an "entity".

- We have also carried out large-scale experiments in Spanish and French which show positive medium to strong correlation among system's ranks produced by ROUGE and divergence measures that do not use the model summaries.

- We have also presented a new framework, FRESA, for the computation of measures based on Jensen-Shannon divergence. Following the ROUGE approach, FRESA implements word uni-grams, bi-grams and skip n-grams for the computation of divergences. The framework is being made available to the community for research purposes.

Although we have made a number of contributions, this paper leaves many questions open that need to be addressed. In order to verify correlation between ROUGE and JS, in the short term we intend to extend our investigation to other languages and datasets such as Portuguese and Chinese for which we have access to data and summarization technology. We also plan to apply our evaluation framework to the rest of the DUC and TAC summarization tasks to have a full picture of the correlations among measures with and without human models. In the long term we plan to incorporate a representation of the task/topic in the computation of the measures.

Acknowledgements

We thank three anonymous reviewers for their valuable and enthusiastic comments. Horacio Saggion is grateful to the Programa Ramón y Cajal from the Ministerio de Ciencia e Innovación, Spain and to a Comença grant from Universitat Pompeu Fabra (COMENÇA10.004). This work is partially supported by a postdoctoral grant (National Program for Mobility of Research Human Resources; National Plan of Scientific Research, Development and Innovation 2008-2011) given to Iria da Cunha by the Ministerio de Ciencia e Innovación, Spain.

Argument Optionality in the LinGO Grammar Matrix

Abstract

We present a library of implemented HPSG analyses for argument optionality based on typological studies of this phenomenon in the world's languages, developed in the context of a grammar customization system that pairs a cross-linguistic core grammar with extensions for non-universal phenomena on the basis of user input of typological properties. Our analyses are compatible with multiple intersecting phenomena, including person, number, gender, tense, aspect and morphological rule formulation. We achieve 80-100% coverage on test suites from 10 natural languages.

1 Introduction

The LinGO Grammar Matrix customization system (Bender et al., 2002; 2010) is a web-based tool that creates starter grammars based on users' input to a questionnaire. The system comprises a core grammar covering linguistic phenomena that are posited to be universal (e.g. semantic compositionality) and a set of libraries providing analyses for phenomena that vary across languages (e.g. case). These resources are developed in the context of HPSG (Pollard and Sag, 1994), Minimal Recursion Semantics (Copestake et al., 2005), and the LKB grammar development environment (Copestake, 2002).

Previous to the work reported here, the Grammar Matrix customization system did not handle argument optionality—the possibility of leaving arguments unexpressed in lieu of overt pronouns. This phenomenon, also called pro-drop, argument drop, or null instantiation, is extremely common: according to Dryer (2008), 79% of the 674 languages sampled cannot or do not normally use independent pronouns in subject position. Accordingly, adding it to the customization system improves the system's ability to handle a large class of core sentences in many languages.

For example, in Modern Standard Arabic [arb] (Semitic), overt pronominal subjects are dropped in non-emphatic contexts. Previously, the system was able to model only the longer variant of (1).

(1) (hiyya) naama-t
(3.FEM.SG) sleep.PAST-3.FEM.SG
She slept. [arb]

Furthermore, there was no way to adequately account for languages such as Hausa [hau] (Chadic) which do not allow overt simple pronominal subjects and prohibit overt objects after certain verb forms. The grammar would predict the opposite grammaticality for the examples in (2).

(2) (*nī) nā-san amsā
(*1.SG) 1.SG.COMP-know answer
I know the answer. [hau]

It might seem that these facts could be handled by adding a rule that allows arguments to be dropped if an appropriate option is checked in the customization system. However, the data from Arabic and Hausa suggest that such an approach would be insufficient, as languages place different constraints on the contexts in which overt arguments are required or prohibited.

In §2 we discuss the broad range of typological variation in argument optionality in the world's languages. In §3 we offer a set of HPSG analyses for these patterns. §4 explains how these analyses were incorporated into the Grammar Matrix

Coling 2008: Poster Volume, pages 1068–1076,
Beijing, August 2010

customization system and integrated with the existing libraries. We then present the results of a three-tiered evaluation of the implemented system in §5. The results demonstrate that the system is capable of accurately modeling the attested syntactic argument optionality patterns exhibited by a typologically diverse group of languages as well as the currently unattested but logically possible co-occurrence restrictions on affixes and overt arguments. To our knowledge, this is the first such system. The paper closes with a brief look at how the library could be extended even further to capture the range of semantic distinctions.

2 Typological Patterns

The typological literature shows that argument optionality is extremely common: Dryer (2008) found that of 674 geographically and genetically diverse languages, only 141 normally or obligatorily used independent pronominal subjects. Dryer distinguishes 4 categories in the remaining 533 languages, corresponding to how information about the person, number, and gender (PNG) of the subject is encoded: affixation on the verb, clitics on variable hosts, no encoding, or a mixed strategy. In addition, there are other dimensions in which languages vary, e.g., constraints on contexts in which dropping is done (see (1)–(2)).

Although we were unable to find a similar comprehensive survey of unexpressed objects, there is evidence to suggest that it too may be very widespread. In particular, lexically-licensed object dropping seems to be very common. Even English, which has a very strong preference for overt subjects, can be analyzed as licensing lexically-based object dropping (Fillmore, 1986). As with subject dropping, we also found a number of different co-occurrence restrictions on the presence of verbal affixes and overt objects. Some languages always encode the PNG of an object on the verb, others optionally do so if an overt object is present and obligatorily do so if one is not, while still others do not encode this information at all.

Drawing on work by Dryer and others, Table 1 summarizes the 6 major dimensions along which the rules licensing argument dropping differ. The first constraint is syntactic context. Most languages that license argument dropping do so regardless of tense/aspect, mood, or person. Finnish [fin] and Hebrew [heb] are two notable exceptions (Vainikka and Levy, 1999).

The second constraint, lexically-based licensing, is most commonly found in object dropping. For example, while English usually prohibits argument dropping, it arguably licenses it with verbs such as 'found out', 'agree', and 'promise' (Fillmore, 1986). Lexically-based subject drop is found in Tamil [tam], which generally licenses subject dropping aside from some weather related verbs (Asher, 1985).

The third constraint, noun phrase type, captures the difference between a language such as Hausa which generally prohibits independent pronouns from appearing as subjects and other languages, which allow pronouns in subject position (possibly with emphatic interpretations).

The fourth constraint concerns the position of PNG markers. Of the languages with subject PNG markers and subject dropping, many encode subject PNG as a verbal affix. This pattern is exhibited by such geographically and genetically diverse languages as Spanish [spa], Arabic [arb], West Greenlandic [kal], Tamil [tam], and Nkore-Kiga [nyn]. Other languages such as Chemehuevi [ute], Polish [pol], and Warlpiri [wbp] make use of a clitic which can attach to different types of hosts (Dryer, 2008).

The final two constraints concern co-occurrence restrictions between PNG markers and overt objects. In some Bantu languages such as Nkore-Kiga, a verbal affix is not used unless the object precedes the verb or is pronominal. Object markers are not used when a full NP follows the verb (Taylor, 1985). In written French [fra], verbal affixes[1] are required if an object is dropped and not permitted if it is overt. In Arabic, for most transitive verbs, an object marker is required if an object is dropped and is optional if it is present. Hausa exhibits a more complex pattern: for tenses in which the verbal affix denoting PNG is morphologically separable from the tense marker, the PNG affix is optional if an overt noun phrase is present and required if it is not (Newman, 2000).

[1] See (Miller and Sag, 1997) for convincing arguments that so-called 'clitics' in French are actually affixes.

Constraint	(GF)	Possible Values
Syntactic context	(SUBJ)	{ All, select } tenses/aspects/moods/persons
Lexically-based	(SUBJ, OBJ)	{ All, select } verbs
Noun phrase type	(SUBJ, OBJ)	Independent pronouns { allowed, prohibited }
Placement of PNG marker	(SUBJ)	{ Verb, variable host }
PNG marking w/ dropped argument	(OBJ)	{ Required, optional, not permitted }
PNG marking w/ overt argument	(OBJ)	{ Required, optional, not permitted }

Table 1: Typological variation in licensing argument dropping

Noting these differences led us to posit that when an argument is dropped, there are three possibilities. A verbal affix can be: not permitted, optional, or required. The same three possibilities exist for overt objects as well. Combining what happens when an argument is dropped with what happens when it is present, gives us nine logically possible co-occurrence patterns.

Our review of the typological literature has shown that languages place different constraints on argument dropping. These constraints can be lexical, syntactic, or related to affixation and affix/overt-argument co-occurrence restrictions.

3 Analysis

This section presents HPSG analyses modeling the six dimensions of variation described in §2.

HPSG models natural language by positing lexical entries, lexical rules, and phrase structure rules, all described in terms of feature structures. A central idea, inspired by earlier work in Categorial Grammar (Ajdukiewicz, 1935; Bar-Hillel, 1953), is the notion of valence features. These list-valued features (including SUBJ and COMPS) contain information about the dependents required by a head. The valence lists are projected up the tree within the domain of each head, but shortened as the dependents are realized. A sentence is thus a verbal projection with empty SUBJ and COMPS lists.

In this context, argument dropping is the shortening of a valence list without the overt realization of the argument. Formally, this can be accomplished in at least three different ways: (1) In the mapping of arguments from the ARG-ST (argument structure) feature to the valence lists, one or more arguments can be suppressed, (2) lexical rules can operate on the valence lists, shortening them, or (3) unary (non-branching) phrase structure rules can cancel off valence elements. In this work, we take the third approach, as we find it affords us the most flexibility to deal with variations across languages in constraints on argument optionality, while promoting similarity of analyses across languages.

We control the applicability of the unary-branching rules with the boolean feature OPT, marked on elements of valence lists.[2] For languages which allow subject/object dropping, we instantiate new phrase structure rules: *head-opt-subj-phrase* and/or *head-opt-comp-phrase*. These rules allow the head verb to satisfy a valence requirement without combining with another expression. To undergo these rules, the head daughter (the verb) must specify that the argument that is to be dropped is compatible with [OPT +]. This is sufficient to account for many languages. However, to ensure that languages which have lexical, syntactic context, and affix co-occurrence restrictions do not overgenerate, further additions to the grammar are necessary.

For lexical and affix-co-occurrence restrictions, we prevent overgeneration by manipulating the OPT feature. In languages which only license argument dropping for certain lexical items, we force those verbs which do not allow argument dropping to have arguments that are constrained to be [OPT −]. This prevents them from undergoing the subject/object dropping rules. Verbs are then classified into four different types based on whether or not they allow subject and/or object dropping. Individual lexical items instantiate these types. For those verbs which do not allow a particular argument to be dropped, the only way to satisfy the valence requirement is to combine with an overt argument.

[2]This feature was provided by the core Matrix but was not previously used in the customization system. To our knowledge it is not commonly used within HPSG analyses aside from in grammars that were derived from the Matrix.

Dropped/Overt Argument Affix	Overt Arg Rule	No-Marker-Rule	Marker-Rule	Transitive Verb Lex
required/required	underspecified	none	underspecified	needs lex rule
optional/optional	underspecified	none	underspecified	underspecified
not permitted/not permitted	underspecified	none	none	underspecified
required/optional	OPT −	OPT −	underspecified	needs lex rule
optional/not permitted	OPT −	none	OPT +	underspecified
not permitted/required	OPT −	OPT +	OPT −	needs lex rule
required/not permitted	OPT −	OPT −	OPT +	needs lex rule
optional/required	OPT −	OPT +	underspecified	needs lex rule
not permitted/optional	OPT −	none	OPT −	underspecified

Table 2: Constraints associated with logically possible affix co-occurrence

Languages with complex affix co-occurrence restrictions are modeled by manipulating the OPT feature in a different way: Constraints are placed on lexical and phrase structure rules, as well as on lexical types. In particular, we constrain the rules which combine verbs with overt arguments to check that that argument position is compatible with [OPT −]. This allows the lexical rules attaching the affixes to constrain the optionality of the corresponding argument position. In some of the nine logical possibilities, enforcing these constraints requires sending the verb through "no-marker" lexical rules so that constraints associated with markerless verbs can be enforced. Table 2 summarizes the constraints on the OPT feature on lexical and phrase structure rules, as well as the constraints on lexical types. The first column of this table lists the nine logically possible combinations described in §2. For example, the row labeled "required/required" gives the analysis for a language like West Greenlandic, which allows object dropping and always requires an object marker on the verb regardless of whether or not an overt object is present. In such a language, neither the lexical rules nor the overt-complement phrase structure rule constrain OPT, but the transitive verb lex type is required to undergo some object marking lexical rule.

For licensing that is based on syntactic context (subject dropping only) such as the Finnish and Hebrew examples presented in §2, we place constraints on the daughter of the unary subject drop rule which restrict its application to the right contexts. For example, to account for the argument optionality pattern present in Finnish, we constrain the *head-opt-subj-phrase* rule to require that the item on the head daughter's SUBJ list be specified as non-third-person ([PER *non-third*]). Verbs not meeting this constraint are only allowed to empty their SUBJ lists by combining with an overt subject via the standard, binary *head-subj-phrase* rule. We have not seen a language which licenses subject dropping in syntactic contexts which do not form a natural class according to our feature system. However, our analysis easily lends itself to modeling this type of pattern if it exists by creating multiple different subtypes of the subject drop rule.

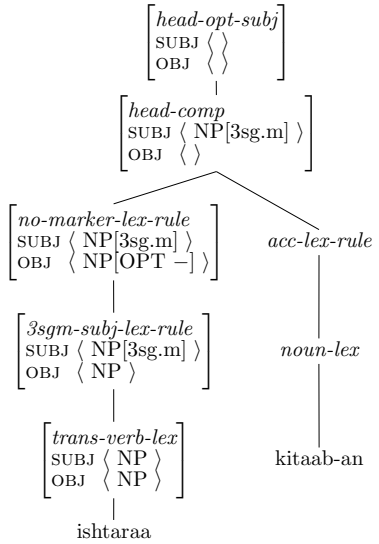

Figure 1: Parse structure for (3)

We close this section by illustrating our analysis with an example from Arabic. The sentence in (3) involves subject drop and an overt object. Since the object is overt, the verb bears only marking of subject PNG. The grammar that our system generates for Arabic assigns (3) the structure sketched in Figure 1.

4 Customized Grammar Creation

Before the addition of the argument optionality library, the phenomena covered in the Grammar Matrix customization system included word order, person, number, gender, case, tense/aspect, coordination, matrix yes-no questions, and sentential negation. The user is also allowed to specify lexical items and the morphological rules associated with each of them. Each of the phenomena correspond to a page of the questionnaire.

As the user answers questions, the choices are saved in a 'choices' file. The questionnaire is dynamic and the answers contained in the 'choices' file affect the types of features that the user is able to choose from on subsequent pages. For example, if the user describes the language as having 1st, 2nd, and 3rd persons on the Person page, then on the lexicon page, the user can create separate noun types for each person. Once the 'choices' file contains responses to required sections, the user is able to create the customized starter grammar by clicking on the 'create grammar' button. This invokes the customization script which uses the responses contained in the file to create a grammar that is compatible with the LKB grammar development environment.

Our implementation entailed additions to two major components of the system: the web-based questionnaire and the customization script. To determine which, if any, of the analyses presented in §3 should be included in the customized grammar, we needed to elicit the type of argument optionality pattern the language exhibited. Thus, we added an Argument Optionality page to the questionnaire. The page is divided into two sections—one for subject dropping and one for object dropping. In the section on subject dropping, the user is asked whether subject dropping exists and if so, whether it is context-dependent. For context-dependent subject dropping, the user is allowed to specify the syntactic contexts in which subject dropping is licensed by choosing from a multi-select list of features. There is the option to create multiple contexts. The features that appear in the list are drawn from those that the user chose on previous pages in the questionnaire. The user is also directed to select whether subject dropping is lexically-based, whether affixes are required, optional or not permitted with overt arguments and whether affixes are required, optional or not permitted with dropped arguments. The questions presented in the object dropping section are identical to those in the subject dropping section with the exception that there is no question about context-dependent object dropping.

Since some of the constraints must be placed on individual lexical items and morphological rules, the page also includes instructions to the user on additional steps that need to be taken when completing the Lexicon page. For example, when describing a language where affixes are optional if an argument is dropped and not permitted if an overt argument is present, users are instructed to select 'overt-arg-not-permitted' for those affixes on the Lexicon page.

The changes to the customization script included adding each of the analyses described in §3 along with a mechanism for determining which of the analyses should be included in the grammar depending on the choices related to argument optionality, lexical items, and morphological rules contained in the 'choices' file. The resulting customized grammars include the rules and constraints necessary to allow and prohibit strings that do not contain overt arguments based upon the facts of a particular language as described by the user in the questionnaire.

5 Evaluation

The evaluation was conducted in a three stage process. Each stage involves constructing a set of test suites containing grammatical and ungrammatical strings representing the argument optionality pattern of a set of languages, generating grammars for the languages by answering the Grammar Matrix questionnaire, using the grammars to parse the sentences in the test suite, and hand-verifying the results. The three stages differed in the nature of the languages, the method by which the languages were selected, and the breadth of the customized grammars. The test suites are small, as they are specifically targeted at the phenomenon of argument optionality, but representative in the sense that they cover the space of relevant contrasts in each language.

5.1 Set 1: Pseudo-Languages

In the first stage, we tested the analyses presented in §3 by creating and then using the Grammar Matrix customization system to generate grammars for 38 pseudo-languages (sets of strings with associated grammaticality assignments) which collectively exhaustively exhibit each of the lexical, syntactic context or affix co-occurrence restriction patterns described in Table 1 (§2). All of the possible values identified for these given patterns are present in at least one language, as well as cross-classifications of different dimensions of constraints where appropriate. For example, there are pseudo-languages which share the property of always requiring object markers but differ in that one has lexically licensed object dropping and the other general object dropping. These pseudo-languages test the argument optionality analyses in isolation in that argument optionality is not constrained by other phenomena such as word order.

The customized grammars were able to accurately parse grammatical strings and rule out ungrammatical ones. Coverage on this set of 38 pseudo-languages was 100% with 0% overgeneration and no spurious ambiguity, thus validating the functioning of our analyses across the known typological space.

5.2 Set 2: Illustrative Languages

Next, we tested the system's performance in modeling part of a natural language. For this stage we deliberately chose several languages which exemplified interesting licensing and co-occurrence restriction patterns, including some which were considered during the development of the system. Each test suite included examples of grammatical and ungrammatical strings that were constructed based on the descriptions of the language given in the following sources: Suleiman 1990 (Arabic), Sulkala and Merja 1992 (Finnish), Newman 2000 (Hausa), and Asher 1985 (Tamil). As the test suites were designed to evaluate argument optionality, we restricted the test items to this phenomenon only. Other syntactic phenomena were only included if they affected the argument optionality pattern in the language. For example, gender distinctions were considered only for languages in which this was relevant to affix marking. A brief description of the argument optionality patterns found in these languages follows.

Arabic [arb] (Semitic) Pronominal subjects and objects are generally dropped. Subject affixes are always required whether or not an overt noun phrases is present. Affixes marking object person, number, and gender are required for strictly transitive verbs when an overt noun phrase is not present. Other transitive verbs appear to allow object drop without the object affix.

Finnish [fin] (Uralic) First and second person subjects are freely dropped and markers appear on the verb whether or not an overt noun phrase is present. Third person subjects are not allowed to be dropped with a referential interpretation; however, third person pronouns are obligatorily dropped for what Sulkala and Merja (1992) describe as a generic impersonal meaning. This description fits into what some linguists refer to as the fourth person—a non-referential impersonal syntactic/semantic distinction that is often realized in English as the impersonal pronoun *one*. Since Finnish shows evidence of further syntactic distinctions between generic and referential use of the third person marker, we have analyzed this marker as actually corresponding to two homophonous morphemes. One requires an overt subject and the other requires a dropped subject. There are no verbal affixes for PNG of the object.

Hausa [hau] (Chadic) Hausa generally requires pronominal subjects to be dropped. Simple, unmodified, uncoordinated independent pronouns are ungrammatical in subject position. Subject PNG is marked in a person aspect complex (PAC) along with tense and aspect information. The PAC precedes the lexical verb. When the PNG marker is morphologically segmentable from the tense/aspect, the PNG marker can be omitted if an overt noun phrase is present and is required if the noun phrase is not present. PNG is not marked for objects; however the verb form changes depending on whether a full noun phrase, pronoun, or no object immediately follows the verb.

Tamil [tam] (Dravidian) Subjects and objects can be freely dropped aside from a special class of weather verbs requiring overt subjects. Subject

PNG markers are always required whether a subject is overt or not. PNG is not marked for objects.

Lg.	Items	Grammatical	Ungrammatical	Coverage/ Overgeneration (%)
Arabic	13	10	3	90/0
Finnish	11	9	3	100/0
Hausa	20	8	12	100/0
Tamil	7	5	2	100/0

Table 3: Illustrative Languages Results

As shown in Table 3 we achieved 100% coverage over every test suite in this set except for Arabic. In addition, there was no overgeneration or spurious ambiguity. One Arabic item did not parse because the current implementation of our analyses does not elegantly account for obligatory object marking (with object drop) on some transitive verbs and optional object marking on others. We could have customized a grammar that included another, parallel set of lexical rules that would account for this item. Improvements to this aspect of the argument optionality library depend on upgrades to the morphotactic system.

5.3 Set 3: Held-out Languages

Finally, we tested a set of 'held out' languages not considered during development and chosen for their geographic and genetic diversity without regard for argument dropping patterns. We had previously created the non-argument optionality portions of these test suites and choices files to test the coverage of other libraries in the customization system and thus they include a wider variety of linguistic phenomena than Sets 1 or 2. As before, the construction and grammaticality judgements of the strings were based on descriptive grammars: Chirikba 2003 (Abkhaz), Press 1979 (Chemehuevi), Smirnova 1982 and Newman 2000 (Hausa), Pensalfini 2003 (Jingulu), Asher and Kumari 1997 (Malayalam), Taylor 1985 (Nkore-Kiga), and Fortescue 2003 (W. Greenlandic).

Due to space constraints, we provide only a summary of the argument optionality patterns in these languages (Table 4). All the languages licensed both subject and object dropping and in two of the six, dropping pronominal arguments was strongly preferred. Three languages have word order constraints on how argument optionality is realized: Abkhaz restricts the appearance of one of the third person affixes depending on verb-object order. Nkore-Kiga requires and prohibits the appearance of an object marker depending on where the overt object occurs. Chemehuevi requires that the clitic which is used to mark the subject appear in second position. It is also the only language that has lexical constraints on object dropping. Malayalam was the only language which did not mark person, number, and gender information for the subject.

The customized grammars were able to account for the majority of the patterns demonstrated in these languages (Table 5). We achieved 100% coverage on four languages with zero (Jingulu, Malayalam, West Greenlandic) or moderate (Abkhaz) overgeneration. The main source of errors found in the results is the handling of word order constraints: The grammars were unable to license (Chemehuevi) or restrict (Nkore-Kiga and Abkhaz) argument optionality based on the verb's and argument's positions in the sentence. Once the Grammar Matrix word order library has been improved and is able to account for second position clitics and fine-grained head-complement word order constraints, it will be a simple process to add the new feature(s) to existing lexical rules to account for these patterns. Incorporating the new functionality will not require any major changes to the argument optionality library aside from modifying the questionnaire to elicit the new information from the user.

Language	Items	Grammatical	Ungrammatical	Coverage/ Overgeneration (%)
Abkhaz	10	6	4	100/10
Chemehuevi	8	6	2	83.3/0
Jingulu	9	6	3	100/0
Malayalam	4	4	0	100/0
Nkore-Kiga	10	4	6	100/83.3
W. Greenlandic	5	3	2	100/0

Table 5: Held-out Language Results

In addition, we verified that the addition of argument optionality didn't reduce coverage on any other portion of these testsuites. This indicates that the new argument optionality library is interacting properly with existing libraries. Additional interactions will be tested as we add new libraries to the customization system.

	Object Dropping	Subject Dropping	Word Order Constraints	Lexical Constraints
Abkhaz	opt	opt	yes	none
Chemehuevi	opt	opt	yes	yes
Jingulu	opt	opt	none	none
Malayalam	opt	opt	no	none
Nkore-Kiga	pref	pref	yes	none
W. Greenlandic	pref	pref	none	none

Table 4: Existence of and constraints on argument optionality in six languages

6 Related Work

Subject dropping has been studied extensively within theoretical linguistics under many different frameworks (Rizzi, 1986; Bresnan, 2001; Ackema et al., 2006; Ginzburg and Sag, 2000). Within the context of HPSG, our analysis is similar to the one in the Grammar Matrix-derived Portuguese grammar (Branco and Costa, 2008) and to Müller's (2009) treatment of subject dropping in Maltese. These analyses differ from Ginzburg and Sag's (2000) HPSG analysis which uses language specific variations on the Argument Realization Principle to control whether the subject/object is placed onto the COMPS and/or SUBJ lists.

Language specific analyses have been implemented in deep, broad-coverage grammars for languages such as Japanese (Masuichi et al. (2003), Siegel and Bender (2002)) and Portuguese (Branco and Costa (2008)). Within the ParGram project (Butt et al., 2002), Kim et al. (2003) were able to directly port the argument optionality related rules from a Japanese grammar to Korean. However, to our knowledge, no one has implemented an analysis that has been applied to a large number of typologically, geographically, and genetically diverse languages.

7 Conclusion

Our current work has focused on modeling the variation in syntactic constraints on the licensing and restriction of argument dropping. To our knowledge, this is the first analysis of argument optionality that combines typological breadth with precision analyses that have been implemented and tested on a number of geographically and genetically diverse languages. Although we have tried to account for the patterns found in the typological literature, there may be variants that we are unaware of. We hope to learn of more patterns as the Grammar Matrix customization system is applied to an ever wider set languages.

While the current work focuses on syntactic variation, we intend to expand the argument optionality library to include semantic distinctions as well. A likely starting point would be the proposal given by Bender and Goss-Grubbs (2008) who present a way to model the discourse status (Prince, 1981) of an NP taking into account the differences between definite and indefinite null instantiation described by Fillmore (1986). In addition, ongoing work to improve the word order library may eventually allow us to more accurately model word-order based constraints.

Log-linear weight optimisation via Bayesian Adaptation in Statistical Machine Translation

Abstract

We present an adaptation technique for statistical machine translation, which applies the well-known Bayesian learning paradigm for adapting the model parameters. Since state-of-the-art statistical machine translation systems model the translation process as a log-linear combination of simpler models, we present the formal derivation of how to apply such paradigm to the weights of the log-linear combination. We show empirical results in which a small amount of adaptation data is able to improve both the non-adapted system and a system which optimises the above-mentioned weights on the adaptation set only, while gaining both in reliability and speed.

1 Introduction

The adaptation problem is a very common issue in statistical machine translation (SMT), where it is frequent to have very large collections of bilingual data belonging to e.g. proceedings from international entities such as the European Parliament or the United Nations. However, if we are currently interested in translating e.g. printer manuals or news data, we will need to find a way in which we can take advantage of such data.

The grounds of modern SMT were established in (Brown et al., 1993), where the machine translation problem was defined as follows: given a sentence $\mathbf{f}$ from a certain source language, an equivalent sentence $\hat{\mathbf{e}}$ in a given target language that maximises the posterior probability is to be found. According to the Bayes decision rule, such statement can be specified as follows:

$$\hat{\mathbf{e}} = \operatorname*{argmax}_{\mathbf{e}} \Pr(\mathbf{e}|\mathbf{f}) \tag{1}$$

Recently, a direct modelling of the posterior probability $\Pr(\mathbf{e}|\mathbf{f})$ has been widely adopted, and, to this purpose, different authors (Papineni et al., 1998; Och and Ney, 2002) proposed the use of the so-called log-linear models, where

$$p(\mathbf{e}|\mathbf{f}) = \frac{\exp \sum_{k=1}^{K} \lambda_k h_k(\mathbf{f}, \mathbf{e})}{\sum_{\mathbf{e}'} \exp \sum_{k=1}^{K} \lambda_k h_k(\mathbf{f}, \mathbf{e}')} \tag{2}$$

and the decision rule is given by the expression

$$\hat{\mathbf{e}} = \operatorname*{argmax}_{\mathbf{e}} \sum_{k=1}^{K} \lambda_k h_k(\mathbf{f}, \mathbf{e}) \tag{3}$$

where $h_k(\mathbf{f}, \mathbf{e})$ is a score function representing an important feature for the translation of $\mathbf{f}$ into $\mathbf{e}$, as for example the language model of the target language, a reordering model or several translation models. K is the number of models (or features) and λ_k are the weights of the log-linear combination. Typically, the weights $\mathbf{\Lambda} = [\lambda_1, \ldots, \lambda_K]^T$ are optimised with the use of a development set.

The use of log-linear models implied an important break-through in SMT, allowing for a significant increase in the quality of the translations produced. In this work, we present a Bayesian technique for adapting the weights of such log-linear models according to a small set of adaptation data.

In this paper, we will be focusing on adapting the weights vector $\mathbf{\Lambda}$, since appropriate values of such vector for a given domain do not necessarily imply a good combination in other domains. One naïve way in which some sort of adaptation can be performed on $\mathbf{\Lambda}$ is to re-estimate these weights

Coling 2008: Poster Volume, pages 1077–1085,
Beijing, August 2010

from scratch only on the adaptation data. However, such re-estimation may not be a good idea, whenever the amount of adaptation data available is not too big. On the one hand, because small amounts of adaptation data may easily yield overtrained values of $\mathbf{\Lambda}$, which may even lead to a degradation of the translation quality. On the other hand, because in some scenarios it is not feasible to re-estimate them because of the time it would take. Moreover, considering a re-estimation of $\mathbf{\Lambda}$ by using both the out-of-domain data and the adaptation set would not be appropriate either. For small amounts of adaptation data, such data would have no impact on the final value of $\mathbf{\Lambda}$, and the time required would be even higher. One such situation may be the Interactive Machine Translation (IMT) paradigm (Barrachina et al., 2009), in which a human translator may start translating a new document, belonging to a specific domain, and the system is required to produce an appropriate output as soon as possible without any prior re-training.

In this paper, a Bayesian adaptation approach solving both problems is presented. Nevertheless, adapting Λ constitutes just a first step towards the adaptation of all the parameters of the SMT model.

The rest of this paper is structured as follows. In next Section, we perform a brief review of current approaches to adaptation and Bayesian learning in SMT. Section 3 describes the typical framework for phrase-based translation in SMT. In Section 4, we present the way in which we apply Bayesian adaptation (BA) to log-linear models in SMT. In Section 5, we describe the practical approximations applied before implementing the BA technique described. In Section 6, experimental design and results are detailed. Conclusions and future work are explained in Section 7.

2 Related work

Adaptation in SMT is a research field that is receiving an increasing amount of attention. In (Nepveu et al., 2004), adaptation techniques were applied to IMT, following the ideas by (Kuhn and Mori, 1990) and adding cache language models (LM) and TMs to their system. In (Koehn and Schroeder, 2007), different ways to combine available data belonging to two different sources was explored; in (Bertoldi and Federico, 2009) similar experiments were performed, but considering only additional source data. In (Civera and Juan, 2007), alignment model mixtures were explored as a way of performing topic-specific adaptation. Other authors (Zhao et al., 2004; Sanchis-Trilles et al., 2009), have proposed the use of clustering in order to extract sub-domains of a large parallel corpus and build more specific LMs and TMs, which are re-combined in test time.

With respect to BA in SMT, the authors are not aware of any work up to the date that follows such paradigm. Nevertheless, there have been some recent approaches towards dealing with SMT from the Bayesian learning point of view. In (Zhang et al., 2008), Bayesian learning was applied for estimating word-alignments within a synchronous grammar.

3 Phrase-based SMT

One of the most popular instantiations of log-linear models in SMT are phrase-based (PB) models (Zens et al., 2002; Koehn et al., 2003). PB models allow to capture contextual information to learn translations for whole phrases instead of single words. The basic idea of PB translation is to segment the source sentence into phrases, then to translate each source phrase into a target phrase, and finally reorder the translated target phrases in order to compose the target sentence. For this purpose, phrase-tables are produced, in which a source phrase is listed together with several target phrases and the probability of translating the former into the latter. PB models were employed throughout this work.

Typically, the weights of the log-linear combination in Equation 3 are optimised by means of Minimum Error Rate Training (MERT) (Och, 2003). Such algorithm consists of two basic steps. First, n-best hypotheses are extracted for each one of the sentences of a given development set. Next, the optimum $\mathbf{\Lambda}$ is computed so that the best hypotheses in the n-best list, according to a reference translation and a given metric, are ranked higher within such n-best list. These two steps are repeated until convergence.

This approach has two main problems. On the

one hand, that it heavily relies on having a fair amount of data available as development set. On the other hand, that it *only* relies on the data in the development set. These two problems have as consequence that, if the development set made available to the system is not big enough, MERT will most likely become unstable and fail in obtaining an appropriate weight vector $\mathbf{\Lambda}$.

However, it is quite common to have a great amount of data available in a given domain, but only a small amount from the specific domain we are interested in translating. Precisely this scenario is appropriate for BA: under this paradigm, the weight vector $\mathbf{\Lambda}$ is *biased* towards the optimal one according to the adaptation set, while avoiding over-training towards such set by not forgetting the generality provided by the training set. Furthermore, recomputing $\mathbf{\Lambda}$ from scratch by means of MERT may imply a computational overhead which may not be acceptable in certain environments, such as SMT systems configured for online translation, IMT or Computer Assisted Translation, in which the final human user is waiting for the translations to be produced.

4 Bayesian adaptation for SMT

The main idea behind Bayesian learning (Duda et al., 2001; Bishop, 2006) is that model parameters are viewed as random variables having some kind of a priori distribution. Observing these random variables leads to a posterior density, which typically peaks at the optimal values of these parameters. Following the notation in Equation 1, previous statement is specified as

$$p(\mathbf{e}|\mathbf{f};T) = \int p(\mathbf{e},\theta|\mathbf{f};T)d\theta \quad (4)$$

where T represents the complete training set and θ are the model parameters.

However, since we are interested in Bayesian *adaptation*, we need to consider one training set T and one adaptation set A, leading to

$$p(\mathbf{e}|\mathbf{f};T,A) \approx \int p(\theta|T,A)p(\mathbf{e}|\mathbf{f},\theta)d\theta \quad (5)$$

In Equation 5, the integral over the complete parametric space forces the model to take into account all possible values of the model parameters, although the prior over the parameters implies that our model will prefer parameter values which are closer to our prior knowledge. Two assumptions have been made: first, that the output sentence $\mathbf{e}$ only depends on the model parameters (and not on the complete training and adaptation data). Second, that the model parameters do not depend on the actual input sentence $\mathbf{f}$. Such simplifications lead to a decomposition of the integral in two parts: the first one, $p(\theta|T,A)$ will assess how good the current model parameters are, and the second one, $p(\mathbf{e}|\mathbf{f},\theta)$, will account for the quality of the translation $\mathbf{e}$ given the current model parameters.

Then, the decision rule given in Equation 1 is redefined as

$$\hat{\mathbf{e}} = \underset{\mathbf{e}}{\operatorname{argmax}} \Pr(\mathbf{e}|\mathbf{f};T,A) \quad (6)$$

Operating with the probability of θ, we obtain:

$$p(\theta|T,A) = \frac{p(A|\theta;T)\,p(\theta|T)}{\int p(A|\theta)\,p(\theta|T)\,d\theta} \quad (7)$$

$$p(A|\theta;T) = \prod_{\forall a\in A} p(\mathbf{f}_a|\theta)\,p(\mathbf{e}_a|\mathbf{f}_a,\theta) \quad (8)$$

where the probability of the adaptation data has been assumed to be independent of the training data and has been modelled as the probability of each bilingual sample $(\mathbf{f}_a,\mathbf{e}_a) \in A$ being generated by our translation model.

Assuming that the model parameters depend on the training data and follow a normal distribution, we obtain

$$p(\theta|T) = \frac{1}{(2\pi)^{d/2}}\exp\left\{-\frac{1}{2}(\theta-\theta_T)^T(\theta-\theta_T)\right\} \quad (9)$$

where θ_T is the set of parameters estimated on the training set and the variance has been assumed to be bounded for all parameters. d is the dimensionality of θ.

Lastly, assuming that our translation model is a log-linear model as described in Equation 3 and that the only parameters we want to adapt are the log-linear weights:

$$p(\mathbf{e}|\mathbf{f},\theta) = \frac{\exp\sum_k \lambda_k\, f_k(\mathbf{f},\mathbf{e})}{\sum_{\mathbf{e}'}\exp\sum_k \lambda_k\, f_k(\mathbf{f},\mathbf{e}')} \quad (10)$$

where the model parameters θ have been instantiated to include only the log-linear weights $\mathbf{\Lambda}$.

Finally, combining Equations 8, 9 and 10, and considering only as model parameters the log-linear weights, we obtain:

$$p(\mathbf{e}|\mathbf{f};T,A) = \mathcal{Z}\int p(A|\mathbf{\Lambda};T)p(\mathbf{\Lambda}|T)p(\mathbf{e}|\mathbf{f},\mathbf{\Lambda})d\mathbf{\Lambda}$$

$$= \mathcal{Z}\int \prod_{\forall a\in A} \frac{\exp\sum_k \lambda_k\ f_k(\mathbf{f}_a,\mathbf{e}_a)}{\sum_{\mathbf{e}'}\exp\sum_k \lambda_k\ f_k(\mathbf{f}_a,\mathbf{e}')}\cdot$$

$$\exp\left\{-\frac{1}{2}(\mathbf{\Lambda}-\mathbf{\Lambda}_T)^T(\mathbf{\Lambda}-\mathbf{\Lambda}_T)\right\}\cdot$$

$$\frac{\exp\sum_k \lambda_k\ f_k(\mathbf{f},\mathbf{e})}{\sum_{\mathbf{e}'}\exp\sum_k \lambda_k\ f_k(\mathbf{f},\mathbf{e}')}\ d\mathbf{\Lambda} \qquad (11)$$

where $\mathcal{Z}$ is the denominator present in the previous equation and may be factored out because it does not depend on the integration variable. It has also been assumed that $p(\mathbf{f}_a|\theta)$ is uniform and can also be factored out.

5 Practical approximations

Although the integral described in Equation 11 is the right thing to do from the theoretical point of view, there are several issues which need to be treated first before implementing it.

Since computing the integral over the complete parametric space is computationally impossible in the case of SMT, we decided to perform a Monte Carlo like sampling of these parameters by assuming that the parameters follow a normal distribution centred in $\mathbf{\Lambda}_T$, the weight vector obtained from the training data. This sampling was done by choosing alternatively only one of the weights in $\mathbf{\Lambda}_T$, modifying it randomly within a given interval, and re-normalising accordingly. Equation 11 is approximated in practise as

$$p(\mathbf{e}|\mathbf{f};T,A) = \sum_{\Lambda_m\in MC(\Lambda_T)} p(A|\mathbf{\Lambda};T)p(\mathbf{\Lambda}|T)p(\mathbf{e}|\mathbf{f},\mathbf{\Lambda})$$

where $MC(\Lambda_T)$ is the set of Λ_m weights generated by the above-mentioned procedure.

There is still one issue when trying to implement Equation 11. The denominator within the components $p(A|\mathbf{\Lambda};T)$ and $p(\mathbf{e}|\mathbf{f},\mathbf{\Lambda})$ contains a sum over all possible sentences of the target language, which is not computable. For this reason, $\sum_{\mathbf{e}'}$ is approximated as the sum over all the hypothesis within a given n-best list. Moreover, instead of performing a full search of the best possible translation of a given input sentence, we will perform a rerank of the n-best list provided by the decoder according to Equation 11.

Typical state-of-the-art PB SMT systems do not guarantee complete coverage of all possible sentence pairs due to the great number of heuristic decisions involved in the estimation of the translation models. Moreover, out-of-vocabulary words may imply that the SMT model is unable to explain a certain bilingual sentence completely. Hence, $p(A|\mathbf{\Lambda};T)$ is approximated as

$$p(A|\mathbf{\Lambda};T) \approx \prod_{\forall a\in A} \frac{\exp\sum_k \lambda_k\ f_k(\mathbf{f}_a,\mathbf{e}_a^*)}{\sum_{\mathbf{e}'}\exp\sum_k \lambda_k f_k(\mathbf{f}_a,\mathbf{e}')} \qquad (12)$$

where $\mathbf{e}^*$ represents the best hypothesis the search algorithm is able to produce, according to a given translation quality measure. As in Equation 11, $p(\mathbf{f}_a|\theta)$ has been assumed uniform.

Once the normalisation factor within Equation 7 has been removed, and the above-mentioned approximations have been introduced, $p(\mathbf{e}|\mathbf{f};T,A)$ is no longer a probability. This fact cannot be underestimated, since it means that the terms $p(A|\mathbf{\Lambda};T)$ and $p(\mathbf{e}|\mathbf{f},\mathbf{\Lambda})$ on the one hand, and $p(\mathbf{\Lambda}|T)$ on the other, may have very different numeric ranges. For this reason, and in order to weaken the influence of this fact, we introduce a leveraging term δ, such that

$$p(\mathbf{e}|\mathbf{f};T,A) = \sum_{\Lambda_m\in MC(\Lambda_T)} \left(p(A|\mathbf{\Lambda};T)p(\mathbf{e}|\mathbf{f},\mathbf{\Lambda})\right)^{\frac{1}{\delta}} p(\mathbf{\Lambda}|T) \qquad (13)$$

Although there are other, more standard, ways of adding this leveraging term, we chose this one for numeric reasons.

6 Experiments

6.1 Experimental setup

Translation quality will be assessed by means of BLEU and TER scores. BLEU measures n-gram precision with a penalty for sentences that are too short (Papineni et al., 2001), whereas TER (Snover et al., 2006) is an error metric that

		Spanish	English
Training	Sentences	731K

	Run. words	50K	53K
	OoV. words	1247	1201
Test 2010	Sentences	2489	
	Run. words	62K	66K
	OoV. words	1698	1607

Table 2: Main figures of the News-Commentary test sets. *OoV* stands for Out of Vocabulary words with respect to the Europarl corpus.

computes the minimum number of edits required to modify the system hypotheses so that they match the references. Possible edits include insertion, deletion, substitution of single words and shifts of word sequences.

For computing $\mathbf{e}^*$ as described in Equation 12, TER was used, since BLEU implements a geometrical average which is zero whenever there is no common 4-gram between reference and hypothesis. Hence, it is not well suited for our purposes since the complete set of n-best candidates provided by the decoder can score zero.

As a first baseline system, we trained a SMT system on the Europarl Spanish–English training data, in the partition established in the Workshop on SMT of the NAACL 2006 (Koehn and Monz, 2006), using the training and development data provided that year. The Europarl corpus (Koehn, 2005) is built from the transcription of European Parliament speeches published on the web. Statistics are provided in Table 1.

We used the open-source MT toolkit Moses (Koehn et al., 2007)[1] in its default monotonic setup, and estimated the weights of the log-linear combination using MERT on the Europarl development set. A 5-gram LM with interpolation and Kneser-Ney smoothing (Kneser and Ney, 1995) was also estimated.

Since our purpose is to adapt the initial weight vector obtained during the training stage (i.e. the one obtained after running MERT on the Europarl development set), the tests sets provided for the 2008 and 2010 evaluation campaigns of the above-mentioned workshop (Table 2) were also used. These test sets, unlike the one provided in 2006, were extracted from a news data corpus, and can be considered out of domain if the system has been trained on Europarl data.

All the experiments displaying BA results were carried out by sampling a total of 100 random weights, according to preliminary investigation, following the procedure described in Section 5. For doing this, one single weight was added a random amount between 0.5 and -0.5, and then the whole $\mathbf{\Lambda}$ was re-normalised.

With the purpose of providing robustness to the results, every point in each plot of this paper constitutes the average of 10 repetitions, in which the adaptation data was randomly drawn from the News-Commentary test set 2008.

6.2 Comparison between BA and MERT

The effect of increasing the number of adaptation samples made available to the system was investigated. The adaptation data was used either for estimating $\mathbf{\Lambda}$ using MERT, or as adaptation sample for our BA technique. Results can be seen in Figure 1. The δ scaling factor described in Equation 13 was set to 8. As it can be seen, the BA adaptation technique is able to improve consistently the translation quality obtained by the non-adapted system, both in terms of BLEU and TER. These improvements are quite stable even with as few as 10 adaptation samples. This result is very interesting, since re-estimating $\mathbf{\Lambda}$ by means of MERT is only able to yield improvements when provided with at least 100 adaptation samples, displaying a very chaotic behaviour until that point.

In order to get a bit more insight about this chaotic behaviour, confidence interval sizes are shown in Figure 2, at a 95% confidence level, resulting of the repetitions described above. MERT yields very large confidence intervals (as large as 10 TER/BLEU points for less than 100 samples), turning a bit more stable from that point on, where the size of the confidence interval converges slowly to 1 TER/BLEU point. In contrast,

[1] Available from http://www.statmt.org/moses/

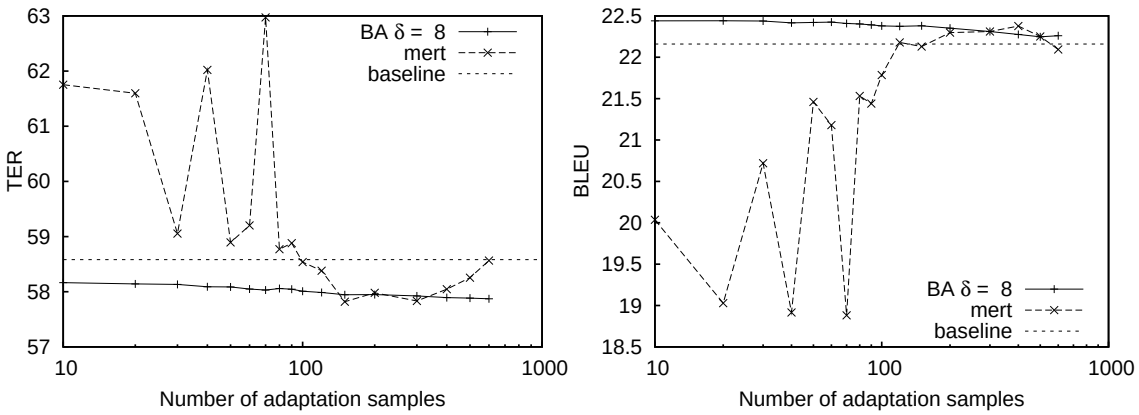

Figure 1: Comparison of translation quality, as measured by BLEU and TER, for baseline system, adapted systems by means of BA and MERT. Increasing number of samples is considered.

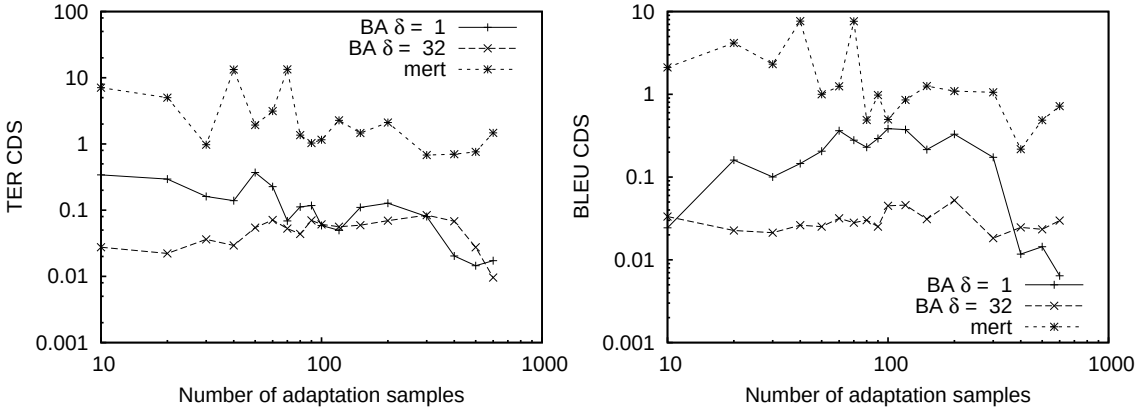

Figure 2: Confidence interval sizes (CDS) for MERT and two BA systems, for different number of adaptation samples. For visibility purposes, both axes are in logarithmic scale.

our BA technique yields very small confidence intervals, about half a TER/BLEU point in the worst case, with only 10 adaptation samples. This is worth emphasising, since estimating $\mathbf{\Lambda}$ by means of MERT when very few adaptation data is available may improve the final translation quality, but may also degrade it to a much larger extent. In contrast, our BA technique shows stable and reliable improvements from the very beginning. Precisely under such circumstances is an adaptation technique useful: when the amount of adaptation data is small. In other cases, the best thing one can do is to re-estimate the model parameters from scratch.

Example translations, extracted from the experiments detailed above, are shown in Figure 5.

6.3 Varying δ

So as to understand the role of scaling factor δ, results obtained varying it are shown in Figure 3. Several things should be noted about these plots:

- Increasing δ leads to smoother adaptation curves. This is coherent with the confidence interval sizes shown in Figure 1.
- Smaller values of δ lead to a slight degradation in translation quality when the amount of adaptation samples becomes larger. The reason for this can be explained by looking at Equation 13. Since $p(A|\mathbf{\Lambda};T)$ is implemented as a product of probabilities, the more adaptation samples the smaller becomes $p(A|\mathbf{\Lambda};T)$, and a higher value of δ is needed to compensate this fact. This suggests the need of a δ which depends on the size of the adaptation sample.
- Larger values of δ do not suffer the problem described above, but yield smaller improvements in terms of translation quality for smaller amount of samples.

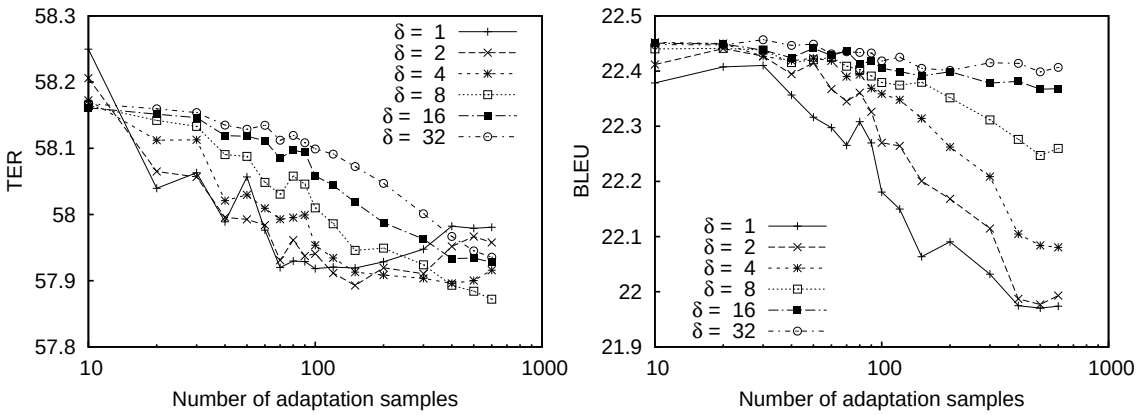

Figure 3: Translation quality comparison for different δ values and number of adaptation samples.

It might seem odd that translation quality as measured by BLEU drops almost constantly as the number of adaptation samples increases. However, it must be noted that the BA technique implemented is set to optimise TER, and not BLEU. Analysing the BLEU scores obtained, we realised that the n-gram precision does increase, but the final BLEU score drops because of a worsening brevity penalty, which is not taken into account when optimising the TER score.

6.3.1 Increasing the n-best order

The effect of increasing the order of n-best considered was also analysed. In order to avoid an overwhelming amount of results, only those obtained when considering 100 adaptation samples are displayed in Figure 4. As it can be seen, TER drops monotonically for all δ values, until about 800, where it starts to stabilise. Similar behaviour is observed in the case of BLEU, although depending on δ the curve shows an improvement or a degradation. Again, this is due to the brevity penalty, which TER does not implement, and which induces this inverse correlation between TER and BLEU when optimising TER.

7 Conclusions and future work

We have presented a Bayesian theoretical framework for adapting the parameters of a SMT system. We have derived the equations needed to implement BA of the log-linear weights of a SMT system, and present promising results with a state-of-the-art SMT system using standard corpora in SMT. Such results prove that the BA framework can be very effective when adapting the mentioned weights. Consistent improvements are obtained over the baseline system with as few as 10 adaptation samples. The BA technique implemented is able to yield results comparable with a complete re-estimation of the parameters even when the amount of adaptation data is sufficient for such re-estimation to be feasible. Experimental results show that our adaptation technique proves to be much more stable than MERT, which relies very heavily on the amount of adaptation data and turns very unstable whenever few adaptation samples are available. It should be emphasised that an adaptation technique, by nature, is only useful whenever few adaptation data is available, and our technique proves to behave well in such context.

Intuitively, the BA technique presented needs first to compute a set of random weights, which are the result of sampling a gaussian distribution whose mean is the best weight vector obtained in training. Then, each hypothesis of a certain test source sentence is rescored according to the following three components:

- The probability of the adaptation corpus under each specific random weight
- The probability of such random weight according to a prior over the weight vector
- The probability of the current hypothesis under those weights

Concerning computational time, our adaptation technique can easily be implemented within the decoder itself, without any significant increase in computational complexity. We consider this im-

portant, since it implies that rerunning MERT for each adaptation set is not needed, and this is important whenever the final system is set up in an on-line environment.

The derivation presented here can be easily extended in order to adapt the feature functions of the log-linear model (i.e. not the weights). This is bound to have a more important impact on translation quality, since the amount of parameters to be adapted is much higher. We plan to address this issue in future work.

In addition, very preliminary experiments show that, when considering reordering, the advantages described here are larger.

A preliminary version of the present paper was accepted at the Joint IAPR International Workshops on Structural and Syntactic Pattern Recognition and Statistical Techniques in Pattern Recognition 2010. The main contributions of the present paper constitute more extensive experiments, which have been conducted on standard SMT corpora. Furthermore, in this paper we present the results of adding the leveraging term δ, of applying a random, Monte-Carlo like weight sampling (which was not done previously), and an extensive analysis of the effect of varying the order of n-best considered.

We also plan to implement Markov Chain Monte Carlo for sampling the parameters, and analyse the effect of combining the in-domain and out of domain data for MERT. Such results were not included here for time constraints.

Abstract

This paper presents a constraint-based graph partitioning approach to coreference resolution solved by relaxation labeling. The approach combines the strengths of groupwise classifiers and chain formation methods in one global method. Experiments show that our approach significantly outperforms systems based on separate classification and chain formation steps, and that it achieves the best results in the state of the art for the same dataset and metrics.

1 Introduction

Coreference resolution is a natural language processing task which consists of determining the *mentions* that refer to the same entity in a text or discourse. A mention is a noun phrase referring to an entity and includes named entities, definite noun phrases, and pronouns. For instance, "Michael Jackson" and "the youngest of Jackson 5" are two mentions referring to the same entity.

A typical machine learning-based coreference resolution system usually consists of two steps: (i) classification, where the system evaluates the *coreferentiality* of each pair or group of mentions, and (ii) formation of chains, where given the confidence values of the previous classifications the system forms the coreference chains.

Research supported by the Spanish Science and Innovation Ministry, via the KNOW2 project (TIN2009-14715-C04-04) and from the European Community's Seventh Framework Programme (FP7/2007-2013) under Grant Agreement number 247762 (FAUST)

Regarding the classification step, pioneer systems developed were based on *pairwise* classifiers. Given a pair of mentions, the process generates a feature vector and feeds it to a classifier. The resolution is done by considering each mention of the document as *anaphor*[1] and looking backward until the *antecedent* is found or the beginning of the document is reached (Aone and Bennett, 1995; McCarthy and Lehnert, 1995; Soon et al., 2001).

A first approach towards *groupwise* classifiers is the twin-candidate model (Yang et al., 2003). The model faces the problem as a competition between two candidates to be the antecedent of the anaphor into account. Each candidate mention is compared with all the others in a round robin contest. Following the *groupwise* approach, rankers consider all the possible antecedent mentions at once (Denis and Baldridge, 2008). Rankers can obtain more accurate results due to a more informed context where all candidate mentions are considered at the same time.

Coreference chains are formed after classification. Many systems form the chains by joining each positively-classified pair (i.e. *single-link*) or with simple improvements such as linking an anaphor only to its antecedent with maximum confidence value (Ng and Cardie, 2002).

Some works propose more elaborated methods than single-link for chain formation. The approaches used are Integer Linear Programming

[1] Typically a pair of coreferential mentions m_i and m_j ($i < j$) are called antecedent and anaphor respectively, though m_j may not be anaphoric.

Coling 2008: Poster Volume, pages 1086–1094,
Beijing, August 2010

(ILP) (Denis and Baldridge, 2007; Klenner and Ailloud, 2009; Finkel and Manning, 2008), graph partitioning (Nicolae and Nicolae, 2006), and clustering (Klenner and Ailloud, 2008). The main advantage of these types of *post-processes* is the enforcement of transitivity sorting out the contradictions that the previous classification process may introduce.

Although chain formation processes search for global consistency, the lack of contextual information in the classification step is propagated forward. Few works try to overcome the limitations of keeping classification and chain formation apart. Luo et al. (2004) search the most probable path comparing each mention with the partial-entities formed so far using a Bell tree structure. McCallum and Wellner (2005) propose a graph partitioning cutting by distances, with the peculiarity that distances are learned considering coreferential chains of the labeled data instead of pairs. Culotta et al. (2007) combine a groupwise classifier with a clustering process in a First-Order probabilistic model.

The approach presented in this paper follows the same research line of joining group classification and chain formation in the same step. Concretely, we propose a graph representation of the problem solved by a relaxation labeling process, reducing coreference resolution to a graph partitioning problem given a set of constraints. In this manner, decisions are taken considering the whole set of mentions, ensuring consistency and avoiding that classification decisions are independently taken. Our experimental results on the ACE dataset show that our approach outperforms systems based on separate classification and chain formation steps, and that it achieves the best results in the state of the art for the same dataset and metrics.

The paper is organized as follows. Section 2 describes the graph representation of the task. Section 3 explains the use of relaxation labeling algorithm and the machine learning process. Finally, experiments and results are explained in Section 4 before paper is concluded.

2 Graph Representation

Let $G = G(V, E)$ be an undirected graph where V is a set of vertices and E a set of edges. Let $\mathbf{m} = (m_1, ..., m_n)$ be the set of mentions of a document with n mentions to resolve. Each mention m_i in the document is represented as a vertex $v_i \in V$. An edge $e_{ij} \in E$ is added to the graph for pairs of vertices (v_i, v_j) representing the possibility that both mentions corefer. The list of adjacent vertices of a vertex v_i is $A(v_i)$.

Let C be our set of constraints. Given a pair of mentions (m_i, m_j), a subset of constraints $C_{ij} \subseteq C$ restrict the compatibility of both mentions. C_{ij} is used to compute the weight value of the edge connecting v_i and v_j. Let $w_{ij} \in W$ be the weight of the edge e_{ij}:

$$w_{ij} = \sum_{k \in C_{ij}} \lambda_k f_k(m_i, m_j) \quad (1)$$

where $f_k(\cdot)$ is a function that evaluates the constraint k. And λ_k is the weight associated to the constraint k (λ_k and w_{ij} can be negative).

In our approach, each vertex (v_i) in the graph is a variable (v_i) for the algorithm. Let L_i be the number of different values (labels) that are possible for v_i. The possible labels of each variable are the partitions that the vertex can be assigned. Note that the number of partitions (entities) in a document is unknown, but it is at most the number of vertices (mentions), because in a extreme case, each mention in a document could be referring to a different entity. A vertex with index i can be in the first i partitions (i.e. $L_i = i$).

Each combination of labelings for the graph vertices is a partitioning (Ω). The resolution process searches the partitioning Ω^* which optimizes the goodness function $F(\Omega, W)$, which depends on the edge weights W. In this manner, Ω^* is optimal if:

$$F(\Omega^*, W) \geq F(\Omega, W), \forall \Omega \quad (2)$$

The next section describes the algorithm used in the resolution process.

3 Relaxation Labeling

Relaxation labeling (Relax) is a generic name for a family of iterative algorithms which perform

function optimization, based on local information. The algorithm has been widely used to solve NLP problems such as PoS-tagging (Màrquez et al., 2000), chunking, knowledge integration, and Semantic Parsing (Atserias, 2006).

Relaxation labeling solves our weighted constraint satisfaction problem dealing with the edge weights. In this manner, each vertex is assigned to a partition satisfying as many constraints as possible. To do that, the algorithm assigns a probability for each possible label of each variable. Let $\mathbf{H} = (\mathbf{h}^1, \mathbf{h}^2, \ldots, \mathbf{h}^n)$ be the weighted labeling to optimize, where each $\mathbf{h}^i$ is a vector containing the probability distribution of v_i, that is: $\mathbf{h}^i = (h_1^i, h_2^i, \ldots, h_{L_i}^i)$. Given that the resolution process is iterative, the probability for label l of variable v_i at time step t is $h_l^i(t)$, or simply h_l^i when the time step is not relevant.

The support for a pair variable-label (S_{il}) expresses how compatible is the assignment of label l to variable v_i considering the labels of adjacent variables and the edge weights. Although several support functions may be used (Torras, 1989), we chose the following one, which defines the support as the sum of the edge weights that relate variable v_i with each adjacent variable v_j multiplied by the weight for the same label l of v_j:

$$S_{il} = \sum_{j \in A(v_i)} w_{ij} \times h_l^j \qquad (3)$$

where w_{ij} is the edge weight obtained in Equation 1. In our version of the algorithm, $A(v_i)$ is the list of adjacent vertices of v_i but only including the ones with an index $k < i$. Consequently, the weights only have influence in one direction which is equivalent to using a directed graph. Although the proposed representation is based on a general undirected graph, preliminary experiments showed that using directed edges yields higher perfomance in this particular problem.

The aim of the algorithm is to find a weighted labeling such that global consistency is maximized. Maximizing global consistency is defined as maximizing the average support for each variable. Formally, $\mathbf{H}^*$ is a consistent labeling if:

Initialize:
  $H := H_0$,

Main loop:
  repeat
  For each variable v_i
    For each possible label l for v_i
      $S_{il} = \sum_{j \in A(v_i)} w_{ij} \times h_l^j$
    End for
    For each possible label l for v_i
      $h_l^i(t+1) = \frac{h_l^i(t) \times (1 + S_{il})}{\sum_{k=1}^{L_i} h_k^i(t) \times (1 + S_{ik})}$
    End for
  End for
  Until no more significant changes

Figure 1: Relaxation labeling algorithm

$$\sum_{l=1}^{L_i} h_l^{*i} \times S_{il} \geq \sum_{l=1}^{L_i} h_l^i \times S_{il} \quad \forall \mathbf{h}, \forall i \qquad (4)$$

A partitioning Ω is directly obtained from the weighted labeling $\mathbf{H}$ assigning to each variable the label with maximum probability. The supports and the weighted labeling depend on the edge weights (Equation 3). To satisfy Equation 4 is equivalent to satisfy Equation 2. Many studies have been done towards the demonstration of the consistency, convergence and cost reduction advantages of the relaxation algorithm (Rosenfeld et al., 1976; Hummel and Zucker, 1987; Pelillo, 1997). Although some of the conditions required by the formal demonstrations are not fulfilled in our case, the presented algorithm –that forces a stop after a number of iterations– has proven useful for practical purposes.

Figure 1 shows the pseudo-code of the relaxation algorithm. The process updates the weights of the labels in each step until convergence. The convergence is met when no more significant changes are done in an iteration. Specifically, when the maximum change in an update step ($max_{i,l}(|h_l^i(t+1) - h_l^i(t)|)$) is lower than a parameter ϵ, a small value (0.001 in our experiments), or a fixed number of iterations is reached (2000 in our experiments). Finally, the assigned label for a variable is the one with the highest weight. Figure 2 shows a representation.

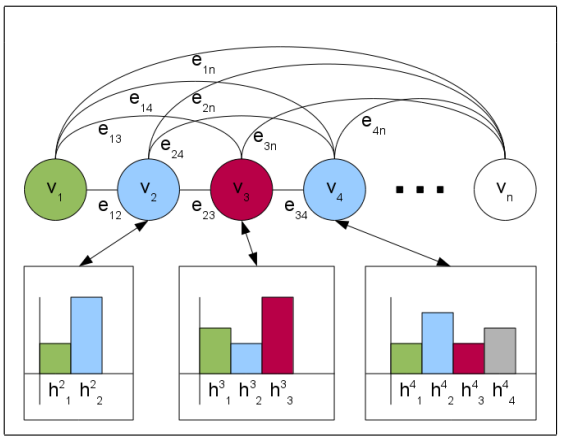

Figure 2: Representation of Relax. The vertices representing mentions are connected by weighted edges e_{ij}. Each vertex has a vector $\mathbf{h}^i$ of probabilities to belong to different partitions. The figure shows $\mathbf{h}^2$, $\mathbf{h}^3$ and $\mathbf{h}^4$.

DIST: Distance between m_i and m_j in sentences: number
DIST_MEN: Distance between m_i and m_j in mentions: number
APPOSITIVE: One mention is in apposition with the other: y,n
I/J_IN_QUOTES: $m_{i/j}$ is in quotes or inside a NP or a sentence in quotes: y,n
I/J_FIRST: $m_{i/j}$ is the first mention in the sentence: y,n
I/J_DEF_NP: $m_{i/j}$ is a definitive NP: y,n
I/J_DEM_NP: $m_{i/j}$ is a demonstrative NP: y,n
I/J_INDEF_NP: $m_{i/j}$ is an indefinite NP: y,n
STR_MATCH: String matching of m_i and m_j: y,n
PRO_STR: Both are pronouns and their strings match: y,n
PN_STR: Both are proper names and their strings match: y,n
NONPRO_STR: String matching like in Soon et al. (2001) and mentions are not pronouns: y,n
HEAD_MATCH: String matching of NP heads: y,n
NUMBER: The number of both mentions match: y,n,u
GENDER: The gender of both mentions match: y,n,u
AGREEMENT: Gender and number of both mentions match: y,n,u
I/J_THIRD_PERSON: $m_{i/j}$ is 3rd person: y,n
PROPER_NAME: Both mentions are proper names: y,n,u
I/J_PERSON: $m_{i/j}$ is a person (pronoun or proper name in a list): y,n
ANIMACY: Animacy of both mentions match (persons, objects): y,n
I/J_REFLEXIVE: $m_{i/j}$ is a reflexive pronoun: y,n
I/J_TYPE: $m_{i/j}$ is a pronoun (p), entity (e) or nominal (n)
NESTED: One mention is included in the other: y,n
MAXIMALNP: Both mentions have the same NP parent or they are nested: y,n
I/J_MAXIMALNP: $m_{i/j}$ is not included in any other mention: y,n
I/J_EMBEDDED: $m_{i/j}$ is a noun and is not a maximal NP: y,n
BINDING: Conditions B and C of binding theory: y,n
SEMCLASS: Semantic class of both mentions match: y,n,u (the same as Soon et al. (2001))
ALIAS: One mention is an alias of the other: y,n,u (only entities, else unknown)

Figure 3: Feature functions used

3.1 Constraints

The performance of the resolution process depends on the edge weights obtained by a set of weighted constraints (Equation 1). Any method or combination of methods to generate constraints can be used. For example, a set of constraints handwritten by linguist experts can be added to another automatically obtained set.

This section explains the automatic constraint generation process carried out in this work, using a set of feature functions and a training corpus. Màrquez et al. (2000) have successfully used similar processes to acquire constraints for constraint satisfaction algorithms.

Each pair of mentions (m_i, m_j) in a training document is evaluated by a set of feature functions (Figure 3). The values returned by these functions form a positive example when the pair of mentions corefer, and a negative one otherwise. Three specialized models are constructed depending on the type of anaphor mention (m_j) of the pair: pronoun, named entity or nominal.

For each specialized model, a decision tree (DT) is generated and a set of rules is extracted with C4.5 rule-learning algorithm (Quinlan, 1993). These rules are our set of constraints. The C4.5rules algorithm generates a set of rules for each path from the learnt tree. It then generalizes the rules by dropping conditions.

The weight assigned to a constraint (λ_k) is its precision over the training data (P_k), but shifted to be zero-centered: $\lambda_k = P_k - 0.5$.

3.2 Pruning

Analyzing the errors of development experiments, we have found two main error patterns that can be solved by a pruning process. First, the contribution of the edge weights for the resolution depends on the size of the document. And second, many weak edge weights may sum up to produce a bias in the wrong direction.

The weight of an edge depends on the weights assigned for the constraints which apply to a pair of mentions according to Equation 1. Each vertex is adjacent to all the other vertices. This produces that the larger the number of adjacencies, the smaller the influence of a constraint is. A consequence is that resolution for large and short documents has different results.

Many works have to deal with similar problems, specially the ones looking backward for antecedents. The larger the document, the more pos-

sible antecedents the system has to classify. This problem is usually solved looking for antecedents in a window of few sentences, which entails an evident limitation of recall.

Regarding the weak edge weights, it is notable that some kind of mention pairs are very weakly informative. For example, the pairs (pronoun, pronoun). Many stories have a few main characters which monopolize the pronouns of the document. This produces many positive training examples for pairs of pronouns matching in gender and person, which may lead the algorithm to produce large coreferential chains joining all these mentions even for stories where there are many different characters. For example, we have found in the results of some documents a huge coreference chain including every pronoun "he". This is because a pair of mentions ("he", "he") is usually linked with a small positive weight. Although the highest adjacent edge weight of a "he" mention may link with the correct antecedent, the sum of several edge weights linking the mention with other "he" causes the problem.

A pruning process is perfomed solving both problems and reducing computational costs from $O(n^3)$ to $O(n^2)$. For each vertex's adjacency list $A(v_i)$, only a maximum of N edges remain and the others are pruned. Concretely, the N/2 edges with largest positive weight and the N/2 with largest negative weight. The value of N is empirically chosen by maximizing performances over training data. On the one hand, the pruning forces the maximum adjacency to be constant and the contribution of the edge weights does not depend on the size of the document. On the other hand, most edges of the less informative pairs are discarded avoiding further confusion. There are no limitations in distance or other restrictions which may cause a loss of recall.

3.3 Initial State

The initial state of the vertices define the *a priori* probabilities for each vertex to be in each partition. There are several possible initial states. In the case where no prior information is available, a random or uniformly distributed state is commonly used. However, a well-informed initial state should drive faster the relaxation process to a better solution. This section describes the well-informed initial state chosen in our approach and the random one. Both are compared in the experiments (Section 4.2).

The well-informed initial state favors the creation of new chains. Variable v_i has $L_i = i$ possible values while variable v_{i+1} has $L_i + 1$. The probability distribution of v_{i+1} is equiprobable for values from 1 to L_i but it is the double for the probability to start a new chain $L_i + 1$.

$$h^i_l = \frac{1}{L_i+1}, \qquad \forall l = 1..L_i - 1$$
$$h^i_{L_i} = \frac{2}{L_i+1}$$

Pronouns do not follow this distribution but a totally equiprobable one, given that they are usually anaphoric.

$$h^i_l = \frac{1}{L_i}, \qquad \forall l = 1..L_i$$

This configuration enables the resolution process to determine as singletons the mentions for which little evidence is available. This small difference between initial probability weights is also introduced in order to avoid exceptional cases where all support values contribute with the same value.

The random initial state is also used in our experiments to test that our proposed configuration is better-informed than random. Given the equiprobability state, we add a random value to each probability to be in a partition:

$$h^i_l = \frac{1}{L_i} + \epsilon_{il}, \qquad \forall l = 0..L_i$$

where ϵ_{il} is a random value $\frac{-1}{2L_i} \leq \epsilon_{il} \leq \frac{1}{2L_i}$. These little random differences may help the algorithm to avoid local minima.

3.4 Reordering

The vertices of the graph would usually be placed in the same order as the mentions are found in the document (*chronological*). In this manner, v_i corresponds to m_i. However, as suggested by Luo (2007), there is no need to generate the model following that order. In our approach, the first variables have a lower number of possible labels. Moreover, an error in the first variables has more influence on the performance than an error in the later ones. Placing named entities at the beginning is reasonably to expect that is helpful for the algorithm, given that named entities are usually the most informative mentions.

	Tokens	Mentions	Entities
bnews train	66627	9937	4408
bnews test	17463	2579	1040
npaper train	68970	11283	4163
npaper test	17404	2483	942
nwire train	70832	10693	4297
nwire test	16772	2608	1137

Figure 4: Statistics about ACE-phase02

Suppose we have three mentions appearing in this order somewhere in a document: "A. Smith", "he", "Alice Smith". For proximity, mention "he" may tend to link with "A. Smith". Then, the third mention "Alice Smith" clearly is the whole name of "A. Smith" but the gender with "he" does not agree. Given that our implementation acts like a directed graph only looking backward (see Section 3), mention "he" won't change its tendency and it may cause a split in the "Alice Smith" coreference chain. However, having named entities in first place and pronouns at the end, enables the mention "he" to determine that "A. Smith" and "Alice Smith" having the same label are not good antecedents.

Reordering only affects on the number of possible labels of the variables and the list of adjacencies $A(v_i)$. The chronological order of the document is taken into account by the constraints regardless of the graph representation. Our experiments confirm (Section 4) that placing first named entity mentions, then nominal mentions and finally the pronouns, the precision increases considerably. Inside of each of these groups, the order is the same order of the document.

4 Experiments and Results

We evaluate our approach to coreference resolution using ACE-phase02 corpus, which is composed of three sections: Broadcast News (BNEWS), Newswire (NWIRE) and Newspaper (NPAPER). Each section is in turn composed of a training set and a test set. Figure 4 shows some statistics about this corpus.

In our experiments, we consider the *true mentions* of ACE. This is because our focus is on evaluating pairwise approach versus the graph partitioning approach and also comparing them to some state-of-the-art approaches which also use true mentions. Moreover, details on mention identifier systems and their performances are rarely published by the systems based on automatic identification of mentions and it difficults the comparison.

To evaluate our system we use CEAF (Luo, 2005) and B^3 (Bagga and Baldwin, 1998). CEAF is computed based on the best one-to-one map between key coreference chains and response ones. We use the mention-based similarity metric which counts the number of common mentions shared by key coreference chains and response ones. As we are using *true mentions* for the experiments, precision, recall and F_1 are the same value and only F_1 is shown. B^3 scorer is used for comparison reasons. B^3 algorithm looks at the presence/absence of mentions for each entity in the system output. Precision and recall numbers are computed for each mention, and the average gives the final precision and recall numbers.

MUC scorer (Vilain et al., 1995) is not used in our experiments. Although it has been widely used in the state of the art, we consider the newer metrics have overcome some MUC limitations (Bagga and Baldwin, 1998; Luo, 2005; Klenner and Ailloud, 2008; Denis and Baldridge, 2008).

Our preprocessing pipeline consists of FreeLing (Atserias et al., 2006) for sentence splitting and tokenization, SVMTool (Gimenez and Marquez, 2004) for part of speech tagging and BIO (Surdeanu et al., 2005) for named entity recognition and classification. No lemmatization neither syntactic analysis are used.

4.1 Baselines

4.1.1 DT with automatic feature selection

The baseline developed in our work is based on Soon et al. (2001) with the improvements of Ng and Cardie (2002), which uses a Decision Tree (DT). Many research works use the same references in order to evaluate possible improvements done by their new models or by the incorporation of new features.

The features used in the baseline are the same than those used in our proposed system (Figure 3). However, some features are noisy and many others have redundancy which causes low performances using DTs. In order to select the best set

Table 2: Results on documents shorter than 200 mentions of ACE-phase02

of features a Hill Climbing process has been performed doing a five-fold cross-validation over the training corpus. A similar feature selection process has been done by Hoste (2005).

The Hill Climbing process starts using the whole set of features. A cross-validation is done (un)masking each feature. The (un)masked feature with more improvement is (added to) removed from the set. The process is repeated until an iteration without improvements is reached.

Note that this optimization process is biased by the metric used to evaluate each feature combination. We use CEAF in our experiments, which encourages precision and consistency.

4.1.2 Integer Linear Programming

The second baseline developed forms the coreference chains given the output of the pair classification of the first baseline. A set of binary variables (x_{ij}) symbolize whether pairs of mentions (m_i, m_j) corefer ($x_{ij} = 1$) or not ($x_{ij} = 0$). An objective function is defined as follows:

$$min \sum_{i<j} -log(Pc_{ij})x_{ij} - log(1 - Pc_{ij})(1 - x_{ij})$$

where Pc_{ij} is the confidence value of mentions m_i and m_j to corefer obtained by the pair classifier. The minimization of the objective function is done by Integer Linear Programming (ILP) in a similar way to (Klenner, 2007; Denis and Baldridge, 2007; Finkel and Manning, 2008). In order to keep consistency in the results, which is the goal of this *post-process*, a set of *triangular* constraints is required. For each three mentions with indexes $i < j < k$ the corresponding variables have to satisfy three constraints:

- $x_{ik} \geq x_{ij} + x_{jk} - 1$
- $x_{ij} \geq x_{ik} + x_{jk} - 1$
- $x_{jk} \geq x_{ij} + x_{ik} - 1$

This implies that this model needs, for a document with n mentions, $\frac{1}{2}n(n-1)$ variables and $\frac{1}{2}n(n-1)(n-2)$ constraints to assure consistency[2]. This is an important limitation with a view to scalability. In our experiments only documents shorter than 200 mentions can be solved by this baseline due to its computational cost.

4.2 Experiments

Four experiments have been done in order to evaluate our proposed approach. This section describes and analyzes the results of each experiment. Finally, our performances are compared with the state of the art.

The first experiment compares the performances of our baselines (Table 1). "DT" is the system based on Decision Tree using all the features of Figure 3 and "DT+Hill" is a DT using the features selected by the Hill Climbing process (Section 4.1.1). There is a significant improvement in the performances (5.1 points with CEAF, 5.3 with B^3) after the automatic feature selection process is done.

[2] $\frac{1}{6}n(n-1)(n-2)$ for each one of the three triangular constraints

	bnews	npaper	nwire	Global			
Metric:	CEAF			CEAF	B^3		
Model	F1	F1	F1	F1	P	R	F1
Relax	67.3	64.4	69.5	67.2	**88.4**	62.7	73.3
Relax pruning	68.6	65.2	70.1	68.0	82.3	**66.9**	73.8
Relax pruning & reorder	**69.5**	**67.3**	**72.1**	**69.7**	85.3	66.8	**74.9**
Relax random IS	68.2	66.1	71.0	68.5	83.5	66.7	74.2
MaxEnt+ILP (Denis, 2007)	-	-	-	66.2	81.4	65.6	72.7
Rankers (Denis, 2007)	65.7	65.3	68.1	67.0	79.8	66.8	72.7

Table 3: Results ACE-phase02.

In the second experiment the ILP chain formation process is applied using the output of both DTs. Results are shown in Table 2. Note that ILP only applies to documents shorter than 200 mentions due to its excessive computational cost (Section 4.1.2). Results for Relax applied to the same documents are also included for comparison. ILP forces consistency of the results producing an increase in precision score with B^3 metric in both cases. However, "DT+Hill" has been optimized for CEAF metric which encourages precision and consistency. For this, a post-process forcing consistency seems unnecessary for a classifier already optimized. Relax significantly outperforms all the baselines.

The third experiment shows the improvements achieved by the use of pruning and reordering techniques (Sections 3.2 and 3.4). Table 3 shows the results. Pruning improves performances with both metrics. B^3 precision is decreased but the global F_1 is increased due to a considerably improvement of recall. Reordering recovers the precision lost by the pruning without loosing recall, which achieves the best performances of 69.7 with CEAF and 74.9 with B^3.

The fourth experiment evaluates the influence of the initial state. A comparison is done with the proposed initial state (Section 3.3) and the random one. The results shown in Table 3 for random initial state are the average of 3 executions. The system called "Relax random IS" is using the same values for pruning and reordering techniques than the best result of previous experiment: "Relax pruning & reorder". As expected, results with a well-informed initial state outperform the random ones.

Finally, Relax performances are compared with the best scores we have found using the same corpora and metrics. We compare our approach with specialized Rankers –groupwise classifier–, and a system using ILP not only forcing consistency but also using information about anaphoricity and named entities. Relax outperforms both systems with both metrics (Table 3).

5 Conclusion

The approach for coreference resolution presented in this paper is a constraint-based graph partitioning solved by relaxation labeling.

The decision to join or not a set of mentions in the same entity is taken considering always the whole set of previous mentions like in groupwise classifiers. Contrarily to the approaches where variables are the linkage of each pair of mentions, in this model consistency is implicitly forced. Moreover, the influence of the partial results of the other mentions at the same time avoids that decisions are independently taken.

The capacity to easily incorporate constraints from different sources and using different knowledge is also remarkable. This flexibility gives a great potencial to the approach. Anaphoricity filtering is not needed given that the necessary knowledge can be also introduced by constraints.

In addition, three tecniques to improve results have been presented: reordering, pruning and feature selection by Hill Climbing. The experiments confirm their utility.

The experimental results clearly outperform the baselines with separate classification and chain formaiton. The approach also outperforms others in the state of the art using same corpora and metrics.

"Expresses-an-opinion-about": using corpus statistics in an information extraction approach to opinion mining

Abstract

We present a technique for identifying the sources and targets of opinions without actually identifying the opinions themselves. We are able to use an information extraction approach that treats opinion mining as relation mining; we identify instances of a binary "expresses-an-opinion-about" relation. We find that we can classify source-target pairs as belonging to the relation at a performance level significantly higher than two relevant baselines.

This technique is particularly suited to emerging approaches in corpus-based social science which focus on aggregating interactions between sources to determine their effects on socio-economically significant targets. Our application is the analysis of information technology (IT) innovations. This is an example of a more general problem where opinion is expressed using either sub- or supersets of expressive words found in newswire. We present an annotation scheme and an SVM-based technique that uses the local context as well as the corpus-wide frequency of a source-target pair as data to determine membership in "expresses-an-opinion-about". While the presence of conventional subjectivity keywords appears significant in the success of this technique, we are able to find the most domain-relevant keywords without sacrificing recall.

1 Introduction

Two problems in sentiment analysis consist of source attribution and target discovery—who has an opinion, and about what? These problems are usually presented in terms of techniques that relate them to the actual opinion expressed. We have a social science application in which the identification of sources and targets over a large volume of text is more important than identifying the actual opinions particularly in experimenting with social science models of opinion trends. Consequently, we are able to use lightweight techniques to identify sources and targets without using resource-intensive techniques to identify opinionated phrases.

Our application for this work is the discovery of networks of influence among opinion leaders in the IT field. We are interested in answering questions about who the leaders in the field are and how their opinion matches the social and economic success of IT innovation. Consequently, it became necessary for us to construct a system (figure 1) that finds the expressions in text that refer to an opinion leader's activities in promoting or deprecating a technology.

In this paper, we demonstrate an information extraction (Mooney and Bunescu, 2005) approach based in relation mining (Girju et al., 2007) that is effective for this purpose. We describe a technique by which corpus statistics allow us to classify pairs of entities and sentiment analysis targets as instances of an "expresses-an-opinion-about" relation in documents in the IT business press. This genre has the characteristic that many entities and targets are represented within individual sentences and paragraphs. Features based on the

Coling 2008: Poster Volume, pages 1095–1103,
Beijing, August 2010

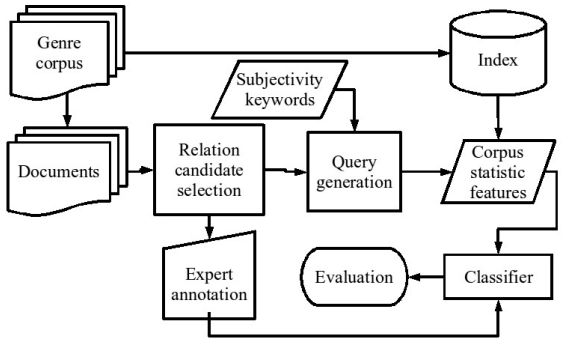

Figure 1: Opinion relation classification system.

frequency counts of query results allow us to train classifiers that allow us to extract "expresses-an-opinion-about" instances, using a very simple annotation strategy to acquire training examples.

In the IT business press, the opinionated language is different from the newswire text for which many extant sentiment tools were developed. We use an existing sentiment lexicon alongside other non-sentiment-specific measures that adapt resources from newswire-developed sentiment analysis projects without imposing the full complexity of those techniques.

1.1 Corpus-based social science

The "expresses-an-opinion-about" relation is a binary relation between opinion sources and targets. Sources include both people—typically known experts, corporate representatives, and other businesspeople—as well as organizations such as corporations and government bodies. The targets are the innovation terms. Therefore, the use of named-entity recognition in this project only focuses on persons and organizations, as the targets are a fixed list.

1.2 Reifying opinion in an application context

A hypothesis implicit in our social science task is that opinion leaders create trends in IT innovation adoption partly by the text that their activities generate in the IT business press. This text has an effect on readers, and these readers act in such a way that in turn may generate more or less prominence for a given innovation—and may also generate further text.

Some of these text-generating activities include expressions of private states in an opinion source (e.g., "I believe that *Web 2.0 is the future*"). These kinds of expressions suggest a particular ontology of opinion analysis involving discourse relations across various types of clauses (Wilson and Wiebe, 2005; Wilson et al., 2005a). However, if we are to track the relative adoption of IT innovations, we must take into account the effect of the text on the reader's opinion about these innovations—there are expressions other than those of private states that have an effect on the reader. These can be considered to be "opinionated acts[1]."

Opinionated acts can include things like purchasing and adoption decisions by organizations. For example:

> And like other top suppliers to **Wal-Mart Stores Inc.**, **BP** has been involved in a mandate to affix *radio frequency identification* tags with embedded electronic product codes to its crates and pallets. (ComputerWorld, January 2005)

In this case, both Wal-Mart and BP have expressed implicit approval for radio frequency identification by adopting it. This may affect the reader's own likelihood of support or adoption of the technology. In this context, we do not directly consider the subjectivity of the opinion source, even though that may be present.

Opinionated acts include things like implications of technology use, not just adoption. We thus define opinion expressions as follows: any expression involving some actor that is likely to affect a reader's own potential to adopt, reject, or speak positively or negatively of a target. This would include "conventional" expressions of private states as well as opinionated acts.

Our definition of "expresses-an-opinion-about" follows immediately. Source A expresses an opinion about target B if an interested third party C's actions towards B may be affected by A's textually recorded actions, in a context where actions

[1] Somasundaran and Wiebe (2009) mention a related category of "pragmatic opinions" that involve world knowledge.

have positive or negative weight (e.g. purchasing, promotion, etc.).

1.3 Domain-specific sentiment detection

We construct a system that uses named-entity recognition and supervised machine learning via SVMs to automatically discover instances of "expresses-an-opinion-about" as a binary relation at reasonably high accuracy and precision.

The advantage of our approach is that, outside of HMM-based named-entity detection (BBN's IdentiFinder), we evade the need for resource-intensive techniques such as sophsticated grammatical models, sequence models, and semantic role labelling (Choi et al., 2006; Kim and Hovy, 2006) by removing the focus on the actual opinion expressed. Then we can use a simple supervised discriminative technique with a joint model of local term frequency information and corpus-wide co-occurrence distributions in order to discover the raw data for opinion trend modelling. The most complex instrument we use from sentiment analysis research on conventional newswire is a sentiment keyword lexicon (Wilson et al., 2005b); furthermore, our techniques allow us to distinguish sentiment keywords that indicate opinion in this domain from keywords that actually indicate that there is no opinion relation between source and target.

While we show that this lightweight technique works well at a paragraph level, it can also be used in conjunction with more resource-intensive techniques used to find "conventional" opinion expressions. Also, the use of topic aspects (Somasundaran and Wiebe, 2009) in conjunction with target names has been associated with an improvement in recall. However, our technique still performs well above the baseline without these improvements.

2 Methodology

2.1 Article preparation

We have a list of IT innovations on which our opinion leader research effort is most closely focused. This list contains common names that refer to these technologies as well as some alternate names and abbreviations. We selected articles at random from the ComputerWorld IT journal that contained mentions of members of the given list. These direct mentions were tagged in the document as XML entities.

Each article was processed by BBN's IdentiFinder 3.3 (Bikel et al., 1999), a named entity recognition (NER) system that tags named mentions of person and organization entities[2].

The articles were then divided into paragraphs. For each paragraph, we generated candidate relations from the entities and innovations mentioned therein. To generate candidates, we paired every entity in the paragraph with every innovation. Redundant pairs are sometimes generated when an entity is mentioned in multiple ways in the paragraph. We eliminated most of these by removing entities whose mentions were substrings of other mentions. For example, "Microsoft" and "Microsoft Corp." are sometimes found in the same paragraph; we eliminate "Microsoft."

2.2 Annotation

We processed 20 documents containing 157 relations in the manner described in the previous section. Then two domain experts (chosen from the authors) annotated every candidate pair in every document according to the following scheme (illustrated in figure 2):

- If the paragraph associated with the candidate pair describes a valid source-target relation, the experts annotated it with `Y`.
- If the paragraph does not actually contain that source-target relation, the experts annotated it with `N`.
- If either the source or the target is misidentified (e.g., errors in named entity recognition), the experts annotated it with `X`.

The Cohen's κ score was 0.6 for two annotators. While this appears to be only moderate agreement, we are still able to achieve good performance in our experiments with this value.

[2] In a separate research effort, we found that IdentiFinder has a high error rate on IT business press documents, so we built a system to reduce the error *post hoc*. We ran this system over the IdentiFinder annotations.

Davis says she has especially enjoyed working with the **PowerPad**'s *bluetooth* interfaces to phones and printers. "It's nice getting into new wireless technology," she says. The *bluetooth* capability will allow couriers to transmit data without docking their devices in their trucks.

Source	Target	Class
Davis	bluetooth	**Y**/N/X
PowerPad	bluetooth	Y/N/**X**

Figure 2: Example paragraph annotation exercise.

We then selected 75 different documents for each annotator and processed and annotated them as above. At this point we have the instances and the classes to which they belong. We labelled 466 instances of Y, 325 instances of N, and 280 instances of X, for a total of 1071 relations.

2.3 Feature vector generation

We have four classes of features for every relation instance. Each type of feature consists of counts extracted from an index of 77,227 ComputerWorld articles from January 1988 to June 2008 generated by the University of Massachusetts search engine Indri (Metzler and Croft, 2004). Each vector is normalized to the unit vector. The index is not stemmed for performance reasons.

The first type of feature consists of simple document frequency statistics for source-target pairs throughout the corpus. The second type consists of document frequency counts of source-target pairs when they are in particularly close proximity to one another. The third type consists of document frequency counts of source target pairs proximate to keywords that reflect subjectivity. The fourth and final type consist of TFIDF scores of vocabulary items in the paragraph containing the putative opinion-holding relation (unigram context features). We use the first three features types to represent the likelihood in the "world" that the source has an opinion about the target and the last feature type to represent the likelihood of the specific paragraph containing an opinion that reflects the source-target relation.

We have a total of 7450 features. Each vector is represented as a sparse array. 806 features represent queries on the Indri index. For all the features, we therefore have 863,226 index queries. We perform the queries in parallel on 25 processors to generate the full feature array, which takes approximately an hour on processors running at 8Ghz. We eliminate all values that are smaller in magnitude than 0.000001 after unit vector normalization.

2.3.1 Frequency statistics

There are two simple frequency statistics features generated from Indri queries. The first is the raw frequency counts of within-document co-occurrences of the source and target in the relation. The second is the mean co-occurrence frequency of the source and target per ComputerWorld document.

2.3.2 Proximity counts

For every relation, we query Indri to check how often the source and the target appear in the same document in the ComputerWorld corpus within four word ranges: 5, 25, 100, and 500. That is to say, if a source and a target appear within five words of one another, this is included in the five-word proximity feature. This generates four features per relation.

2.3.3 Subjectivity keyword proximity counts

We augment the proximity counts feature with a third requirement: that the source and target appear within one of the ranges with a "subjectivity keyword." The keywords are taken from University of Pittsburgh subjectivity lexicon; the utility of this lexicon is supported in recent work (Somasundaran and Wiebe, 2009).

For performance reasons, we did not use all of the entries in the subjectivity lexicon. Instead, we used a TFIDF-based measure to rank the keywords by their prevalence in the ComputerWorld corpus where the term frequency is defined over the entire corpus. Then we selected 200 keywords with the highest score.

For each keyword, we use the same proximity ranges (5, 25, 100, and 500) in queries to Indri where we obtain counts of each keyword-source-target triple for each range. There are threfore 800 subjectivity keyword features.

Positive class	Negative class	System	Prec / Rec / F	Accuracy
Y	N	Random baseline	0.60 / 0.53 / 0.56	0.52
Y	N	Maj.-class (Y) baseline	0.59 / *1.00* / 0.74	0.59
Y	N	Linear kernel	0.70 / 0.73 / 0.72	0.66
Y	N	RBF kernel	**0.72 / 0.76 / 0.75**	**0.69**
Y	N/X	Random baseline	0.44 / 0.50 / 0.47	0.50
Y	N/X	RBF kernel	0.65 / 0.55 / 0.59	0.67

Table 1: Results with all features against majority class and random baselines. All values are mean averages under 10-fold cross validation.

2.3.4 Word context (unigram) features

For each relation, we take term frequency counts of the paragraph to which the relation belongs. We multiply them by the IDF of the term across the ComputerWorld corpus. This yields 6644 features over all paragraphs.

2.4 Machine learning

On these feature vectors, we trained SVM models using Joachims' (1999) svmlight tool. We use a radial basis function kernel with an error cost parameter of 100 and a γ of 0.25. We also use a linear kernel with an error cost parameter of 100 because it is straightforwardly possible with a linear kernel to extract the top features from the model generated by svmlight.

3 Experiments

We conducted most of our experiments with only the Y and N classes, discarding all X; this restricted most of our results to those assuming correct named entity recognition. Y was the positive class for training the svmlight models, and N was the negative class. We also performed experiments with N and X together being the negative class; this represents the condition that we are seeking "expresses-an-opinion-about" even with a higher named-entity error rate.

We use two baselines. One is a random baseline with uniform probability for the positive and negative classes. The other is a majority-class assigner (Y is the majority class).

The best system for the Y vs. N experiment was subjected to feature ablation. We first systematically removed each of the four feature types individually. The feature type whose removal had the largest effect on performance was removed permanently, and the rest of the features were tested without it. This was done once more, at which point only one feature type was present in the models tested.

3.1 Evaluation

All evaluation was performed under 10-fold cross validation, and we report the mean average of all performance metrics (precision, recall, harmonic mean F-measure, and accuracy) across folds.

We define these measures in the standard information retrieval form. If tp represents true positives, tn true negatives, fp false positives, and fn false negatives, then precision is $tp/(tp+fp)$, recall $tp/(tp+fn)$, F-measure (harmonic mean) is $2(prec*rec)/(prec+rec)$, and accuracy is $(tp+tn)/(tp+fp+fn+tn)$.

4 Results and discussion

The results of the experiments with all features are listed in table 1.

4.1 "Perfect" named entity recognition

We achieve best results in the Y versus N case using the radial basis function kernel. We find improvement in F-measure and accuracy at 19% and 17% respectively. Simply assigning the majority class to all test examples yields a very high recall, by definition, but poor precision and accuracy; hence its relatively high F-measure does not reflect high applicability to further processing, as the false positives would amplify errors in our social science application.

The linear kernel has results that are below the RBF kernel for all measures, but are relatively close to the RBF results.

Subjectivity	Proximity	Frequency	Unigram	Prec / Rec / F	Accuracy
✓	✓	✓	✓	0.72 / 0.76 / 0.75	0.69
	✓	✓	✓	0.67 / 0.89 / 0.76	0.67
✓		✓	✓	0.71 / 0.77 / 0.73	0.68
✓	✓		✓	0.70 / 0.78 / 0.74	0.67
✓	✓	✓		0.69 / 0.77 / 0.73	0.67
		✓	✓	0.63 / 0.91 / 0.75	0.64
	✓		✓	0.66 / 0.89 / 0.76	0.67
	✓	✓		0.65 / 0.90 / 0.76	0.66
		✓		0.61 / 0.92 / 0.73	0.60
			✓	0.61 / 0.94 / 0.74	0.60

Table 2: Feature ablation results for RBF kernel on `Y` vs. `N` case. The first line is the RBF result with all features from table 1.

4.2 Introducing erroneous named entities

The case of `Y` versus `N` and `X` together unsurprisingly performed worse than the case where named entity errors were eliminated. However, relative to its own random baseline, it performed well, with a 12% and 17% improvement in F-measure and accuracy using the RBF kernel. This suggests that the errors do not introduce enough noise into the system to produce a large decline in performance.

As `X` instances are about 26% of the total and we see a considerable drop in recall, we can say that some of the `X` instances are likely to be similar to valid `Y` ones; indeed, examination of the named entity recognizer's errors suggests that some incorrect organizations (e.g. product names) occur in contexts where valid organizations occur. However, precision and accuracy have not fallen nearly as far, so that the quality of the output for further processing is not hurt in proportion to the introduction of `X` class noise.

4.3 Feature ablation

Table 2 contains the result of our feature ablation experiments. Overall, the removal of features causes the SVM models to behave increasingly like a majority class assigner. As we mentioned earlier, higher recall at the expense of precision and accuracy is not an optimal outcome for us even if the F-measure is preserved. In our results, the F-measure values are remarkably stable.

In the first round of feature removal, the subjectivity keyword features have the biggest effect with the largest drop in precision and the largest increase in recall; high-TFIDF words from a general-purpose subjectivity lexicon allow the model to assign more items to the negative class.

The next round of feature removal shows that the proximity features have the next largest amount of influence on the classifier, as precision drops by 4%. The proximity features are very similar to the subjectivity features in that they too involve queries over windows of limited word sizes; the subjectivity keyword features only differ in that a subjectivity keyword must be within the window as well. That the proximity features are not more important than the subjectivity features, implies that the subjectivity keywords matter to the classifier, even though they are not specific to the IT domain. However, the proximity of sources and targets also matters, even in the absence of the subjectivity keywords.

Finally, we are left with the frequency features and the unigram context features. Either set of features supports a level of performance greater than the random baseline in table 1. However, the unigram features allow for slightly better recall than the frequency features without loss of precision, but this may not be very surprising, as there are *many* more unigram features than frequency features. More importantly, however, either of these feature types is sufficient to prevent the classifier from assigning the majority class all of the time, although they come close.

Feature type	Range	Keyword
Subjectivity	500	agreement
Subjectivity	500	critical
Subjectivity	500	want
Subjectivity	100	will
Subjectivity	100	able
Subjectivity	500	worth
Subjectivity	500	benefit
Subjectivity	100	trying
Subjectivity	500	large
Subjectivity	500	competitive

Table 3: The 10 most positive features via a linear kernel in descending order.

Feature type	Range	Keyword
Subjectivity	500	low
Subjectivity	500	ensure
Subjectivity	25	want
Subjectivity	100	vice
Subjectivity	500	slow
Subjectivity	100	large
Subjectivity	500	ready
Subjectivity	100	actually
Subjectivity	100	ready
Subjectivity	100	against

Table 4: The 10 most negative features via a linear kernel in descending order.

4.4 Most discriminative features

The models generated by svmlight under a linear kernel allow for the extraction of feature weights by a script written by svmlight's creator. We divided the instances into a single 70%/30% train/test split and trained a classifier with a linear kernel and an error cost parameter of 100, with results similar to those reported under 10-fold cross-validation in table 1. We used all features.

Then we were able to extract the 10 most positive (table 3) and 10 most negative (table 4) features from the model.

Interestingly, all of these are subjectivity keyword features, even the negatively weighted features. The top positive features are often evocative of business language, such as "agreement", "critical", and "competitive". Most of them emerge from queries at the 500-word range, suggesting that their presence in the document itself is evidence that a source is expressing an opinion about a target. That most of them are subjectivity features is reflected in the feature ablation results in the previous section.

It is less clear why "ensure" and "against" should be evidence that a source-target pair is *not* an instance of "expresses-an-opinion-about". On the other hand, words like "ready" (which appears twice) and "actually" can conceivably reflect situations in the IT domain that are not matters of opinion. In either case, this demonstrates one of the advantages of our technique, as these are features that actively assist in classifying some relation instances as not expressing sentiment. For example, contrary to what we would expect, "want" in a 25-word window with a source and a target is actually evidence against an "expresses-an-opinion-about" relation in text about IT innovations (ComputerWorld, July 2007):

> But **Klein**, who is director of information services and technology, didn't want IT to become the *blog* police.

In this example, Klein is expressing a desire, but not about the innovation (blogs) in question.

5 Conclusions and future work

5.1 Summary

We constructed and evaluated a system that detects at paragraph level whether entities relevant to the IT domain have expressed an opinion about a list of IT innovations of interest to a larger social science research program. To that end, we used a combination of co-occurrence statistics gleaned from a document indexing tool and TFIDF values from the local term context. Under these novel conditions, we successfully exceeded simple baselines by large margins.

Despite only moderate annotator agreement, we were able to produce results coherent enough to successfully train classifiers and conduct experiments.

Our feature ablation study suggests that all of the feature types played a role in improving the performance of the system over the random and

majority-class baselines. However, the subjectivity keyword features from an existing lexicon played the largest role, followed by the proximity and unigram features. Subjectivity keyword features dominated the ranks of feature weights under a linear kernel, and the features most predictive of membership in "expresses-an-opinion-about" are words with semantic significance in the context of the IT business press.

5.2 Application to other domains

We used somewhat naïve statistics in a simple machine learning system in order to implement a form of opinion mining for a particular domain. The most direct linguistic guidance we provided our system were the query ranges and the subjectivity lexicon. The generality of this approach yields the advantage that it can be applied to other domains where there are ways of expressing sentiment unique to those domains outside of newswire text and product reviews.

5.3 Improving the features

Our use of an existing sentiment lexicon opens the door in future work for the use of techniques to bootstrap a larger sentiment lexicon that emphasizes domain-specific language in the expression of opinion, including opinionated acts. In fact, our results suggest that terminology in the existing lexicon that is most prominently weighted in our classifier also tends to be domain-relevant. In a further iteration, we might also improve performance by using terms outside the lexicon that tend to co-occur with terms from the lexicon.

5.4 Data generation

Our annotation exercise was a very simple one involving a short reading exercise and the selection of one of three choices per relation instance. This type of exercise is ideally suited to the "crowdsourcing" technique of paying many individuals small amounts of money to perform these simple annotations over the Internet. Previous research (Snow et al., 2008) suggests that we can generate very large datasets very quickly in this way; this is a requirement for expanding to other domains.

5.5 Scalability

In order to classify on the order of 1000 instances, it took nearly a million queries to the Indri index, which took a little over an hour to do in parallel on 25 processors by calling the Indri query engine afresh at each query. While each query is necessary to generate each feature value, there are a number of optimizations we could implement to accelerate the process. Various types of dynamic programming and caching could be used to handle related queries. One way of scaling up to larger datasets would be to use the MapReduce and cloud computing paradigms on which text processing tools have already been implemented (Moreira et al., 2007).

The application for this research is a social science exercise in exploring trends in IT adoption by analysing the IT business press. In the end, the perfect discovery of all instances of "expresses-an-opinion-about" is not as important as finding enough reliable data over a large number of documents. This work brings us several steps closer in finding the right combination of features in order to acquire trend-representative data.

Abstract

Sentiment analysis systems can benefit from the *translation* of sentiment information. We present a novel, graph-based approach using SimRank, a well-established graph-theoretic algorithm, to transfer sentiment information from a source language to a target language. We evaluate this method in comparison with semantic orientation using pointwise mutual information (SO-PMI), an established unsupervised method for learning the sentiment of phrases.

1 Introduction

Sentiment analysis is an important topic in computational linguistics that is of theoretical interest but is also useful in many practical applications. Usually, two aspects are of importance in sentiment analysis. The first is the detection of subjectivity, i.e., whether a text or an expression is meant to express sentiment at all; the second is the determination of sentiment orientation, i.e., what sentiment is to be expressed in a structure that is considered subjective.

Work on sentiment analysis most often covers resources or analysis methods in a single language, usually English. However, the transfer of sentiment analysis between languages can be advantageous by making use of resources for a source language to improve the analysis of the target language.

This paper presents an approach to the transfer of sentiment information between two languages that does not rely on resources with limited availability like parallel corpora. It is built around SimRank, a graph similarity algorithm that has successfully been applied to the acquisition of bilingual lexicons (Laws et al., 2010) and semantic similarity (Michelbacher et al., 2010). It uses linguistic relations extracted from two monolingual corpora to determine the similarity of words in different languages. One of the main benefits of our method is its ability to handle sparse data about the relations between the languages well (i.e., a small seed lexicon). Further, we experiment with combining multiple types of linguistic relations for graph-based translation. Our experiments are carried out using English as a source language and German as a target language. We evaluate our method using a hand-annotated set of German adjectives which we intend to publish.

In the following section, related work is discussed. Section 3.1 gives an introduction to SimRank and its application to lexicon induction, while section 3.2 reviews SO-PMI (Turney, 2002), an unsupervised baseline method for the generation of sentiment lexicons. In section 4, we define our sentiment transfer method which we apply in experiments in section 5.

2 Related Work

Mihalcea et al. (2007) propose two methods for translating sentiment lexicons. The first method simply uses bilingual dictionaries to translate an English sentiment lexicon. A sentence-based classifier built with this list achieved high precision, but low recall on a small Romanian test set. The second method is based on parallel corpora. The source language in the corpus is annotated with sentiment information, and the information is then projected to the target language. Problems arise due to mistranslations.

Banea et al. (2008) use machine translation for multilingual sentiment analysis. Given a corpus annotated with sentiment information in one language, machine translation is used to produce an annotated corpus in the target language, by preserving the annotations. The original annotations

Coling 2008: Poster Volume, pages 1104–1112,
Beijing, August 2010

can be produced either manually or automatically.

Wan (2009) constructs a multilingual classifier using co-training. In co-training, one classifier produces additional training data for a second classifier. In this case, an English classifier assists in training a Chinese classifier.

The induction of a sentiment lexicon is the subject of early work by Hatzivassiloglou and McKeown (1997). They construct graphs from coordination data from large corpora based on the intuition that adjectives with the same sentiment orientation are likely to be coordinated. For example, *fresh and delicious* is more likely than *rotten and delicious*. They then apply a graph clustering algorithm to find groups of adjectives with the same orientation. Finally, they assign the same label to all adjectives that belong to the same cluster.

Corpus work and bilingual dictionaries are promising resources for translating sentiment. In contrast to previous approaches, the work presented in this paper uses corpora that are not annotated with sentiment.

Turney (2002) suggests a corpus-based extraction method based on his pointwise mutual information (PMI) synonymy measure. He assumes that the sentiment orientation of a phrase can be determined by comparing its pointwise mutual information with a positive (*excellent*) and a negative phrase (*poor*). An introduction to this method is given in Section 3.2.

3 Background

3.1 Lexicon Induction via SimRank

We use the extension of the SimRank (Jeh and Widom, 2002) node similarity algorithm proposed by Dorow et al. (2009). Given two graphs $\mathcal{A}$ and $\mathcal{B}$, the similarity between two nodes a in $\mathcal{A}$ and b in $\mathcal{B}$ is computed in each iteration as:

$$S(a,b) = \frac{c}{|N_A(a)||N_B(b)|} \sum_{k \in N_A(a), l \in N_B(b)} S(k,l).$$

$N_X(x)$ is the neighborhood of node x in graph X. To compute similarities between two graphs, some initial links between these graphs have to be given, called seed links. These form the recursion basis which sets $S(a,b) = 1$ if there is a seed link between a and b. At the beginning of each iteration, all known equivalences between nodes are reset to 1.

Multi-Edge Extraction (MEE). MEE is an extension of SimRank that, in each iteration, computes the average node-node similarity of several different SimRank matrices. In our case, we use two different SimRank matrices, one for coordinations and one for adjective modification. See (Dorow et al., 2009) for details. We also used the node degree normalization function $h(n) = \sqrt{n} \times \sqrt{\max_k(|N(k)|)}$ (where n is the node degree, and $N(k)$ the degree of node k) to decrease the harmful effect of high-degree nodes on final similarity values. See (Laws et al., 2010) for details.

3.2 SO-PMI

Semantic orientation using pointwise mutual information (SO-PMI) (Turney, 2002) is an algorithm for the unsupervised learning of semantic orientation of words or phrases. A word has positive (resp. negative) orientation if it is associated with positive (resp. negative) terms more frequently than with negative (resp. positive) terms. Association of terms is measured using their pointwise mutual information (PMI) which is defined for two words w_1 and w_2 as follows:

$$\text{PMI}(w_1, w_2) = log\left(\frac{p(w_1, w_2)}{p(w_1)p(w_2)}\right)$$

Using PMI, Turney defines SO-PMI for a word w as

$$\text{SO-PMI}(w) =$$

$$log\frac{\prod_{p \in P} hits(word \text{ NEAR } p) \times \prod_{n \in N} hits(n)}{\prod_{n \in N} hits(word \text{ NEAR } n) \times \prod_{p \in P} hits(p)}$$

$hits$ is a function that returns the number of hits in a search engine given the query. P is a set of known positive words, N a set of known negative words, and `NEAR` an operator of a search engine that returns documents in which the operands occur within a close range of each other.

4 Sentiment Translation

Unsupervised methods like SO-PMI are suitable to acquire basic sentiment information in a language. However, since hand-annotated resources for sentiment analysis exist in other languages, it seems plausible to use automatic translation of sentiment information to leverage these resources. In order to translate sentiment, we will use multiple sources of information that we represent in a MEE graph as given in Section 3.1.

In our first experiments (Scheible, 2010), coordinated adjectives were used as the sole training source. Two adjectives are coordinated if they are linked with a conjunction like *and* or *but*. The intuition behind using coordinations – based on work by Hatzivassiloglou and McKeown (1997) and Widdows and Dorow (2002) – was that words which are coordinated share properties. In particular, coordinated adjectives usually express similar sentiments even though there are exceptions (e.g., "The movie was both good and bad").

In this paper, we focus on using multiple edge types for sentiment translation. In particular, the graph we will use contains two types of relations, *coordinations* and *adjective-noun modification*. In the sentence "The movie was enjoyable and fun", *enjoyable* and *fun* are coordinated. In *This is an enjoyable movie*, the adjective *enjoyable* modifies the noun *movie*.

We selected these two relation types for two reasons. First, the two types provide clues for sentiment analysis. Coordination information is an established source for sentiment similarity (e.g. Hatzivassiloglou and McKeown (1997)) while adjective-noun relations provide a different type of information on sentiment. For example, nouns with positive associations (*vacation*) tend to occur with positive adjectives and nouns with negative associations (*pain*) tend to occur with negative adjectives. Second, we have successfully used these two types for a similar acquisition task, the acquisition of word-to-word translation pairs (Laws et al., 2010).

In the resulting graph, adjectives and nouns are represented as nodes, each containing a word and its part of speech, and relations are represented as links which are distinguished by their edge types. Two graphs, one in the source language and one in the target language, are needed to translate words between those languages. Figure 1 shows an example for such a setup. Black links in this graph are coordinations, grey links are seed relations.

In order to calculate sentiment for all nodes in the target language, we apply the SimRank algorithm to the graphs which gives us similarities between all nodes in the source graph and all nodes in the target graph. Using the similarity $S(n_s, n_t)$ between a node n_s in the source language graph $\mathcal{S}$ and a node n_t in the target language graph $\mathcal{T}$, the sentiment score ($\text{sent}(n_t)$) is the similarity-weighted average of all sentiment scores in the target language:

$$\text{sent}(n_t) = \sum_{n_s \in \mathcal{S}} \text{sim}_{\text{norm}}(n_s, n_t)\, \text{sent}(n_s)$$

We assume that sentiment scores in the source language are expressed on a numeric scale. The normalized similarity sim_{norm} is defined as

$$\text{sim}_{\text{norm}}(n_s, n_t) = \frac{S(n_s, n_t)}{\sum_{n_s \in \mathcal{S}} S(n_s, n_t)}.$$

The normalization assures that all resulting sentiment values are within $[-1, 1]$, with -1 being the most negative sentiment and 1 the most positive.

5 Experiments

5.1 Data Acquisition

For our experiments, we needed coordination data to build weighted graphs and a bilingual lexicon to define seed relations between those graphs. Coordinations were extracted from the English and German versions of Wikipedia[1] by applying pattern-based search using the Corpus Query Processor (CQP) (Christ et al., 1999). We annotated both corpora with parts of speech using the Tree Tagger (Schmid, 1994). A total of 477,291 English coordinations and 112,738 German coordinations were collected. A sample of this data is given in Figure 2. We restrict these experiments to the use of *and*/*und* since other coordinations

[1] `http://www.wikipedia.org/` (01/19/2009)

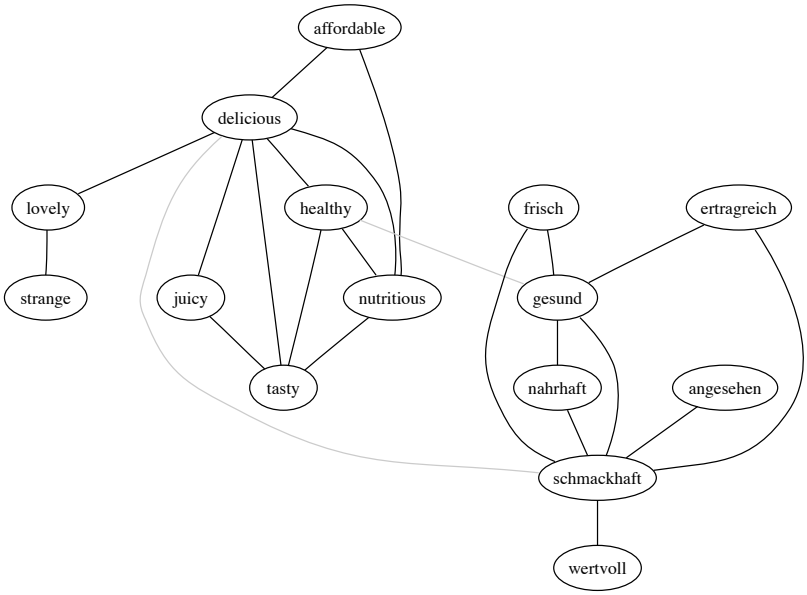

Figure 1: A German and an English graph with coordinated adjectives including seed links

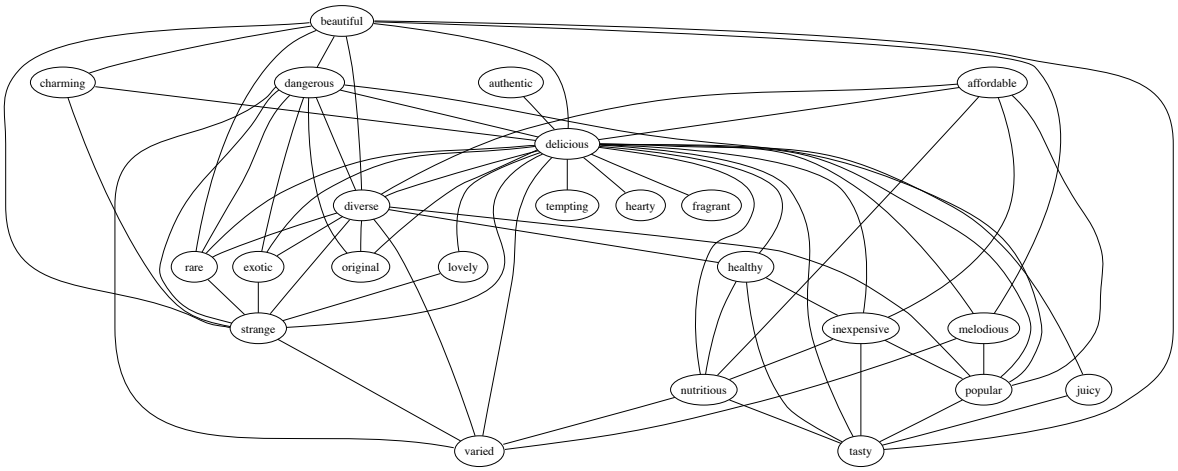

Figure 2: English sample coordinations (adjectives)

behave differently and might even express dissimilarity (e.g. *Was the weather good or bad?*).

The seed lexicon was constructed from the dict.cc dictionary[2]. While the complete dictionary contains 30,551 adjective pairs, we reduced the number of pairs used in the experiments to 1,576.

To produce a smaller seed lexicon which still makes sense from a semantic point of view, we used the General Service List (GSL) (West, 1953) which contains about 2000 words the author considered central to the English language. More specifically, a revised list was used[3].

SO-PMI needs a larger amount of training data. Since Wikipedia does not satisfy this need, we collected additional coordination data from the web using search result counts from Google. In Turney's original paper, he uses the `NEAR` operator, which returns documents that contain two search terms that are within a certain distance of each other, to collect collocations. Unfortunately, Google does not support this operator, so instead, we searched for coordinations using the queries

`+ "w and s"` and
`+ "w und s"`

for English and German, respectively. We added the quotes and the + operator to make sure that both spelling correction and synonym replacements were disabled.

The original experiments were made for English, so we had to construct our own set of seed words. For German, we chose *gut (good)*, *nett (nice)*, *richtig (right)*, *schön (beautiful)*, *ordentlich (neat)*, *angenehm (pleasant)*, *aufrichtig (honest)*, *gewissenhaft (faithful)*, and *hervorragend (excellent)* as positive seed words, and *schlecht (bad)*, *teuer (expensive)*, *falsch (wrong)*, *böse (evil)*, *feindlich (hostile)*, *verhasst (invidious)*, *widerlich (disgusting)*, *fehlerhaft (faulty)*, and *mangelhaft (flawed)* as negative ones.

5.2 Sentiment Lexicon

For our experiments, we used two different polarity lexicons. The lexicon of Wilson et al. (2005) contains sentiment annotations for 8,221 words which are tagged as *positive*, *neutral*, or *negative*. A few words are tagged as *weakneg*, implying weak negativity. These categorial annotations are mapped to the range [-1,1] using the assignment scheme given in Table 1.

annotation	value
positive	1.0
weakpos	0.5
neutral	0.0
weakneg	−0.5
negative	−1.0

Table 1: Assigned values for Wilson et al. set

5.3 Human Ratings

In order to manually annotate a test set, we chose 200 German adjectives that occurred in the Wikipedia corpus and that were part of a coordination. From these words, we removed those which we deemed uncommon, too complicated, or which were mislabeled as adjectives by the tagger. The test set contained 150 adjectives of which seven were excluded after annotators discarded them.

We asked 9 native speakers of German to annotate the adjectives. Possible annotations were *very positive*, *slightly positive*, *neutral*, *slightly negative*, or *very negative*. These categories are the same as the ones used in the training data.

In order to capture the general sentiment, i.e., sentiment that is not related to a specific context, the judges were asked to stay objective and not let their personal opinions influence the annotation. However, some words with strong political implications were annotated by some judges as non-neutral which led to disagreement beyond the usual level. *Nuklear* (*nuclear*) is an example for such a word. We measured the agreement of the judges with Kendall's coefficient of concordance (W) with tie correction (Legendre, 2005), yielding $W = 0.674$ with a high level of significance ($p < .001$); thus, inter-annotator agreement was high (Landis and Koch, 1977).

5.4 Experimental Setup

Given the relations extracted from Wikipedia, we built a German and an English graph by setting

[2] `http://www.dict.cc`
[3] `http://jbauman.com/aboutgsl.html`

Method	r
MEE	0.63
MEE-GSL	0.47
SR	0.63
SR-GSL	0.48
SO-PMI	0.58

Table 2: Correlation with human ratings

the weight of each link to the log-likelihood ratio of the two words it connects according to the corpus frequencies. There are two properties of the graph transfer algorithm that we intend to investigate. First, we are interested in the merits of applying multi edge extraction (MEE) for sentiment transfer. Second, we are interested in how the transfer quality changes when the seed lexicon is reduced in size. This way, a sparse data situation is simulated where large dictionaries are unavailable. Having these two properties in mind, four possible setups are evaluated: (i) using the full seed lexicon with all $30{,}551$ entries, but using only coordination data (*SR*), (ii) reducing the seed lexicon to $1{,}576$ entries from the General Service List (*SR-GSL*), (iii) applying MEE by adding adjective modification data (*MEE*), and (iv) using MEE with a reduced seed lexicon (*MEE-GSL*). SimRank was run for 6 iterations in all experiments. All experiments use the weight function h as described above. We show that this function improves similarities and thus lexicon induction in Laws et al. (2010).

Correlation. First, we will examine the correlation between the automatic methods (SO-PMI and the aforementioned SimRank variations) and the gold standard as done by Turney in his evaluation. For this purpose, the human ratings are mapped to float values following Table 1 and the average rating over all judges for each word is used. The correlation coefficients r are given in Table 2. Judging from these results, the ordering of SR and MEE matches the human ratings better than SO-PMI, however it decreases when using any of the GSL variations instead which can be attributed to using less data.

Classification. The correct identification of the classes *positive*, *neutral*, and *negative* is more important than the correct assignment of values on a scale since the rank ordering is debatable – this becomes apparent when measuring the agreement of human annotators. Since the assignments made by the human judges are not unanimous in most cases, the averages are distributed across the interval [-1,1]; this means that the borders between the three distinct categories are not clear. Since there is no standard evaluation for this particular problem, we need to devise a way to make the range of the neutral category dynamic. In order to find possible borders, we first assume that sentiment is distributed symmetrically around 0. We then define a threshold x which assumes the values $x \in \{\frac{i}{20} | 0 \leq i \leq 20\}$, covering the interval [0,0.5]. Since 0.5 is *slightly positive*, we do not believe that values above it are plausible. Then, each word w is positive if its human rating $\text{score}_h(w) \geq x$, negative if $\text{score}_h(w) \leq -x$, and neutral if $-x < \text{score}_h(w) < x$. The result of this process is a gold standard for the three categories for each of the values for x. The percentiles of the sizes of those categories are mapped to the values produced by the automatic methods. For example, if $x = 0.35$ means that the top 21% of all adjectives are in the positive class, the top 21% of all adjectives as assigned by SO-PMI and the SimRank varieties are positive as well.

The size of the neutral category increases the larger x becomes. Thus, high values for x are unlikely to produce a correct partitioning of the data. Since *slightly positive* was defined as 0.5, we expect the highest plausible value for x to be below that. The size of the neutral category for each value of x is given in Table 3. (Recall that the total size of the set is 143.)

We can then compute the assignment accuracy on the positive, neutral, and negative classes, as well macro- and micro-averages over these classes.

5.5 Results and Discussion

Figures 3 and 4 show the macro- and micro-averaged accuracies over the positive, negative, and neutral class for each automatic method, respectively. Overall, the SimRank variations perform better for x in the interval $[0, 0.3]$. In particular, MEE has a slightly higher accuracy than SR,

x	0.00	0.05	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50
# neutral	0	13	35	46	56	64	74	82	92	99	99

Table 3: Size of neutral category given x

word (translation)	**humans**	**SO**	**MEE**	**MEE-GSL**	**SR**	**SR-GSL**
chemisch (chemical)	0.00	-20.20	0.185	0.185	0.186	0.184
auferstanden (resurrected)	0.39	-10.96	-0.075	-0.577	-0.057	-0.493
intelligent (intelligent)	0.94	46.59	0.915	0.939	0.834	0.876
versiert (skilled)	0.67 -5.26 0.953 0.447 0.902 0.404					
mean	-0.04	-9.58	0.003	0.146	0.010	0.142
median	0.00	-15.60	0.110	0.157	0.114	0.157

Table 4: Example adjectives including translation, and their scores

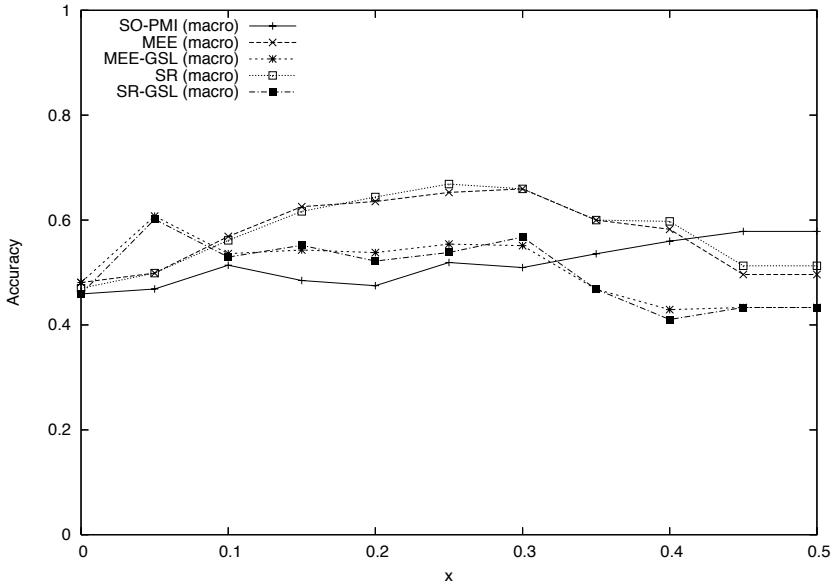

Figure 3: Macro-averaged Accuracy

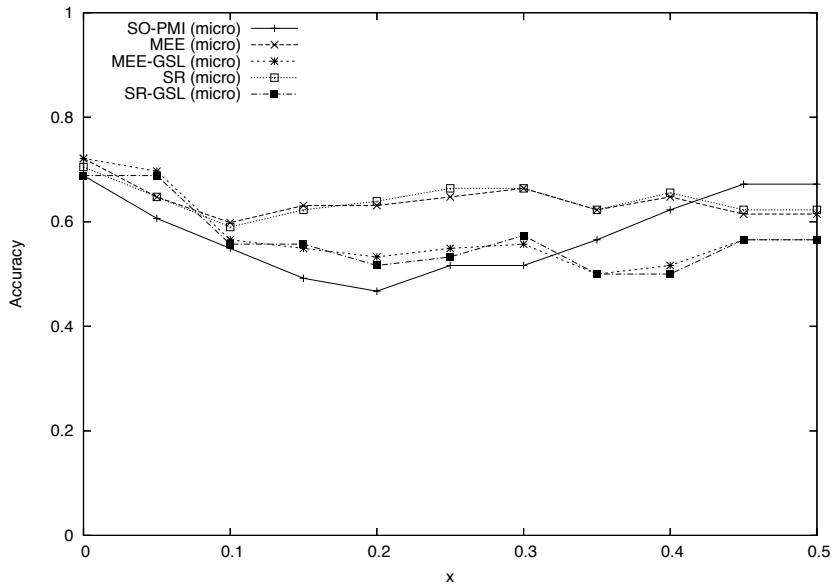

Figure 4: Micro-averaged Accuracy

however, not significantly.

Table 4 shows selected example words with their scores. These values can be understood better together with the means and medians of the respective methods which are given in the table as well. These values give us an idea of where we might expect the neutral point of a particular distribution of polarities.

Chemisch (chemical) is misclassified by SO-PMI since it occurs in negative contexts on the web. SimRank in turn was able to recognize that most words similar to *chemisch* are neutral, the most similar one being its literal translation, *chemical*. *Auferstanden (resurrected)* is an example for misclassification by SimRank which happens because the word is usually coordinated with words that have negative sentiment, e.g. *gestorben (deceased)* and *gekreuzigt (crucified)*. This problem could not be fixed by including adjective-noun modification data since the coordinations produced high log-likelihood values which lead to *dead* being the most similar word to *auferstanden*. *Intelligent* receives a score close to neutral with the original (coordination-only) training method, which could be corrected by applying MEE simply because the ordering of similar words changes through the new weighting method. Nouns modified by *intelligent* include *Leben (life)* and *Wesen (being)* whose translations are modified by positive adjectives. Many words, such as *versiert (skilled)* are classified more accurately due to the new weighting method when compared to our previous experiments (Scheible, 2010) where it received a SimRank polarity of only 0.224.

The inclusion of adjective modifications does not improve the classification results as often as we had hoped. For some cases (cf. *intelligent* mentioned above), the scores do improve, but the overall impact is limited.

6 Conclusion and Outlook

We were able to show that sentiment translation with SimRank is able to classify adjectives more accurately than SO-PMI, an unsupervised baseline method. We demonstrated that SO-PMI is outperformed by SimRank when choosing a reasonable region of neutral adjectives. In addition, we showed that the improvements of SimRank lead to better accuracy in sentiment translation in some cases. In future work, we will apply a sentiment lexicon generated with SimRank in a sentiment classification task for reviews.

The algorithms we compared are different in their purpose of application. While SO-PMI is applicable when large corpora are available for a language, it fails when used in a sparse-data situation, as noted by Turney (2002). We showed that despite reducing the seed lexicon for SimRank to a small fraction of its original size, it still performs better than SO-PMI.

Currently, our experiments are limited by the choice of using adjectives for our test set. While the examination of adjectives is highly important for sentiment analysis (as shown by Pang et al. (2002) who were able to achieve high accuracy even when using only adjectives), the application of our algorithms to a broader set of linguistic units is an important goal for future work.

Acknowledgments. We are grateful to Deutsche Forschungsgemeinschaft for funding this research as part of the WordGraph project.

Controlled Natural Languages for Knowledge Representation

Rolf Schwitter
Centre for Language Technology
Macquarie University
Rolf.Schwitter@mq.edu.au

Abstract

This paper presents a survey of research in controlled natural languages that can be used as high-level knowledge representation languages. Over the past 10 years or so, a number of machine-oriented controlled natural languages have emerged that can be used as high-level interface languages to various kinds of knowledge systems. These languages are relevant to the area of computational linguistics since they have two very interesting properties: firstly, they look informal like natural languages and are therefore easier to write and understand by humans than formal languages; secondly, they are precisely defined subsets of natural languages and can be translated automatically (and often deterministically) into a formal target language and then be used for automated reasoning. We present and compare the most mature of these novel languages, show how they can balance the disadvantages of natural languages and formal languages for knowledge representation, and discuss how domain specialists can be supported writing specifications in controlled natural language.

1 Introduction

Natural languages are probably the most expressive knowledge representation languages that exist; they are easy for humans to use and understand, and they are so powerful that they can even serve as their own metalanguages. Ironically, it is just this expressive quality that makes natural languages notoriously difficult for a computer to process and understand because a lot of relevant information is usually not stated explicitly in an utterance but only implied by the human author or speaker. There exist – of course – many useful resources and automated techniques that partly compensate for the lack of this background knowledge, and there are many useful applications that require only shallow processing of natural languages. But there exist – without doubt – many potential application scenarios that would benefit from deeper (axiom-based) knowledge that can be created and modified in a human-friendly way.

Formal languages (Monin, 2003) have been suggested and used as knowledge representation languages since they have a well-defined syntax, an unambiguous semantics and support automated reasoning. But these languages are often rather difficult for domain specialists to understand and cause a cognitive distance to the application domain that is not inherent in natural language.

One way to bridge the gap between a natural language and a formal language is the use of a controlled natural language (CNL) that can mediate between these languages. CNLs are engineered subsets of natural languages whose grammar and vocabulary have been restricted in a systematic way in order to reduce both ambiguity and complexity of full natural languages.

Traditionally, CNLs have been grouped into two broad categories: human-oriented CNLs and machine-oriented CNLs (Huijsen, 1998). The main objective of human-oriented CNLs is to improve the readability and comprehensibility of technical documentation (e.g. maintenance doc-

Coling 2008: Poster Volume, pages 1113–1121,
Beijing, August 2010

umentation (ASD Simplified Technical English[1]) and to simplify and standardise human-human communication for specific purposes (e.g. for trade or for air traffic control (see (Pool, 2006) for an overview)). The primary goal of machine-oriented CNLs is to improve the translatability of technical documents (e.g. machine translation (Nyberg and Mitamura, 2000)) and the acquisition, representation, and processing of knowledge (e.g. for knowledge systems (Fuchs et al., 2008) and in particular for the Semantic Web (Schwitter et al., 2008)).

Human- and machine-oriented CNLs have been designed with different goals in mind, and it is not surprising that their coverage can be quite different. O'Brien (2003) shows that there is not much overlap between the rule sets of CNLs in these two categories nor among the rule sets within a category. But since the structure of these CNLs is usually simpler and more predictable than the structure of full natural language, CNLs are in general easier for humans to understand and easier for a computer to process. An ideal CNL for knowledge representation should also be effortless to write and expressive enough to describe the problem at hand.

In this paper, we will survey machine-oriented CNLs that can be used for knowledge representation and can serve as high-level interface languages to knowledge systems. The rest of this paper is structured as follows: In Section 2, we introduce the most mature general-purpose CNLs and discuss the motivation for their design and investigate their characteristics. In Section 3, we discuss some theoretical issues regarding the expressivity and complexity of CNLs. Building on these theoretical considerations, we look in Section 4 at a number of machine-oriented CNLs that have been developed specifically as interface languages to the Semantic Web. In Section 5, we discuss the importance of supporting the writing process of CNLs in an suitable way and compare three different techniques. In Section 6, we discuss different approaches that have been used to evaluate the writability and understandability of CNLs, and finally in Section 7, we present our conclusions.

2 General-Purpose CNLs

In this section we focus on a number of machine-oriented CNLs that have been designed to serve as knowledge representation languages. These CNLs are general-purpose languages in the sense that they have not been developed for a specific scenario or a particular application domain. These languages can be used where traditional formal languages are used otherwise. The aim of these languages is to equip domain specialists with an expressive knowledge representation language that is on the one hand easy to learn, use and understand and on the other hand fully processable by a computer.

2.1 Attempto Controlled English (ACE)

ACE (Fuchs et al., 2008) is a CNL that covers a well-defined subset of English that can be translated unambiguously into first-order logic via discourse representation structures (Kamp and Reyle, 1993) and then be used for automated reasoning. ACE is defined by a small set of construction rules that describe its syntax and a small set of interpretation rules that disambiguate constructs that might appear ambiguous in full English. The vocabulary of ACE consists of predefined function words (e.g. determiners, conjunctions, and pronouns), some predefined fixed phrases (e.g. *there is, it is false that*), and content words (nouns, proper names, verbs, adjectives, and adverbs). ACE supports language constructs such as:

- active and passive verbs (and modal verbs);
- strong negation (e.g. *no, does not*) and weak negation (e.g. *is is not provable that*);
- subject and object relative clauses;
- declarative, interrogative, imperative and conditional sentences;
- various forms of anaphoric references to noun phrases (e.g. *he, himself, the man, X*).

It is important to note that the meaning of words in ACE is not predefined; the user is expected to define their meaning by ACE sentences or import these definitions from an existing formal ontology.

Here is a simple example of an ACE text together with a question:

> Every company that buys at least three machines gets a discount. Six Swiss companies each buy one machine. A German company buys four machines. Who gets a discount?

Note that ACE uses disambiguation markers (e.g. *each*) on the surface level and mathematical background knowledge about natural numbers in order to answer the question above. This mathematical knowledge is implemented as a set of Prolog predicates which are executed during the proof (question answering process).

ACE is supported by various tools[2], among them a text editor that helps users to construct correct ACE sentences with the help of hints and error messages, a parser that translates ACE texts into discourse representation structures, a paraphraser that reflects the interpretation of the machine in CNL, and a Satchmo-style reasoning engine that can be used for consistency and redundancy checking as well as for question answering. Applications of ACE include software and hardware specifications, agent control, legal and medical regulations, and ontology construction.

2.2 Processable English (PENG)

PENG (White and Schwitter, 2009) is a CNL that is similar to ACE but adopts a more light-weight approach in the sense that it covers a smaller but fully tractable subset of English. The language processors of ACE and PENG are both based on grammars that are written in a definite clause grammar (DCG) notation. These DCGs are enhanced with feature structures and specifically designed to translate declarative and interrogative sentences into a first-order logic notation via discourse representation structures. In contrast to the original version of ACE that uses the DCG directly and resolves anaphoric references only after a discourse representation structure has been constructed, PENG transforms the DCG into a format that can be processed by a top-down chart parser and resolves anaphoric references during the parsing process while a discourse representation structure is built up. PENG has been designed for an incremental parsing approach and was the first CNL that was supported by a predictive editor (Schwitter et al., 2003). The PENG system provides text- and menu-based writing support that removes some of the burden of learning and remembering the constraints of the CNL from the user and generates a paraphrase that clarifies the interpretation for each sentence that the user enters. PENG's text editor dynamically enforces the grammatical restrictions of the CNL via look-ahead information while a text is written. For each word form that the user enters into the editor, a list of options is generated incrementally by the chart parser to inform the user about how the structure of the current sentence can be continued. The syntactic restrictions ensure that the text follows the rules of the CNL so that it can be translated unambiguously into the formal target language (first-order logic) and be processed by a theorem prover.

In order to illustrate how PENG can be used to reconstruct a problem in controlled natural language, we use an example from the TPTP problem library[3]. The problems in this library are usually used to test the capacity of automated reasoning tools and are translated manually by a human into the formal target language. For reasons of space, we use here one of the simpler problems of the library; the puzzle PUZ012-1 below is also known as "The Mislabeled Boxes":

> There are three boxes a, b, and c on a table. Each box contains apples or bananas or oranges. No two boxes contain the same thing. Each box has a label that says it contains apples or says it contains bananas or says it contains oranges. No box contains what it says on its label. The label on box a says "apples". The label on box b says "oranges". The label on box c says "bananas". You pick up box b and it contains apples. What do the other two boxes contain?

In order to solve this puzzle by a computer, we have to reconstruct it and augment it with the

[2] http://attempto.ifi.uzh.ch/site/tools/

[3] http://www.cs.miami.edu/~tptp/

relevant background knowledge. The main problems that we face here for machine-processing are the following ones: some of the constructions in the problem description are ambiguous (e.g. the antecedent for the personal pronoun *it* is open to two interpretations); the semantic relation between some content words is not explicit (e.g. the relation between the actual things in the box and the names on the labels that describe these things); and some of the constructions are not relevant at all for the solution of the problem (e.g. that the three boxes are on the table). Here is a possible reconstruction of this puzzle in PENG:

> The label of the box a says APPLES. The label of the box b says ORANGES. The label of the box c says BANANAS. APPLES stands for apples. ORANGES stands for oranges. BANANAS stands for bananas. All apples are fruits. All bananas are fruits. All oranges are fruits. Each box contains the apples or contains the bananas or contains the oranges. It is not the case that a box contains fruits and that the label of the box says something that stands for those fruits. It is not the case that a box X contains fruits and that a box Y contains those fruits. The box b contains the apples. What does the box a contain? What does the box c contain?

Note that this reconstruction makes information that is implicit or only assumed in the original problem description explicit in PENG.

PENG has recently been used for the construction of an interface to a situation awareness system (Baader et al., 2009) but the language can be used for similar applications to ACE.

2.3 Computer Processable Language (CPL)

CPL (Clark et al., 2010) is a controlled language that has been developed at Boeing Research and Technology. In contrast to ACE which applies a small set of strict interpretation rules, and in contrast to PENG, which relies on a predictive editor, the CPL interpreter directly resolves various types of ambiguities using heuristic rules for prepositional phrase attachment, word sense disambiguation, semantic role labeling, compound noun interpretation, metonymy resolution, and other language processing activities.

CPL accepts three types of sentences: ground facts, questions, and rules. In the case of ground facts, a basic CPL sentence takes one of the following three forms:

- There is|are *NP*
- *NP verb* [*NP*] [*PP*]*
- *NP* is|are *passive-verb* [by *NP*] [*PP*]*

Verbs can include auxiliaries and particles, and nouns in noun phrases can be modified by other nouns, prepositional phrases, and adjectives. In the case of questions, CPL accepts five forms; the two main forms are:

- What is *NP*?
- Is it true that *Sentence*?

In the case of rules, CPL accepts sentence patterns of the form:

- IF *Sentence* [AND *Sentence*]* THEN *Sentence* [AND *Sentence*]*

Parsing of CPL is performed bottom-up with the help of a broad coverage chart parser that uses preference for common word attachment patterns stored in a manually constructed database. During parsing, a simplified logical form is generated for basic sentences by rules that run in parallel to the grammar rules. There is no explicit quantifier scoping for these basic sentences and some disambiguation decisions (e.g., word sense and semantic relationships) are deferred and handled by the inference engine that makes a "best guess" of word sense assignments using WordNet[4]. The logical form is used to generate ground Knowledge Machine (KM) assertions. KM[5] is a frame-based language with first-order semantics. The KM interpreter employs a sophisticated machinery for reasoning, including reasoning about actions using a situation calculus mechanism. Rules

[4] http://wordnet.princeton.edu/

[5] http://userweb.cs.utexas.edu/users/mfkb/km.html

are entered by the user who writes CPL sentences with the help of rule templates. There exist seven templates for this purpose: three of them create standard logical implications and the rest describe preconditions and effects of actions. Each CPL sentence is interpreted interactively. The system paraphrases its interpretation back to the user, allowing the user to spot and fix misinterpretations. Sentences that express states add facts to a situation, and sentences that express actions trigger rules that update the situation, reflecting the changes that the action has on the situation. The user can ask questions about an emerging situation directly in CPL.

While CPL relies on heuristics, CPL-Lite is a slimmed down version of CPL that can be interpreted deterministically in a similar fashion to PENG. Each CPL-Lite sentence corresponds to a single binary relation between two entities. CPL-Lite distinguishes three types of relations: noun-like relations (e.g. the age of $<x>$ is $<y>$), verb-like relations (e.g. $<x>$ causes $<y>$), and preposition-like relations (e.g. $<x>$ is during $<y>$).

Interestingly, CPL-Lite has the same expressivity as CPL, but CPL-Lite is more verbose and grammatically more restricted. For example, the following two CPL sentences:

1. A man drives a car along a road for 1 hour.
2. The speed of the car is 30 km/h.

can be expressed (or better reconstructed) in an unambiguous way in CPL-Lite:

3. A person drives a vehicle.
4. The path of the driving is a road.
5. The duration of the driving is 1 hour.
6. The speed of the driving is 30 km/h.

Note that the user used here the noun *person* instead of *man* and *vehicle* instead of *car* during this reconstruction process because only these words were available in the system's ontology.

CPL and CPL-Lite have been mainly used to encode general and domain specific commonsense knowledge and to allow knowledge engineers to pose queries in a comprehensible way.

2.4 Other General-Purpose CNLs

Common Logic Controlled English (CLCE)[6] is a proposal for a CNL – similar to ACE and PENG – that has been designed as a human interface language for the ISO standard Common Logic (CL)[7]. However, CLCE itself is not part of this standard but uses Common Logic semantics. CLCE supports full first-order logic with equality supplemented with an ontology for sets, sequences, and integers. The primary syntactic restrictions are the use of present tense verbs, singular nouns, and variables instead of pronouns. Despite these limitations, CLCE can express the kind of English used in software specifications, mathematics textbooks, and definitions and axioms found in formal ontologies.

Formalized-English (Martin, 2002) is another proposal for a CNL that can be used as a general knowledge representation language. This language has a relatively simple structure and is derived from a conventional knowledge representation language. Formalized-English contains a number of formal-looking language elements and is therefore not a strict subset of standard English.

3 Theoretical Considerations

During the design of a CNL one has to pay attention to two important theoretical issues: the expressive power of the envisaged language and its computational complexity. E2V (Pratt-Hartmann, 2003) is a CNL that mainly grew out of theoretical studies about the expressivity and complexity of natural language fragments. E2V corresponds to the decidable two-variable fragment of first-order logic ($\mathcal{L}^2$). This fragment is interesting since it has the so-called finite model property. That means if a formula of $\mathcal{L}^2$ is satisfiable, then it is satisfiable in a finite model. E2V includes determiners (*every, no, a*), nouns, transitive verbs, verb phrase negation, relative, reflexive, and personal pronouns. Without any writing support it is difficult to decide if a sentence is in E2V or not. For example, one reading of sentence (7) is in E2V, the other one is not:

[6] http://www.jfsowa.com/clce/specs.htm
[7] ISO/IEC24707:2007

7. Every artist who employs a carpenter despises every beekeeper who admires him.

On the syntactic level, E2V is a subset of ACE with the exception that pronouns (e.g. *him*) always refer to the closest (acceptable) noun in the syntax tree (e.g. *artist*) and not to the closest (acceptable) noun that occurs in the surface structure (e.g. *carpenter*). This is because the E2V interpretation relies on the two-variable fragment of first-order logic. Note that sentence (7) has the following two possible representations (8 and 9) in first-order logic:

8. $\forall x_1$ (artist(x_1) & $\exists x_2$ (carpenter(x_2) & employ(x_1,x_2)) -> $\forall x_3$ (beekeeper(x_3) & admire(x_3,x_1) -> despise(x_1,x_3)))

9. $\forall x_1$ $\forall x_2$ (artist(x_1) & (carpenter(x_2) & employ(x_1,x_2) -> $\forall x_3$ (beekeeper(x_3) & admire(x_3,x_2) -> despise(x_1,x_3)))

Although there are three variables in the formula (8) that correspond to the three nouns in sentence (7), the variables x_2 and x_3 never occur free in the same sub-formula. Therefore, the number of variables can be reduced by replacing x_3 through x_2. This technique can not be applied to the variables in formula (9).

E2V has been extended in various ways (Pratt-Hartmann and Third, 2006) and one extension includes counting determiners (e.g. *at least three, at most five, exactly four*). These determiners will not in general translate into the two-variable fragment of first-order logic, but into the fragment $\mathcal{C}^2$, which adds counting quantifiers to the two-variable fragment. The satisfiability problem of this fragment is still decidable and its expressivity and computational complexity is similar to those description logic languages that build the foundation of the Semantic Web.

4 CNLs for the Semantic Web

Recently, a number of CNLs have been developed that can serve as front-end to those formal languages that are used in the context of the Semantic Web[8]. These CNLs can be used by domain specialists who prefer familiar natural language-like notations over formal ones for authoring and verbalising formal ontologies.

ACE View (Kaljurand, 2007) is a CNL editor that supports a defined subset of ACE that can be used as an alternative syntax for the Semantic Web languages OWL and SWRL. ACE View integrates two mappings: one from ACE to OWL/SWRL and one from OWL to ACE. These mappings are not bidirectional in a strict sense since the OWL to ACE mapping also covers OWL axioms and expression types that the ACE to OWL mapping does not generate.

Sydney OWL Syntax (SOS) (Cregan et al., 2007) is a proposal for a CNL that builds upon PENG and provides a syntactically bidirectional mapping to OWL-DL. SOS is strictly bidirectional: each statement can be translated into OWL functional-style syntax and vice versa. The bidirectional translation is achieved with the help of a definite clause grammar that generates the target notation during the parsing process. In contrast to ACE, syntactic constructs of OWL are always carried over one-to-one to SOS. Thus, semantically equivalent OWL statements that use different syntactical constructs are always mapped to different SOS statements.

Rabbit (Hart et al., 2008) is a CNL designed for a scenario where a domain expert and an ontology engineer work together to build an ontology. The construction process is supported by a text-based ontology editor. The editor accepts Rabbit sentences, helps to resolve possible syntax errors, and translates well-formed sentences into OWL. The semantics of some Rabbit constructs is controversial (e.g. exclusive interpretation of disjunction) and hard to align with the semantics of OWL.

Lite Natural Language (Bernardi et al., 2007) is a CNL based on Categorial Grammar; it has the same expressivity as the description logic DL-Lite. DL-Lite is a tractable fragment of OWL and has polynomial time complexity for the main reasoning tasks. DL-Lite is expressive enough to capture relational databases and UML (Unified Modeling Language) diagrams.

[8] http://www.w3.org/TR/owl2-overview/

CLOnE (Funk et al., 2007) is a CNL that is built on top of the natural language processing framework GATE[9]. CLOnE is a simple ontology authoring language that consists of eleven sentence patterns which roughly correspond to eleven OWL axiom patterns. It is unclear whether CLOnE can be extended in a systematic way to cover larger fragments of OWL.

The three controlled languages ACE, SOS, and Rabbit are compared in more detail in Schwitter et al. (2008). There exist three other CNL research streams that are closely related to the Semantic Web: CNLs for querying Semantic Web content (Bernstein and Kaufmann, 2006); CNLs for maintaining semantic wikis (Kuhn, 2009; Kuhn, 2010); and CNLs for describing rules and policies (De Coi et al., 2009).

5 Writing Support for CNLs

Writing a specification in CNL is not an easy task since the author has to stick to the rules of the controlled language. Writing in CNL is in essence a normative process that prescribes how humans should use language to communicate effectively with a computer in order to achieve a particular goal. The challenge here is to develop interface techniques that make the writing process as unobtrusive and effortless as possible. Three main techniques have been suggested to support the writing process of CNLs: the use of error messages, conceptual authoring, and predictive feedback.

Error messages seem to be the most obvious way to support the writing of a text in CNL, and many CNLs (among them (Clark et al., 2010; Fuchs et al., 2008)) use this technique. The user is supposed to learn and remember the restrictions of the CNL and then to write the text following the memorised rules. If the parsing process fails, then the CNL system tries to identify the cause of the error and provides one or more suggestions for how to fix the error. The problem with this technique is that the input might be an unrestricted sentence and a useful error message would require in the worst case knowledge of the sort that is needed for processing full natural language.

[9] http://gate.ac.uk/

Conceptual authoring (Power et al., 2009) is a technique that allows authors to edit a knowledge base on the semantic level by refining specific categories and properties that occur in CNL sentences via a hierarchy of menu options. The selection of an option by the author results in an update of the underlying model and triggers the generation of a new sentence that can then be further refined. This method relies on natural language generation techniques and makes the analysis of CNL sentences unnecessary. The problem with this technique is that it does not allow the author to specify new knowledge that is not already encoded in the knowledge base; it is basically a technique for knowledge authoring and visualization and does not provide an independent knowledge representation language.

Predictive feedback (Schwitter et al., 2003; Kuhn and Schwitter, 2008) is a technique that informs the authors during the writing process about the approved structures of the CNL. This technique relies on interfaces that are aware of the grammar and can look-ahead within this grammar. Using this technique the author receives immediate feedback while a text is written and cannot enter sentences that are not in the scope of the grammar. The grammar of the language PENG has been designed from the beginning to be used in a predictive editor and is processed by a chart parser that is able to generate the look-ahead information. The following example illustrates how a predictive editor works:

- A [adjective | common noun]
- A man [verb | who | 'does not']
- A man works ['.' | preposition | adverb]

In this example the look-ahead information consists of syntactic categories, word forms and punctuation marks; all these elements are implemented as hypertext links. Selecting a hypertext link for a syntactic category displays approved word forms and selecting a word form or a punctuation mark directly adds this element to the text. Kuhn (2010) shows in an number of experiments that predictive editors are easy for untrained users to use and argues that predictive feedback is the best way to support the writing process of CNLs.

6 Evaluating CNLs

Over the past years, a number of different user experiments have been designed to measure various usability aspects of CNLs (see (Kuhn, 2010) for an introduction). These experiments can be grouped into three different categories: task-based experiments, paraphrase-based experiments, and graph-based experiments.

In task-based experiments (for example, (Kaufmann and Bernstein, 2007)), human subjects receive a certain task that requires them to use a CNL as an interface language to a knowledge base together with a tool that potentially supports the writing process. These experiments test how easy or difficult it is to write in these controlled languages using the given tool, but they do not test the understandability of these languages.

Paraphrase-based experiments (for example, (Hart et al., 2008)) aim to evaluate the understandability of a CNL in a tool-independent way. Human subjects receive a statement in CNL and a choice of paraphrases in full natural language, and then have to select the correct paraphrase. These experiments scale well with the expressivity of the CNL but it is difficult to guarantee that the paraphrases are understood in the intended way.

Graph-based experiments (for example, (Kuhn, 2010)) try to overcome the problems of paraphrase-based experiments. In order to test the understandability of CNLs and formal languages, a graph-based notation is used to describe a situation accompanied with statements in the language to be tested. The human subjects have to decide which of these statements are true and which ones are false with respect to the situation illustrated by the graph notation.

The reported results of these experiments in the literature provide strong evidence that CNLs are easier to write and easier to understand for domain specialists than formal languages.

7 Conclusions

It is an exciting time to work on controlled natural languages. In this paper, we surveyed a number of machine-oriented controlled natural languages that can be used instead of formal languages for representing knowledge. These controlled natural languages look like English but correspond to a formal target language. Anyone who can read English has already the basic skills to understand these controlled natural languages. Writing a specification in controlled natural language is a bit harder: it requires that the author either learns the language in order to be able to stay within its syntactic and semantic restrictions or that he uses an intelligent authoring tool that supports the writing process and enforces the restrictions of the language.

Machine-oriented controlled natural languages can be translated automatically (and often deterministically) into a formal target language (e.g. into full first-order logic or into a version of description logics). These languages can be used to express the kind of information that occurs in software specifications, formal ontologies, business rules, and legal and medical regulations.

In summary, an ideal machine-oriented controlled natural language should fulfill at least the following requirements: (a) it should have a well-defined syntax and a precise semantics that is defined by an unambiguous mapping into a logic-based representation; (b) it should look as natural as possible and be based on a subset of a certain natural language; (c) it should be easy for humans to write and understand and easy for a machine to process; and (d) it should have the necessary expressivity that is required to describe a problem in the respective application domain.

Of course these requirements can be in conflict with each other and therefore careful compromises need to be made when a new controlled natural language is designed. This design process offers many interesting research challenges for researchers in the area of computational linguistics and artificial intelligence. This research is driven by the overall goal to close the gap between natural and formal languages and to allow for true collaboration between humans and machines in the near future.

Acknowledgments

I would like to thank to three anonymous reviewers of Coling 2010 for their valuable feedback and to Robert Dale for comments and suggestions on previous versions of this paper.

Abstract

We investigate a series of targeted modifications to a data-driven dependency parser of German and show that these can be highly effective even for a relatively well studied language like German if they are made on a (linguistically and methodologically) informed basis and with a parser implementation that allows for fast and robust training and application. Making relatively small changes to a range of very different system components, we were able to increase labeled accuracy on a standard test set (from the CoNLL 2009 shared task), ignoring gold standard part-of-speech tags, from 87.64% to 89.40%. The study was conducted in less than five weeks and as a secondary project of all four authors. Effective modifications include the quality and combination of auto-assigned morphosyntactic features entering machine learning, the internal feature handling as well as the inclusion of global constraints and a combination of different parsing strategies.

1 Introduction

The past years have seen an enormous surge of interest in dependency parsing, mainly in the data-driven paradigm, and with a particular emphasis on covering a whole set of languages with a single approach. The reasons for this interest are manifold; the availability of shared task data from various CoNLL conferences (among others (Buchholz and Marsi, 2006; Hajič et al., 2009)), comprising collections of languages based on a single representation format, has certainly been instrumental. But likewise, the straightforward usefulness of dependency representations for a number of tasks plays an important role. The relative language independence of the representations makes dependency parsing particularly attractive for multilingually oriented work, including machine translation.

As data-driven approaches to dependency parsing have reached a certain level of maturity, it may appear as if further improvements of parsing performance have to rely on relatively advanced tuning procedures, such as sophisticated automatic feature selection procedures or combinations of different parsing approaches with complementary strengths. It is indeed still hard to pinpoint the structural properties of a language (or annotation scheme) that make the parsing task easier for a particular approach, so it may seem best to leave the decision to a higher-level procedure.

This paper starts from the suspicion that while sophisticated tuning procedures are certainly helpful, one should not underestimate the potential of relatively simple modifications of the experimental set-up, such as a restructuring of aspects of the dependency format, a targeted improvement of the quality of automatically assigned features, or a simplification of the feature space for machine learning – the modifications just have to be made in an informed way. This

Coling 2008: Poster Volume, pages 1122–1130,
Beijing, August 2010

presupposes two things: (i) a thorough linguistic understanding of the issues at hand, and (ii) a relatively powerful and robust experimental machinery which allows for experimentation in various directions and which should ideally support a fast turn-around cycle.

We report on a small pilot study exploring the potential of relatively small, informed modifications as a way of improving parsing accuracy even for a language that has received considerable attention in the parsing literature, including the dependency parsing literature, namely German. Within a timeframe of five weeks and spending only a few hours a day on the project (between a group of four people), we were able to reach some surprising improvements in parsing accuracy.

By way of example, we experimented with modifications in a number of rather different system areas, which we will discuss in the course of this paper after a brief discussion of related work and the data basis in Section 2. Based on a second-order maximum spanning tree algorithm, we used a hash kernel to facilitate the mapping of the features onto their weights for a very large number of features (Section 3); we modified the dependency tree representation for prepositional phrases, adding hierarchical structure that facilitates the picking up of generalizations (Section 4). We take advantage of a morphological analyzer to train an improved part-of-speech tagger (Section 5), and we use knowledge about the structure of morphological paradigms and the morphology-syntax interface in the feature design for machine learning (Section 6). As is known from other studies, the combination of different parsing strategies is advantageous; we include a relatively simple parser stacking procedure in our pilot study (Section 7), and finally, we apply Integer Linear Programming in a targeted way to add some global constraints on possible combinations of arc labels with a single head (Section 8). Section 9 offers a brief conclusion.

2 Related Work and Data Basis

We quickly review the situation in data-driven dependency parsing in general and on applying it to German specifically.

The two main approaches to data-driven dependency parsing are transition based dependency parsing (Nivre, 2003; Yamada and Matsumoto, 2003; Titov and Henderson, 2007) and maximum spanning tree based dependency parsing (Eisner, 1996; Eisner, 2000; McDonald and Pereira, 2006). Transition based parsers typically have a linear or quadratic complexity (Attardi, 2006). Nivre (2009) introduced a transition based non-projective parsing algorithm that has a worst case quadratic complexity and an expected linear parsing time. Titov and Henderson (2007) combined a transition based parsing algorithm, using beam search, with a latent variable machine learning technique.

Maximum spanning tree based dependency parsers decompose a dependency structure into *factors*. The factors of the first order maximum spanning tree parsing algorithm are edges consisting of the head, the dependent (child) and the edge label. This algorithm has a quadratic complexity. The second order parsing algorithm of McDonald and Pereira (2006) uses a separate algorithm for edge labeling. In addition to the first order factors, this algorithm uses the edges to those children which are closest to the dependent and has a complexity of O(n^3). The second order algorithm of Carreras (2007) uses in addition to McDonald and Pereira (2006) the child of the dependent occurring in the sentence between the head and the dependent as well as the edge from the dependents to a grandchild. The edge labeling is an integral part of the algorithm which requires an additional loop over the labels. This algorithm therefore has a complexity of O(n^4). Johansson and Nugues (2008) reduced the required number of loops over the edge labels by considering only the edges that existed in the training corpus for a distinct head and child part-of-speech tag combination.

Predating the surge of interest in data-based dependency parsing, there is a relatively long tradition of dependency parsing work on German, including for instance Menzel and Schröder (1998) and Duchier and Debusmann (2001). German was included in the CoNLL shared tasks in 2006 (Multilingual Dependency Parsing, (Buchholz and Marsi, 2006)) and in 2009 (Syntactic and Semantic Dependencies in Multiple Languages, (Hajič et al., 2009)) with data based on the TIGER

corpus (Brants et al., 2002) in both cases. Since the original TIGER treebank is in a hybrid phrase-structural/dependency format with a relatively flat hierarchical structure, conversion to a pure dependency format involves some non-trivial steps. The 2008 ACL Workshop on Parsing German included a specific shared task on dependency parsing of German (Kübler, 2008), based on two sets of data: again the TIGER corpus – however with a different conversion routine than for the CoNLL tasks – and the TüBa-D/Z corpus (Hinrichs et al., 2004).

In the 2006 CoNLL task and in the 2008 ACL Workshop task, the task was dependency parsing with given gold standard part-of-speech tags from the corpus. This is a valid way of isolating the specific subproblem of parsing, however it is clear that the task does not reflect the application setting which includes noise from automatic part-of-speech tagging. In the 2009 CoNLL task, both gold standard tags and automatically assigned tags were provided. The auto-tagged version was created with the standard model of the TreeTagger (Schmid, 1995) (i.e., with no domain-specific tagger training).

In our experiments, we used the data set from the 2009 CoNLL task, for which the broadest comparison of recent parsing approaches exists. The highest-scoring system in the shared task was Bohnet (2009) with a labeled accuracy (LAS) of 87.48%, on auto-tagged data. The highest-scoring (in fact the only) system in the dependency parsing track of the 2008 ACL Workshop on parsing German was Hall and Nivre (2008) with an LAS of 90.80% on gold-tagged data, and with a data set that is not comparable to the CoNLL data.[1]

3 Hash Kernel

Our parser is based on a second order maximum spanning tree algorithm and uses MIRA (Crammer et al., 2006) as learning technique in combination with a hash kernel. The hash kernel has a higher accuracy since it can use additional features found during the creation of the dependency tree in addition to the features extracted from the training examples. The modification to MIRA is simple: we replace the feature-index mapping that maps the features to indices of the weight vector by a random function. Usually, the feature-index mapping in the support vector machine has two tasks: The mapping maps the features to an index and it filters out features that never occurred in a dependency tree. In our approach, we do not filter out these features, but use them as additional features. It turns out that this choice improves parsing quality. Instead of the feature-index mapping we use the following hash function:[2]

$h \leftarrow |(l\ xor(l \vee \text{0xffffffff00000000} >> 32))\%\ \text{size}|$

The Hash Kernel for structured data uses the hash function $h : J \rightarrow \{1...n\}$ to index ϕ where ϕ maps the observations X to a feature space. We define $\phi(x, y)$ as the numeric feature representation indexed by J. The learning problem is to fit the function F so that the errors of the predicted parse tree y are as low as possible. The scoring function of the Hash Kernel is defined as:[3]

$$F(x, y) = \overrightarrow{w} * \overline{\phi}(x, y)$$

For different j, the hash function $h(j)$ might generate the same value k. This means that the hash function maps more than one feature to the same weight which causes weight collisions. This procedure is similar to randomization of weights (features), which aims to save space by sharing values in the weight vector (Blum, 2006; Rahimi and Recht, 2008). The Hash Kernel shares values when collisions occur that can be considered as an approximation of the kernel function, because a weight might be adapted due to more than one feature. The approximation works very well with a weight vector size of 115 million values.

With the Hash Kernel, we were able to improve on a baseline parser that already reaches a quite high LAS of 87.64% which is higher than the top score for German (87.48%) in the CoNLL Shared task 2009. The Hash Kernel improved that value by 0.42 percentage points to 88.06%. In addition to that, we obtain a large speed up in terms of parsing time. The baseline parser spends an average of 426 milliseconds to parse a sentence of the test

[1] To get an idea of how the data sets compare, we trained the version of our parser described in Section 3 (i.e., without most of the linguistically informed improvements) on this data, achieving labeled accuracy of 92.41%, compared to 88.06% for the 2009 CoNLL task version.

[2] $>> n$ shifts n bits right, and % is the modulo operation.

[3] $\overrightarrow{w}$ is the weight vector and the size of $\overrightarrow{w}$ is n.

set and the parser with Hash Kernel only takes 126 milliseconds which is an increase in speed of 3.4 times. We get the large speed up because the memory access to a large array causes many CPU cache misses which we avoid by replacing the feature-index mapping with a hash function. As mentioned above, the speedup influences the experimenters' opportunities for explorative development since it reduces the turnaround time for experimental trials.

4 Restructuring of PPs

In a first step, we applied a treebank transformation to our data set in order to ease the learning for the parser. We concentrated on prepositional phrases (PP) to get an idea how much this kind of transformation can actually help a parser. PPs are notoriously flat in the TIGER Treebank annotation (from which our data are derived) and they do not embed a noun phrase (NP) but rather attach all parts of the noun phrase directly at PP level. This annotation was kept in the dependency version and it can cause problems for the parser since there are two different ways of annotating NPs: (i) for normal NPs where all dependents of the noun are attached as daughters of the head noun and (ii) for NPs in PPs where all dependents of the noun are attached as daughters to the preposition thus being sisters to their head noun. We changed the annotation of PPs by identifying the head noun in the PP and attaching all of its siblings to it. To find the correct head, we used a heuristic in the style of Magerman (1995). The head is chosen by taking the rightmost daughter of the preposition that has a category label according to the heuristic and is labeled with NK (noun kernel element).

Table 1 shows the parser performance on the data after PP-restructuring.[4] The explanation for the benefit of the restructuring is of course that now there is only one type of NP in the whole corpus which eases the parser's task to correctly learn and identify them.

	dev. set		test set	
	LAS	UAS	LAS	UAS
hash kernel	87.40	89.79	88.06	90.24
+restructured	87.49	89.97	88.30	90.44

Table 1: Parser performance on restructured data

Since restructuring parts of the corpus seems beneficial, there might be other structures where more consistent annotation could help the parser, e. g., coordination or punctuation (like in the 2008 ACL Workshop data set, cp. Footnote 1).

5 Part-of-Speech Tagging

High quality part-of-speech (PoS) tags can greatly improve parsing quality. Having a verb wrongly analyzed as a noun and similar mistakes are very likely to mislead the parser in its decision process. A lot of the parser's features include PoS tags and reducing the amount of errors during PoS tagging will therefore reduce misleading feature values as well. Since the quality of the automatically assigned PoS tags in the German CoNLL '09 data is not state-of-the-art (see Table 2 below), we decided to retag the data with our own tagger which uses additional information from a symbolic morphological analyzer to direct a statistical classifier.

For the assignment of PoS tags, we apply a standard maximum entropy classification approach (see Ratnaparkhi (1996)). The classes of the classifier are the PoS categories defined in the *Stuttgart-Tübingen Tag Set (STTS)* (Schiller et al., 1999). We use standard binarized features like the word itself, its last three letters, whether the word is capitalized, contains a hyphen, a digit or whether it consists of digits only. As the only non-binary feature, word length is recorded. These standard features are augmented by a number of binary features that support the classification process by providing a preselection of possible PoS tags. Every word is analyzed by DMOR, a finite state morphological analyzer, from whose output analyses all different PoS tags are collected and added to the feature set. For example, DMOR assigns the PoS tags NN (common noun) and ADJD (predicative adjective) to the word *gegan-*

[4] Note that we are evaluating against a gold standard here (and in the rest of the paper) which has been restructured as well. With a different gold standard one could argue that the absolute figures we obtain are not fully comparable with the original CoNLL shared task. However, since we are doing dependency parsing, the transformation does neither add nor remove any nodes from the structure nor do we change any labels. The only thing that is done during the transformation is the reattachment of some daughters of a PP. This is only a small modification, and it is certainly linguistically warranted.

gen (gone). From these analyses two features are generated, namely *possible-tag:NN* and *possible-tag:ADJD*, which are strong indicators for the classifier that one of these classes is very likely to be the correct one. The main idea here is to use the morphological analyzer as a sort of lexicon that preselects the set of possible tags beforehand and then use the classifier to do the disambiguation (see Jurish (2003) for a more sophisticated system based on Hidden-Markov models that uses roughly the same idea). Since the PoS tags are included in the feature set, the classifier is still able to assign every class defined in *STTS* even if it is not in the preselection. Where the morphological analyzer does not know the word in question we add features for every PoS tag representing a productive word class in German, making the reasonable assumption that the morphology knows about all closed-class words and word forms. Finally, we add word form and possible tag features for the previous and the following word to the feature set thus simulating a trigram tagger. We used the method of Kazama and Tsujii (2005) which uses inequality constraints to do a very efficient feature selection[5] to train the maximum entropy model.

We annotated the entire corpus with versions of our own tagger, i.e., the training, development and test data. In order to achieve a realistic behavior (including remaining tagging errors, which the parser may be able to react to if they are systematic), it was important that each section was tagged without any knowledge of the gold standard tags. For the development and test portion, this is straightforward: we trained a model on the gold PoS of the training portion of the data and applied it to retag these two portions. Retagging the training portion was a bit trickier since we could not use a model trained on the same data, but at the same time, we wanted to use a tagger of similarly high quality – i.e. one that has seen a similar amount of training data. The training set was therefore split into 20 different parts and for every split, a tagging model was trained on the other 19 parts which then was used to retag the remaining 20th part. Table 2 shows the quality of our tagger evaluated on the German CoNLL '09 data in terms of accuracy and compares it to the originally annotated PoS tags which have been assigned by using the TreeTagger (Schmid, 1995) together with the German tagging model provided from the TreeTagger website. Tagging accuracy improves consistently by about 2 percentage points which equates to an error reduction of 44.55 % to 49.0 %.

	training	development	test
original	95.69	95.51	95.46
retagged	97.61	97.71	97.52
error red.	44.55%	49.00%	45.37%

Table 2: Tagging accuracy

Table 3 shows the parser performance when trained on the newly tagged data. The considerable improvements in tagging accuracy visibly affect parsing accuracy, raising both the labeled and the unlabeled attachment score by 0.66 percentage points (LAS) and 0.51 points (UAS) for the development set and by 0.45 points (LAS) and 0.64 points (UAS) for the test set.

	dev. set		test set	
	LAS	UAS	LAS	UAS
restructured	87.49	89.97	88.30	90.44
+retagged	88.15	90.48	88.75	91.08

Table 3: Parser performance on retagged data

6 Morphological Information

German, as opposed to English, exhibits a relatively rich morphology. Predicate arguments and nominal adjuncts are marked with special case morphology which allows for a less restricted word order in German. The German case system comprises four different case values, namely nominative, accusative, dative and genitive case. Subjects and nominal predicates are usually marked with nominative case, objects receive accusative or dative case and genitive case is usually used to mark possessors in possessive constructions. There are also some temporal and spatial nominal adjuncts which require certain case values. Since case is used to mark the function of a noun phrase in a clause, providing case information to a parser might improve its performance.

The morphological information in the German CoNLL '09 data contains much more information than case alone and previous models (baseline,

[5] We used a width factor of 1.0.

hash kernel, retagged) have used all of it. However, since we aim to improve a syntactic parser, we would like to exclude all morphological information from the parsing process that is not obviously relevant to syntax, e. g. mood or tense. By reducing the morphological annotations to those that are syntactically relevant, we hope to reduce the noise that is introduced by irrelevant information. (One might expect that machine learning and feature selection should "filter out" irrelevant features, but given the relative sparsity of unambiguous instances of the linguistically relevant effects, drawing the line based on just a few thousand sentences of positive evidence would be extremely hard even for a linguist.)

We annotated every case-bearing word in the corpus with its case information using DMOR. With case-bearing words, we mean nouns, proper nouns, attributive adjectives, determiners and all kinds of pronouns. Other types of morphological information was discarded. We did not use the manually annotated and disambiguated morphological information already present in the corpus for two reasons: the first one is the same as with the PoS tagging. Since it is unrealistic to have gold-standard annotation in a real-world application which deals with unseen data, we want the parser to learn from and hopefully adapt to imperfectly annotated data. The second reason is the German-inherent form syncretism in nominal paradigms. The German noun inflection system is with over ten different (productive and non-productive) inflectional patterns quite complicated, and to make matters worse, there are only five different morphological markers to distinguish 16 different positions in the pronoun, determiner and adjective paradigms and eight different positions in the noun paradigms. Some positions in the paradigm will therefore always be marked in the same way and we would like the parser to learn that some word forms will always be ambiguous with respect to their case value.

We also conducted experiments where we annotated number and gender values in addition to case. The idea behind this is that number and gender might help to further disambiguate case values. The downside of this is the increase in feature values. Combining case and number features means a multiplication of their values creating eight new feature values instead of four. Adding gender annotation raises this number to 24. Beside the disambiguation of case, there is also another reason why we might want to add number and gender: Inside a German noun phrase, all parts have to agree on their case and number feature in order to produce a well-formed noun phrase. Furthermore, the head noun governs the gender feature of the other parts. Thus, all three features can be relevant to the construction of a syntactic structure.[6] Table 4 shows the results of our experiments with morphological features.

	dev. set		test set	
	LAS	UAS	LAS	UAS
retagged	88.15	90.48	88.75	91.08
no morph.	87.78	90.18	88.60	90.92
+case	88.04	90.48	88.77	91.13
+c+n	88.21	90.62	88.88	91.13
+c+n+g	87.96	90.33	88.73	90.99

Table 4: Parser performance with morph. information (c=case, n=number, g=gender)

The *no morph* row in Table 4 shows, that using no morphological information at all decreases parser performance. When only case values are annotated, the parser performance does not change much in comparison to the retagged model, so there is no benefit here. Adding number features on the other hand improves parsing results significantly. This seems to support our intuition that number helps in disambiguating case values. However, adding gender information does not further increase this effect but hurts parser performance even more than case annotation alone. This leaves us with a puzzle here. Annotating case and number helps the parser, but case alone or having case, number and gender together affects performance negatively. A possible explanation might be that the effect of the gender information is masked by the increased number of feature values (24) which confuses the parsing algorithm.

7 Parser Stacking

Nivre and McDonald (2008) show how two different approaches to data-driven dependency pars-

[6] Person would be another syntactically relevant information. However, since we are dealing with a newspaper corpus, first and second person features appear very rarely.

ing, the graph-based and transition-based approaches, may be combined and subsequently learn to complement each other to achieve improved parsing results for different languages.

MaltParser (Nivre et al., 2006) is a language-independent system for data-driven dependency parsing which is freely available.[7] It is based on a deterministic parsing strategy in combination with treebank-induced classifiers for predicting parsing actions. MaltParser employs a rich feature representation in order to guide parsing. For the training of the Malt parser model that we use in the stacking experiments, we use learner and parser settings identical to the ones optimized for German in the CoNLL-X shared task (Nivre et al., 2006). Furthermore, we employ the technique of pseudo-projective parsing described in Nilsson and Nivre (2005) and a split prediction strategy for predicting parse transitions and arc labels (Nivre and Hall, 2008).[8] In order to obtain automatic parses for the whole data set, we perform a 10-fold split. For the parser stacking, we follow the approach of Nivre and McDonald (2008), using MaltParser as a guide for the MST parser with the hash kernel, i.e., providing the arcs and labels assigned by MaltParser as features. Table 5 shows the scores we obtain by parser stacking. Although our version of MaltParser does not quite have the same performance as for instance the version of Hall and Nivre (2008), its guidance leads to a small improvement in the overall parsing results.

	dev. set		test set	
	LAS	UAS	LAS	UAS
MaltParser	82.47	85.78	83.84	86.8
our parser	88.21	90.62	88.88	91.13
+stacking	88.42	90.77	89.28	91.40

Table 5: Stacked parser performance with guidance by MaltParser

[7] http://maltparser.org

[8] The feature models make use of information about the lexical form (FORM), the predicted PoS (PPOS) and the dependency relation constructed thus far during parsing (DEP). In addition, we make use of the predicted values for other morphological features (PFEATS). We employ the arc-eager algorithm (Nivre, 2003) in combination with SVM learners, using LIBSVM with a polynomial kernel.

8 Relabeling

In the relabeling step, we pursue the idea that some erroneous parser decisions concerning the distribution of certain labels might be detected and repaired in post-processing. In German and in most other languages, there are syntactic restrictions on the number of subjects and objects that a verb might select. The parser will learn this behavior during training. However, since it is using a statistical model with a limited context, it can still happen that two or more of the same grammatical functions are annotated for the same verb. But having two subjects annotated for a single verb makes this particular clause uninterpretable for subsequently applied tasks. Therefore, we would like to detect those doubly annotated grammatical functions and correct them in a controlled way.

The detection algorithm is simple: Running over the words of the output parse, we check for every word whether it has two or more daughters annotated with the same grammatical function and if we find one, we relabel all of its daughters.[9] For the relabeling, we applied a dependency-version of the function labeler described in Seeker et al. (2010) which uses a maximum entropy classifier that is restrained by a number of hard constraints implemented as an Integer Linear Program. These constraints model the aforementioned selectional restrictions on the number of certain types of verbal arguments. Since these are hard constraints, the labeler is not able to annotate more than one of those grammatical functions per verb. If we count the number of sentences that contain doubly annotated grammatical functions in the best parsing results from the previous section, we get 189 for the development set and 153 for the test set. About two thirds of the doubly annotated functions are subjects and the biggest part of the remaining third are accusative objects which are the most common arguments of German verbs.

Table 6 shows the final results after relabeling the output of the best performing parser configuration from the previous section. The improvements on the overall scores are quite small, which

[9] The grammatical functions we are looking for are SB (subject), OA (accusative object), DA (dative), OG (genitive object), OP (prepositional object), OC (clausal object), PD (predicate) and OA2 (second accusative object).

	dev. set		test set	
	LAS	UAS	LAS	UAS
stacking	88.42	90.77	89.28	91.40
+relabeling	88.48	90.77	89.40	91.40

Table 6: Parse quality after relabeling

is partly due to the fact that the relabeling affects only a small subset of all labels used in the data. Furthermore, the relabeling only takes place if a doubly annotated function is detected; and even if the relabeling is applied we have no guarantee that the labeler will assign the labels correctly (although we are guaranteed to not get double functions). Table 7 shows the differences in precision and recall for the grammatical functions between the original and the relabeled test set. As one can see, scores stay mostly the same except for SB, OA and DA. For OA, scores improve both in recall and precision. For DA, we trade a small decrease in precision for a huge improvement in recall and vice versa for SB, but on a much smaller scale. Generally spoken, relabeling is a local repair strategy that does not have so much effect on the overall score but can help to get some important labels correct even if the parser made the wrong decision. Note that the relabeler can only repair incorrect label decisions, it cannot help with wrongly attached words.

	original		relabeled	
	rec	prec	rec	prec
DA	64.2	83.2	74.7	79.6
OA	88.9	85.8	90.7	88.2
OA2	0.0	NaN	0.0	NaN
OC	95.2	93.5	95.1	93.7
OG	33.3	66.7	66.7	80.0
OP	54.2	80.8	54.2	79.9
PD	77.1	76.8	77.1	76.8
SB	91.0	90.6	90.7	93.7

Table 7: Improvements on grammatical functions in the relabeled test set

9 Conclusion

We presented a sequence of modifications to a data-driven dependency parser of German, departing from a state-of-the-art set-up in an implementation that allows for fast and robust training and application. Our pilot study tested what can be achieved in a few weeks if the data-driven technique is combined with a linguistically informed approach, i.e., testing hypotheses of what should be particularly effective in a very targeted way. Most modifications were relatively small, addressing very different dimensions in the system, such as the handling of features in the Machine Learning, the quality and combination of automatically assigned features and the ability to take into account global constraints, as well as the combination of different parsing strategies. Overall, labeled accuracy on a standard test set (from the CoNLL 2009 shared task), ignoring gold standard part-of-speech tags, increased significantly from 87.64% (baseline parser without hash kernel) to 89.40%.[10] We take this to indicate that a targeted and informed approach like the one we tested can have surprising effects even for a language that has received relatively intense consideration in the parsing literature.

Abstract

Retrieval evaluation without relevance judgments is a hard but also very meaningful work. In this paper, we use clustering technique to improve the performance of judgment free retrieval evaluation. By using one system to represent all the systems that are similar to it, we can largely reduce the negative effect of similar retrieval results in Retrieval evaluation. Experimental results demonstrated that our method outperformed all the previous judgment free evaluation methods significantly. Its overall average performance outperformed the best previous result by 20.5%. Besides, our work is a general framework that can be applied to any other judgment free evaluation method for performance improvement.

1 Introduction

Generally, to compare the effectiveness of information retrieval systems, we need to prepare a test collection composed of a set of documents, a set of query topics, and a set of relevance judgments indicating which documents are relevant to which topics. Among these requirements, relevance judgment is the most human resource exhausting and time consuming part. It even becomes infeasible when the test collection is extremely large. To address this problem, the TREC conferences used a pooling technology (Voorhees and Harman, 1999), where the top *n* (e.g., *n*=100) documents retrieved by each participating system are collected into a pool and then only the documents in the pool are judged for system comparison. Zobel (1998) has shown that this pooling method leads to reliable results in term of determining the effectiveness of retrieval systems and their relative rankings. Yet, the relevance determination process is still very resource intensive especially when the test collection reaches or exceeds terabyte, or much more queries are included. More seriously, when we change to a new document collection, we have to redo the entire evaluation process.

There are two possible solutions to the problem above, evaluation with incomplete relevance judgments and evaluation without relevance judgments. The former is well studied. Many well designed ranking methods with incomplete judgments were carried out. Two of them, Minimal Test Collection (MTC) method (Carterette et al., 2006) and Statistical evaluation (statMAP) method (Aslam et al., 2006), even got practical application in the Million Query (1MQ) track in TREC 2007 (Allan et al., 2007), and achieved satisfactory evaluation performance. The latter is comparatively less studied. Only a few papers concentrate on the issue of evaluating retrieval systems without relevance judgments. In Section 2 of this paper, we will briefly review some representative methods. We will see what they are and how they work.

Coling 2008: Poster Volume, pages 1131–1139,
Beijing, August 2010

In this paper, we focus our effort on the retrieval evaluation without relevance judgments. Although 'blind' evaluation is really a hard problem and its evaluation performance is far less than that of methods with incomplete judgments, it is undeniable that non-judgment evaluation has its own advantages. In some cases, relevance judgments are non-attainable. For example, when researchers compare their novel retrieval algorithms to existing methods, or search for optimal parameters of their algorithms, or conduct data fusion in a dynamic environment, relevance judgment usually seems impossible. Besides, to construct a good evaluation method without relevance judgments, researchers need to mine the retrieval results thoroughly, and try to find laws that indicate the correlation between the effectiveness of a system and features of its retrieval result. These laws are not only useful for 'blind' evaluation methods but also valuable for evaluation methods with incomplete judgments.

One of the useful laws for 'blind' evaluation methods is Authority Effect (Spoerri, 2005). Yet it always ruined by multiple similar results.

In this work, we use clustering technique to solve this problem. By selecting one system to represent all the systems that are similar to it, we can largely reduce the negative effect of similar retrieval results. Details of this method will be presented Section 3. Experimental results, which are reported in Section 4, also verified that our idea is feasible and effective. Our method outperformed all the previous judgment free evaluation methods on every test bed. The overall average performance outperformed the best previous result by 20.5%. Finally, we conclude our work in Section 5.

2 Related Work

In 2001, Soboroff et al. (2001) firstly proposed the concept of evaluating retrieval systems in the absence of relevance judgments. They generated a set of pseudo-relevance judgments by randomly selecting and declaring some documents from the pool of top 100 documents as relevant. This set of pseudo-relevance judgments (instead of a set of human relevance judgments) was then used to determine the effectiveness of the retrieval systems. Four versions of this random pseudo-relevance method were designed and tested on data from the ad hoc track in TREC 3, 5, 6, 7 and 8. They were simple random pseudo-relevance method, the variant with duplicate documents, the variant with Shallow pools and the variant with Exact-fraction sampling. All their resulting system assessments and rankings were well correlated with actual TREC rankings, and the variant with duplicate documents in pools got the best performance, with an average Kendall's tau value 0.50 over the data of TREC 3, 5, 6, 7 and 8.

Soboroff et al.'s idea came from two results in retrieval evaluation. One is that incomplete judgments do not harm evaluation results greatly. Zobel's (1998) research had showed that the results obtained using pooling technology were quite reliable given a pool depth of 100. He also found that even though the pool depth was limited to 10, the relative performance among systems changed little, although actual precision scores did change for some systems. The other is that partially incorrect relevance judgments do not harm evaluation results greatly. Voorhees (1998) ascertained that despite a low average overlap between assessment sets, and wide variation in overlap among particular topics, the relative rankings of systems remained largely unchanged across the different sets of relevance judgments. These two points are bases of Soboroff et al.'s random pseudo-relevance method, and give explanation to the result that their rankings were positively related to that of the actual TRECs. As a matter of fact, the two points are bases of all the retrieval evaluation methods without or with incomplete relevance judgments.

Aslam and Savell (2003) devised a method to measure the relative retrieval effectiveness of systems through system similarity computation. In their work, the similarity between two retrieval systems was the ratio of the number of documents in their intersection and union. Each system was scored by the average similarity between it and all other systems. This measurement produced results that were highly correlated with the random pseudo-relevance method. Aslam and Savell hypothesized that this was caused by 'tyranny of the masses' effect, and these two related methods were assessing the systems based on 'popularity' instead of 'performance'. The analysis by Spoerri (2005) sug-

gested that the 'popularity' effect was caused by considering all the runs submitted by a retrieval system, instead of only selecting one run per system. Our later experimental results will show that this point of view is partially correct. The 'popularity' effect could not be avoided completely by only selecting one run per system. This is indeed a hard problem for all the evaluation methods without relevance judgments.

Wu and Crestani (2003) developed multiple 'reference count' based methods to rank retrieval systems. They made the distinction between an 'original' document and its duplicates in all other lists, called the 'reference' documents, when computing a document's score. A system's score is the (weighted) sum of the scores of its 'original' documents. Several versions of reference count method were carried out and tested. The basic method (Basic) scored each 'original' document by the number of its 'reference' documents. The first variant (V1) assigned different weights to 'reference' documents based on their ranking positions. The second variant (V2) assigned different weights to the 'original' document based on its ranking position. The third variant (V3) assigned different weights to both the 'original' documents and the 'reference' documents based on their ranking positions. The fourth variant (V4) was similar to V3, except that it normalized the weights to 'reference' documents. Wu and Crestani's method output similar evaluation performance to that of the random pseudo-relevance method. Their work also showed that the similarity between the multiple runs submitted by the same retrieval system affected the ranking process. If only one run was selected for any of the participant system for any query, for 3-9 systems, V3 outperformed random pseudo-relevance method by 45.6%; for 10-15 systems, random pseudo-relevance method outperformed V3 by 6.5%.

Nuray and Can (2006) introduced a method to rank retrieval systems automatically using data fusion. Their method consists of two parts. One is selecting systems for data fusion, and the other is selecting documents as pseudo relevant documents as the fusion result. In the former part, they hypothesized that systems returning documents different from the majority could provide better discrimination among the documents and systems. In return, this could lead to a more accurate pseudo relevant documents and more accurate rankings. To find proper systems, they introduced the 'bias' concept for system selection. In their work, bias was 1 minus the similarity between a system and the majority, where the similarity is a normalized dot product of two vectors. In the latter part, Nuray and Can tested three criterions, namely Rank position, Borda count and Condorcet. Experimental results on data from TREC 3, 5, 6 and 7 showed that bias plus Condorcet got the best evaluation results and it outperformed the reference count method and random pseudo relevance method greatly.

More recently, Spoerri (2007) proposed a method using the structure of overlap between search results to rank retrieval systems. This method provides us a new view on how to rank retrieval systems without relevance judgments. He used local statistics of retrieval results as indicators of relative effectiveness of retrieval systems. Concretely, if there are N systems to be ranked, N groups are constructed randomly with the constraint that each group contains five systems and each system will appear in five groups; then the percentages of a system's documents not found by other systems (Single%) as well as the difference between the percentages of documents found by a single system and all five systems (Single%-AllFive%) are calculated as indicators of relative effectiveness respectively. Spoerri found that these two local statistics were highly and negatively correlated with the mean average precision and precision at 1000 scores of the systems. By utilizing the two statistics to rank systems from subsets of TREC 3, 6, 7 and 8, Spoerri obtained appealing evaluation results. The overlap structure of the top 50 documents were sufficient to rank retrieval systems and produced the best results, which outperformed previous attempts to rank retrieval systems without relevance judgments significantly.

So far, we have reviewed 5 representatives of non-judgment evaluation methods. All these methods faced the same serious problem: similar runs harmed the effectiveness of ranking process. Different methods handled this problem differently. Aslam and Savell (2003) called this the 'tyranny of the masses' and provided no solution. Wu and Crestani (2003) addressed this problem by selecting only one run for any of the participant system for any query. Nuray and Can (2006) selected systems that were less simi-

lar to the majority for data fusion. Spoerri (2007) performed his method on a selected subset of all the systems. All these treatments led to evaluation performance improvement. Yet we will say it could be improved more. In the next section, we will present a new solution to this problem. Its performance is examined in Section 4.

3 Using Clustering to Improve Retrieval Evaluation without Relevance Judgments

3.1 Problem

As we reviewed in Section 2, previous research had shown that incomplete relevance judgments and partially incorrect relevance judgments do not harm retrieval evaluation greatly. This is why pooling technique can lead to reliable retrieval evaluation results. It is also the theoretical foundation of evaluation without relevance judgments.

Besides, non-judgments methods armed with more laws inside retrieval results. These laws indicate the correlation between retrieval effectiveness of a system and features in its retrieval results. One of the most important laws used in non-judgments evaluation is Authority Effect (Spoerri, 2005): document, which is retrieval by more systems, is more likely being relevant. Unfortunately, similar retrieval results ruined this law. Aslam and Savell (2003) called this the 'tyranny of the masses'. So, how to alleviate the negative effect of similar retrieval results is a big issue in non-judgments evaluation.

3.2 Solution

Generally, our solution to the 'tyranny of the masses' is removing similar systems by clustering. The whole process is as follows:

Firstly, all systems to be evaluated are clustered into several subsets.

Secondly, for each subset, one system is selected as a representative.

Thirdly, all the information used for system evaluation comes from these representatives.

Finally, score every system according to the information collected in the previous step.

This is the general framework of our methodology. Notice that, in the third step, only selected systems contribute to the information required for system evaluation. So we can eliminate the negative effect caused by similar retrieval results.

This solution can be applied to any method of retrieval evaluation without relevance judgments. To illustrate how to apply it to a retrieval evaluation method, we will describe using clustering to improve Average System Similarity, which is proposed by Aslam and Savell (2003), in detail as an example.

3.3 Average System Similarity Based on Clustering

In Aslam and Savell's (2003) method, each system is evaluated based on a criterion named Average System Similarity. The average system similarity of a given system S_0 is calculated according to formula (1).

$$\mathrm{AvgSysSim}(S_0) = \frac{1}{n-1}\sum_{S \neq S_0} SysSim(S, S_0) \quad (1)$$

where n is the number of systems to be evaluated, and similarity between two systems S and S_0, SysSim(S, S_0), is calculated based on formula (2).

$$\mathrm{SysSim}(S_1, S_2) = \frac{\left|\mathrm{Ret}_1 \cap \mathrm{Ret}_2\right|}{\left|\mathrm{Ret}_1 \cup \mathrm{Ret}_2\right|} \quad (2)$$

where Ret_i indicates the set of documents returned by System i (i = 1, 2).

When applying clustering technique to the system similarity method, we need to define an equivalence relation first.

Definition 1 (**System Equivalence**): Suppose that all systems are clustered into m clusters namely C_1, C_2, …, C_m. Two systems S_1 and S_2 are equivalent if and only if there exists k ($1 \le k \le m$) so that $S_1 \in C_k$ and $S_2 \in C_k$.

$$S_1 = S_2 \quad iff \quad \exists k, 1 \le k \le m, S_1 \in C_k, S_2 \in C_k \quad (3)$$

Given the definition of System Equivalence, we get the average system similarity based on clustering as follows:

$$\mathrm{AvgSysSim}(S_0) = \frac{1}{m-1}\sum_{R \neq S_0} SysSim(R, S_0) \quad (4)$$

where m is the number of clusters and R is the representative system of a cluster.

Replacing formula (1) with formula (4), we get the retrieval evaluation method Average System Similarity Based on Clustering, shortly ASSBC.

There are two important issues for ASSBC that need to be addressed. Issue 1: How to select representative system from a cluster? Issue 2: How to decide the number of clusters we need?

Before we address Issue 1, we introduce another definition, Cluster Similarity.

Definition 2 (**Cluster Similarity**): for any given two clusters C_1 and C_2, with their respective representative systems S_1 and S_2, the cluster similarity between C_1 and C_2 is the system similarity between S_1 and S_2.

$$\text{ClusterSim}(C_1, C_2) = \text{SysSim}(S_1, S_2) \quad (5)$$

Now we come to selecting representative systems for clusters. Here, we utilize a hierarchical bottom up clustering technique. The entire clustering process is as follows.

Initially, each system forms a cluster.
Loop Until the number of clusters is m
Two most similar clusters merge, and one of their representatives with higher average system similarity survives as the representative of the new cluster.
End Loop.

In the initial step, since every cluster contains only one system, the representative system is unquestionable. Within each loop, two representative systems of the old clusters are candidates of the new cluster, and the one with higher score, which means higher retrieval performance, becomes the representative of the new cluster.

For Issue 2, technically, how to decide the number of clusters is always a problem for clustering. Yet, we do not have to rush in the decision. Let us examine the evaluation performance on different values of *m* first.

4 Experiments

In this section, we will illustrate the evaluation performance of Average System Similarity Based on Clustering vs. different values of *m*. Before we come to the experimental results, we would like to make some details clear first.

4.1 Some Clarification

4.1.1 Dataset

We perform our experiments on the ad hoc tasks of TREC-3, -5, -6 and -7. Most existing works on retrieval evaluation without judgments are tested on these tasks. To make a direct comparison with these work mentioned in Section 2 later, we also choose these tasks as our test bed.

4.1.2 Performance Measurement

One of the measures of retrieval effectiveness used by TREC is mean non-interpolated average precision (MAP). Since average precision is based on much more information than other effectiveness measures such as R-precision or P(10) and known to be a more powerful and more stable effectiveness measure (Buckley and Voorhees, 2000), we utilize MAP as the effective measurement of retrieval systems in our experiments.

The correlation of the ranking with our proposed methods, as well as other methods, to the TREC official rankings is measured using the Spearman's rank correlation coefficient. One reason is that it suits better for evaluating correlation between ratio sequences, e.g. MAP, than Kendall's tau. The other reason is that we can directly compare our results with those of previous attempts reviewed in Section 2, since most of them provided Spearman's rank correlation coefficient results.

4.1.3 Substitute for Number of Clusters

TREC	Runs
3	40
5	61
6	74
7	103

Table 1. Number of TREC runs

As we know, the number of systems (runs) varies in different TREC dataset (see Table 1 for details). Instead of examining the evaluation performance variation when absolute number of clusters *m* changes, we illustrate the evaluation performance vs. the percentage of *m*. Actually, for the sake of convenience, we will plot the correlation of our method to the TREC official rankings vs. the percentage of systems removed from the representative group in the following subsection.

4.2 Experimental results

Figure 1-4 show the plots of the correlation of our method to the TREC official rankings vs. the percentage of systems removed from the representative group on TREC-3, -5, -6 and -7 respectively. The percentage of systems removed goes from 0 to 85%, where 0 means no system removed and represents the original Average System Similarity method, and 85% is an up bound in our experiments. The horizontal line indicates the original performance. The tagged number on the curve says when the performance curve reaches its peak and the peak value.

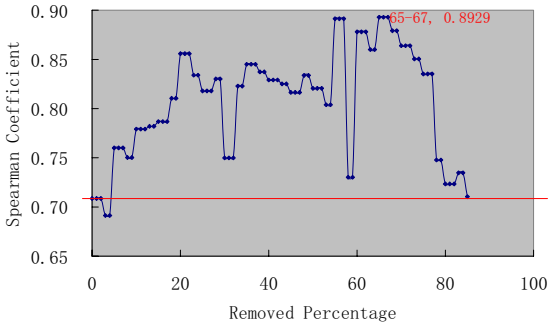

Figure 1. Spearman Coefficient of ASSBC vs. different percentage of removed systems on TREC -3.

In Figure 1, the Spearman coefficients of ASSBC vs. different percentage of removed systems on TREC-3 are presented. Except for the beginning, almost all the points are above the horizontal line. The curve reaches its top at 65%-67%, where the Spearman coefficient is 0.8929.

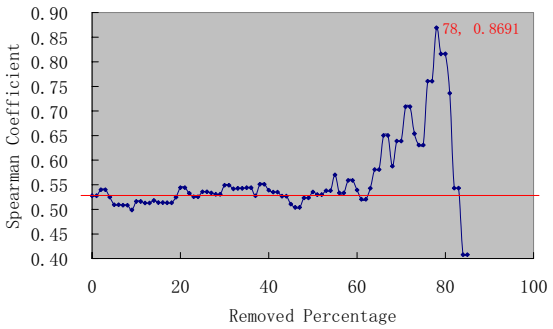

Figure 2. Spearman Coefficient of ASSBC vs. different percentage of removed systems on TREC -5.

Figure 2 depicts the evaluation performance on TREC-5. From 0 to 63%, the performance curve fluctuates around the horizontal line. This means deficient clustering does not bring substantial performance variation. After 63%, the curve begins to rise and reaches its peak at 78%, where the performance is 0.8691. Then it drops dramatically as more systems removed from the representative group.

The situation on TREC-6 is plotted in Figure 3. In this case, the curve rises gently in the interval between 0 and 70% except for some fluctuation. After 70%, the curve starts to climb and reaches the peak at 75% with the peak value of 0.8576. It remains high performance until 80%, and then decline quickly.

Figure 3. Spearman Coefficient of ASSBC vs. different percentage of removed systems on TREC -6.

Figure 4 presents the evaluation performance on TREC-7. The trend in this figure is pretty much like that in Figure 2. The curve fluctuates first, and then climbs the hill, where the peak value is 0.6557 and 75% systems are removed. The only difference is in this figure the curve is gentler. This means on TREC-7 ASSBC does not obtain as much improvement as on TREC-5.

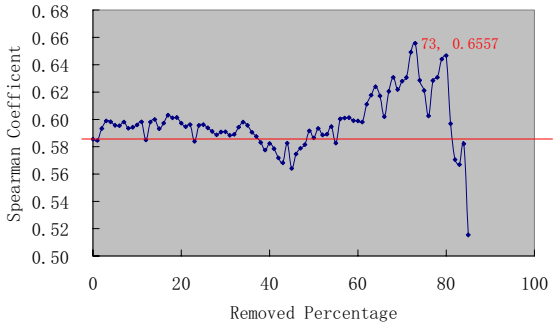

Figure 4. Spearman Coefficient of ASSBC vs. different percentage of removed systems on TREC -7.

According Figure1-4, we can say that clustering systems does bring us evaluation performance improvement. Generally, obvious improvement occurs in the interval between 65% and 80%. TREC-3 is an exception. The curve on TREC-3 reaches its peak at 65%. Notice that in TREC-3 there are only 40 systems (runs), and

65% indicates 26 systems removed and 14 systems left as representatives. Interestingly, for other TRECs, 78% (the biggest peak position) means at least 14 systems left as well. So, this can be interpreted as the minimum number of clusters.

To examine the general effect on evaluation performance of cluster number, we also plot the average performance of TREC -3, -5, -6 and -7 vs. the percentage of systems removed from the representative group in Figure 5. With slight fluctuation, the average performance curve climbs stably, and reaches its peak 0.7754 at the position 78%. Then it drops dramatically.

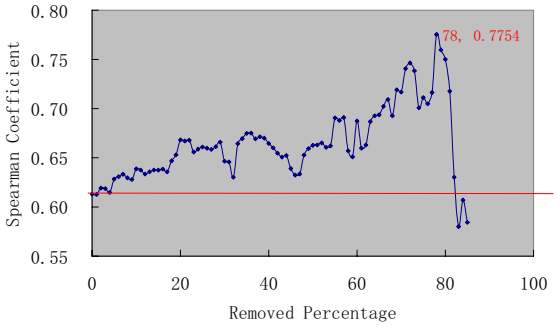

Figure 5. Average Spearman Coefficient of ASSBC vs. different percentage of removed systems on TREC -3, -5, -6 and -7.

To make the result more intuitive, we present a comparison of the performance of original Average System Similarity (ASS) and the best performance of Average System Similarity Based on Clustering (ASSBC) in Table 2. According to the table, we can see that clustering systems improve the evaluation performance significantly.

	ASS	ASSBC	Improvement
Trec3	0.7086	0.8929	26.0%
Trec5	0.5277	0.8691	64.7%
Trec6	0.6300	0.8576	36.1%
Trec7	0.5855	0.6557	12.0%
Avg	0.6129	0.7754	26.5%

Table 2. Spearman coefficients of original Average System Similarity (ASS) and the best performance of Average System Similarity Based on Clustering (ASSBC) on TREC -3, -5, -6, -7 and the over all average.

4.3 Comparison with All Previous Attempts

Meanwhile, we also provide a comparison among the ASSBC method and all the existing non-judgment evaluation methods mentioned in Section 2. The result is given in Table 3.

	RS	RC	CB	Single%	ASS	ASSBC optimal (78% Removed)
Trec3	0.627	0.587	0.867	0.824	0.709	0.893
Trec5	0.429	0.421	0.657*	0.563	0.528	0.869
Trec6	0.436	0.384	0.717	0.618	0.630	0.854
Trec7	0.411	0.382	0.453	0.550	0.585	0.631
Avg	0.476	0.444	0.674	0.639	0.613	0.812

Table 3. Spearman coefficients for best results from different evaluation methods

In Table 3, RS represents the result of random pseudo relevance method, where relevance ratio is set to 10% rather than the actual ratio in its original version; RC is the best result produced by reference count method; BC accounts for the best result of Bias plus Condorcet method, a data fusion based method. Results of these three methods are cited from Nuray and Can's (2006) paper. For the number with a '*' (BC on TREC 5), in their original paper, same result in different tables conflict, and we pick the higher value presenting in Table 3. Single% is the representative of Spoerri's overlap structure based method. Different from its original version, the result in Table 3 is gained on all the systems opposite to on a selected subset, except that runs submitted by the same system are counted only once. ASS is short for Average System Similarity. ASSBC optimal is the best result of our method. Here we utilize both 78%

as the percentage of removed systems and 14 as the minimum number of clusters[1]. Clearly, our method outperforms all the previous attempts on every TREC. The overall average performance outperforms the best previous result (from CB) by 20.5%.

5 Conclusion

Retrieval evaluation without relevance judgments is a hard problem. Meanwhile it is also an important problem that we can not avoid it in many research areas and applications.

One of the main factors that depress the performance of judgments free evaluation is: similar retrieval results ruined the Authority Effect, which is one of the important bases for all the judgment free evaluation methods.

In this paper, we use clustering technique to address this problem. By using one system to represent all the systems that are similar to it, we can largely reduce the negative effect of similar retrieval results. Experimental results also verified our idea. Our method outperforms all the previous judgment free evaluation methods on every test bed. The overall average performance outperforms the best previous result by 20.5%.

Besides, improving judgment free evaluation via clustering is more than just a method. It is a general framework that can be applied to any judgment free evaluation method. The Average System Similarity Based on Clustering method is an example. It works well means that the framework is feasible and successful. We will apply it to other judgment free evaluation methods in our future work.

[1] Since we add a terminal criterion for clustering with 14 as the minimum number of clusters, the average performance in Table 3 gains an improvement compared to that presented in Figure 5 and Table 2.

Abstract

In this paper, we propose a method for mediatory summarization, which is a novel technique for facilitating users' assessments of the credibility of information on the Web. A mediatory summary is generated by extracting a passage from Web documents; this summary is generated on the basis of its relevance to a given query, fairness, and density of keywords, which are features of the summaries constructed to determine the credibility of information on the Web. We demonstrate the effectiveness of the generated mediatory summary in comparison with the summaries of Web documents produced by Web search engines.

1 Introduction

Many pages on the Web contain incorrect or unverifiable information. Therefore, there is a growing demand for technologies that can enable us to obtain reliable information. However, it would be almost impossible to automatically ascertain the accuracy of information presented on the Web. Hence, the second-best approach is the development of a supporting method for judging the credibility of information on the Web.

Presently, when we wish to judge the credibility of information on the Web, we often read some relevant Web documents retrieved via Web search engines. However, Web search engines do not provide any suggestions in cases where the content of some documents conflicts with the content of other documents. Furthermore, the retrieved documents are too many to read and may not be ranked according to the credibility of the information they provide. In other words, information retrieval is not sufficient to support users' assessments of the credibility of information, and therefore, additional techniques are required for the same.

Several previous researches have been conducted for developing such techniques. Juffinger et al. (2009) ranked blogs in terms of their concurrence with well-verified information from sources such as a news corpus. Miyazaki et al. (2009) devised a method for extracting the description of the information sender, namely, the person or organization providing texts in Web pages. Ohshima et al. (2009) proposed a method for reranking Web pages according to users' regionality, which depends on two factors: uniformity and proximity. While the abovementioned studies mainly facilitate users' assessments of the credibility of individual Web pages, the following studies deal with the issues of credibility of information in multiple documents on the Web. Murakami et al. (2009) proposed a method to analyze semantic relationships such as agreement, conflict, or evidence between texts on the Web. Kawahara et al. (2009) reported a method for presenting overviews of evaluative information such as positive/negative opinions.

Although the above techniques facilitate users' assessments of credibility of information on the Web, there is still room for methods that support users' judgment. For example, when the truth of a statement[1] "Diesel engines are harmful to the environment" is to

[1] In this paper, a *statement* is defined as text such as an opinion, evaluation, or objective fact.

Coling 2008: Poster Volume, pages 1140–1148,
Beijing, August 2010

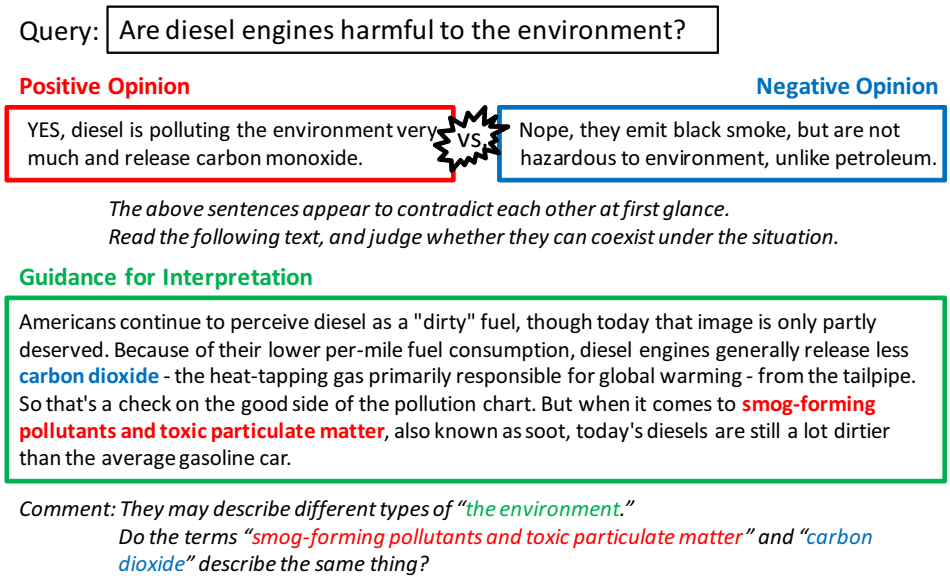

Figure 1: An example of the mediatory summary.

be verified, the following two contradictory groups of Web documents are obtained: one stating that "Diesel engines are harmful to the environment" and the other stating that "Diesel engines are not harmful to the environment." How does one resolve this conflict? Are the contents of one group that contains a less reasonable description wrong? On the other hand, if contents of both these groups are correct, then why do they appear to be contradictory to each other? A display of only the overview of statements in Web documents and the relationships between these statements does not always provide sufficient information to answer these questions.

In order to direct users to a reasonable interpretation written by one author, Kaneko et al. (2009) proposed the notion of a mediatory summary for *pseudo conflicts*, which are relationships between statements that appear to contradict each other at first glance but can coexist under a certain situation. However, Kaneko et al. did not describe any algorithms for automatically generating the mediatory summary. Therefore, in this paper, we propose a method for automatically generating the mediatory summary and demonstrate the effectiveness of generated mediatory summaries.

The rest of this paper is organized as follows. In Section 2, we describe the concept of a mediatory summary and the features required for automatically generating it. In Section 3, we describe an algorithm for generation of the mediatory summary. In Section 4, we present experimental results to demonstrate the effectiveness of the generated mediatory summary. Section 5 provides the conclusion.

2 Mediatory Summary

The generation of the mediatory summary is a type of informative summarization based on passage extraction. Figure 1 shows an example of the ideal mediatory summary for the query "Are diesel engines harmful to the environment?" The text in boxes with thick lines is extracted from Web documents, and the italicized text is generated through templates. The user is shown both positive and negative responses to the query and appropriately guided on how to interpret them. One of the most difficult issues in the automated generation of the mediatory summary is the extraction of the most suitable passage that is used for interpretation.[2]

[2]Owing to space limitations, we have omitted the discussion on generation through templetes.

Nakano et al. (2010) constructed a text summarization corpus for determining the credibility of information on the Web. Their corpus contains six query statements, the Web document collections retrieved for each query, and 24 summaries made by four persons per query. We analyzed these summaries from the viewpoint of mediatory summary generation and observed that mediatory summaries usually display the following three features.

The first feature is the high relevance to a given query. We can approximately determine whether the text displays this feature by examining whether or not it contains content words in the query such as "diesel," as in Figure 1. The second feature is fairness, or in other words, evenly describing both positive and negative opinions. We can approximately determine whether the text displays this feature by examining whether or not it contains words for both opinions and having different, typically opposite meanings such as "lot" and "less," as in Figure 1. It should be noted that words with opposite meanings are not limited to antonyms. In the case of the query "Are diesel engines harmful to the environment?," "carbon dioxide" and "smog-forming pollutants" should be also regarded as words with opposite meanings. The third feature is the high density of words of the above two types in a text. In addition to appropriateness of a text with high density as a summary, such a text is likely to be a text contrasting both sides of contents.

3 Proposed Method

3.1 Outline

We propose a method for generating mediatory summaries by extracting passages that display the features described in the previous section. First, we define the content words related to the topic of a query as *topic keywords*.[3] Next, we define the content words corresponding to the positive and negative opinions as *positive keywords* and *negative keywords*, respectively. Although topic keywords appear in the given query, positive/negative keywords hardly appear in the given query. Therefore, positive/negative keywords have to be extracted from other text.

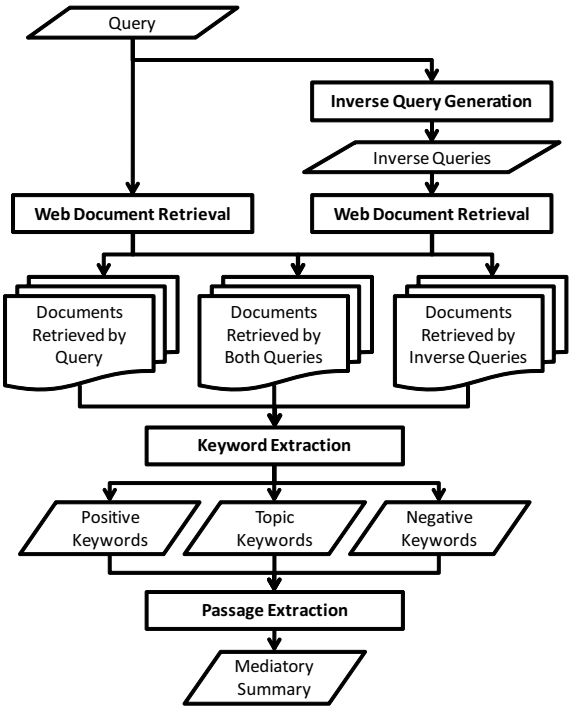

Figure 2: Outline of the proposed method.

Figure 2 shows the outline of the proposed method. First, in order to find contents opposed to a given query, *inverse queries* are generated. We define an inverse query as a query generated by replacing a word in the given query with its antonym. Next, the given query and the inverse queries are used to retain three sets of Web documents, which are likely to contain more positive keywords, negative keywords, and neither. The topic, positive, and negative keywords are then extracted from these sets. Finally, the extracted keywords are used to extract passages from the three sets of Web documents; these passages are ranked in order of the score described in Section 3.5 as a mediatory summary.

[3] Although topic words are not restricted to words in the given query, we use only the words in the given query as topic words in this paper. Inclusion of words other than those in the given query is a topic for future research.

3.2 Inverse Query Generation

Inverse queries are generated by simply replacing a word in the given query with an antonym of the word using a dictionary for antonyms. For example, if the query is "Is safety of LASIK operation high?," and if "risk" and "low" are input into the dictionary as antonyms of "safety" and "high," respectively, then the two generated inverse queries are "Is risk of LASIK operation high?" and "Is safety of LASIK operation low?" Positive keywords are words in the given query that are to be replaced with their opposite words in the inverse queries. On the other hand, the newly introduced opposite words in the inverse queries are regarded as negative keywords. In the above example, "safety" and "high" are positive keywords, whereas "risk" and "low" are negative ones. If there is no replaceable word, the inverse query is not generated.

3.3 Web Document Retrieval

Using a given query and the corresponding inverse queries, Web documents are retrieved via TSUBAKI (Shinzato et al., 2008); TSUBAKI is an open-search engine with aninfrastructure based on deep Japanese natural language processing, and it can accept a natural-language sentence as a query. The number of documents retrieved per query is tentatively set to 100 in our experiment described in Section 4.

The retrieved documents are classified into the following three document sets: one containing documents retrieved by the given query but not retrieved by the inverse queries, one containing documents retrieved by the inverse queries but not retrieved by the given query, and one containing documents retrieved by both the given query and the inverse queries. These three document sets are termed D_{query}, $D_{inverse}$, and D_{both}, respectively. Words appearing frequently in D_{query} are likely to be positive keywords, and those appearing frequently in $D_{inverse}$, negative keywords.

TSUBAKI has an optional function for automatically expanding a submitted query by including the negative form of the main verb in the query. For example, if "Is safety of LASIK operation high?" is the submitted query, then the expanded query is "Is safety of LASIK operation not high?" The documents retrieved for the expanded query derived from the given query are regarded as documents retrieved for inverse queries. Similarly, the documents retrieved for the expanded query derived from the inverse queries are regarded as documents retrieved for the given query. Hence, even if there is no inverse query, possibly conflicting documents can be retrieved.

Table 1: An example of extracted keywords.

word	$rank_{tf}$	$rank_{POS}$	$rank_{NEG}$	polarity
LASIK	1	1	1	other
operation	2	2	2	other
eyesight	3	3	3	other
examination	19	13	60	positive
glasses	47	58	75	other
blindness	61	5,045	20	negative
effect	66	72	111	positive
complications	77	206	58	negative

3.4 Keyword Extraction

Positive and negative keywords are extracted from the retrieved Web documents as follows. First, the positive score $sc_{POS}(w)$ and negative score $sc_{NEG}(w)$ of a word w are calculated by Equations (1) and (2), respectively:

$$sc_{POS}(w) = \frac{df(w, D_{query}) \cdot tf(w)}{df(w, D_{inverse}) + 1} \quad (1)$$

$$sc_{NEG}(w) = \frac{df(w, D_{inverse}) \cdot tf(w)}{df(w, D_{query}) + 1} \quad (2)$$

where $tf(w)$ is the frequency of w in all retrieved documents, and $df(w, D)$ is the number of documents containing w in D. The $sc_{POS}(w)$ is higher and $sc_{NEG}(w)$ is lower if the word w appears more frequently in the documents retrieved by the given query and less frequently in the documents retrieved by the inverse queries. The frequency $tf(w)$ is

used to express these scores in order to consider the global importance of w in the entire retrieved document set.

Because words such as "LASIK" in the query "Is safety of LASIK operation high?" have high scores in terms of both $sc_{POS}(w)$ and $sc_{NEG}(w)$, such words should not be extracted as positive or negative keywords. Because the number of documents in D_{query} is different from that in $D_{inverse}$, $sc_{POS}(w)$ cannot be directly compared with $sc_{NEG}(w)$. Hence, $sc_{POS}(w)$ and $sc_{NEG}(w)$ are normalized, and $rank_{POS}(w)$ and $rank_{NEG}(w)$ are compared. The ranking functions $rank_{POS}(w)$ and $rank_{NEG}(w)$ are defined as the nth place ranks when all words are ranked in the descending order of $sc_{POS}(w)$ and $sc_{NEG}(w)$, respectively. We consider the top C_{rank} words on the $tf()$ ranking as candidates for possible keywords. If $rank_{POS}(w) - rank_{NEG}(w)$ or $rank_{NEG}(w) - rank_{POS}(w)$ is greater than C_{dif}, then we regard w as a positive or negative keyword, respectively. Table 1 shows an example of the extracted keywords when the given query is "Is safety of LASIK operation high?" In this paper, C_{rank} and C_{dif} are tentatively set to 100 and 20, respectively, in a preliminary experiment using several queries except the ones described in Section 4.[4] Finally, the positive/negative keywords, mentioned in Section 3.2, are respectively added to the positive/negative keyword sets described above.

The topic keywords are the words in the given query excluding the positive/negative keywords.

3.5 Passage Extraction

Passages suitable for a mediatory summary are extracted through the following four stages.

For all sentences in the document sets described in Section 3.3, the first stage involves the recognition of sentences that are useless for mediatory summary. We regard insufficient or incomplete sentences as useless sentences. We simply consider a sentence to be sufficient when the sentence has, at least, one verb phrase and one noun phrase and when the sentence contains more than two verb/noun phrases. We simply consider a sentence to be insufficient if it is not a sufficient sentence. When the expression "...," which indicates an omission, appears at the end of a sentence, then we consider the sentence incomplete. This recognition of sentences plays an important role in the calculation of scores in subsequent stages.

The second stage involves the calculation of the score of each sentence. When KW is defined as a set of all the topic, positive, and negative keywords, the basic score $sc_{BAS}(s)$ of sentence s is calculated by Equation (3).

$$sc_{BAS}(s) = \frac{\sum_{w \in KW} appear(w, s)}{|KW|} \qquad (3)$$

where $appear(w, s)$ is a function whose value is 1 if w appears in s and 0 otherwise. If s contains many different keywords, $sc_{BAS}(s)$ acquires a high value. If s is recognized as a useless sentence, then $sc_{BAS}(s)$ is multiplied by $C_{useless}$ as a penalty. In this paper, $C_{useless}$ is tentatively set to 0.5 in the case of ungrammatical sentences and 0 in the case that the end of the sentences is omitted. When the score of a sentence is calculated, the fairness described in Section 2 is determined in the following manner. If s contains positive/negative keywords besides topic keywords, the $sc_{BAS}(s)$ is multiplied by C_{basic}. The negative form of positive/negative keywords is considered, and C_{basic} is tentatively set to two if either a positive or negative expression appears in s and to three if both positive and negative expressions appear in s.

The third stage involves the application of a smoothing method to raw scores of a sentence in order to suppress over-fragmentation of passages. As given in Equation (4), the smoothed score $sc_{SMO}(s_i)$ for the ith sentence s_i in a document is calculated using the Hann

[4]The parameters used in this paper are set tentatively. Determining the optimal parameters is a topic for future research.

function, whose window length is L.

$$sc_{SMO}(s_i) = \sum_{j=-\frac{L}{2}}^{\frac{L}{2}} (sc_{BAS}(s_{i+j}) \cdot hf(j)) \quad (4)$$

$$hf(k) = 0.5 + 0.5 \cos 2\pi \frac{k}{L} \quad (5)$$

The value of L is tentatively set as 5 in this study. Insufficient sentences may convey useful information to readers when they are embedded in an appropriate context. On the other hand, incomplete sentences do not. Therefore, $sc_{SMO}(s)$ of such omitted sentences is set as 0 even after smoothing. If all types of keywords appear in the Hann window, then $sc_{SMO}(s)$ is multiplied by C_{smooth} because a passage containing s is likely to be a part of a mediatory summary. The value of C_{smooth} is tentatively set as 2 in this study.

The fourth stage involves the extraction and ranking of passages. Every series of sentences with $sc_{SMO}(s)$ greater than $\frac{1}{N}$ of the maximum score in the document is extracted as a passage. N is tentatively set as 3. The score $sc_{PAS}(p)$ of passage p is the highest score $sc_{SMO}(s)$ of sentence s in the passage. If all types of keywords appear in p, the $sc_{PAS}(p)$ is multiplied by $C_{passage}$, as in the third stage. Note that the length of the extracted passages is not set to L sentences and that passages that contain sentences multiplied by C_{smooth} are not always multiplied by $C_{passage}$. $C_{passage}$ is tentatively set as 3 in this study. Because of summarization, the passages whose lengths are nearer to the ideal length C_{length} are ranked higher. The final score $sc_{FIN}(p)$ is calculated by Equation (6).

$$sc_{FIN}(p) = \exp\left(sc_{PAS}(p) - \alpha \cdot er(p)\right) \quad (6)$$

$$er(p) = |C_{length} - nc(p)| \quad (7)$$

where $nc(p)$ is the number of characters in p, and α is a coefficient. C_{length} and α are tentatively set to 300 and 0.02, respectively.

4 Experiment

4.1 Conditions

Because the proposed method is the first method for automated generation of mediatory summary, there is no existing method to directly compare our proposed method with. Therefore, we compare the proposed method with the following three methods. The first method, $KWtf$, uses frequent words instead of the three types of keywords described in Section 3.4. The second method, Lin_{TSU}, uses an existing summarization module for summarizing the top documents in order of the score in which TSUBAKI retrieves them. The third method, Lin_{scFIN}, uses the same existing summarization module for summarizing documents containing the top passages in order of the score $sc_{FIN}()$ described in Section 3.5. We employ Lingua::JA::Summarize::Extract[5] as a summarization module, which extracts sentences containing more characteristic words; this extraction is based on the word frequency and word bigram frequency in a given document.

$KWtf$ is compared with the proposed method in order to investigate the effectiveness of keywords in terms of polarity. One of the functions of the proposed method is the classification of the top C_{rank} words on the $tf()$ ranking into positive keywords, negative keywords, and others in order to determine the fairness described in Section 2. $KWtf$ is simply based on frequent words and does not classify them. In other words, all of the top C_{rank} words on the $tf()$ ranking are used as keywords without polarity. It should be noted that no rewards can be obtained using C_{basic}, C_{smooth}, and $C_{passage}$ in the passage extraction described in Section 3.5, although penalties can be obtained using $C_{useless}$ and C_{length}.

Lin_{TSU} is compared with the proposed method in order to clarify the difference between the summarization by our method and that by a method used for general purposes. In other words, we investigate whether or not the extraction of sentences containing more characteristic words is sufficient for generating mediatory summaries.

Lin_{scFIN} is compared with the proposed method in order to investigate the appropri-

Proposed	33.3%	26.7%	13.3%	Proposed	0.0%	0.0%	6.7%
KWtf	0.0%	0.0%	6.7%	KWtf	0.0%	0.0%	0.0%
Lin$_{TSU}$	66.7%	46.7%	26.7%	Lin$_{TSU}$	11.1%	6.7%	3.3%
Lin$_{scFIN}$	33.3%	26.7%	13.3%	Lin$_{scFIN}$	0.0%	0.0%	13.3%

ateness of the extracted passages. Another function of the proposed method is the reranking of passages regardless of the order of documents containing the passages during document retrieval. Therefore, a set of documents summarized by the proposed method may be different from the set of documents summarized by Lin_{TSU}. Therefore, it is observed that Lin_{scFIN} handles the same documents as the proposed method.

Because the mediatory summary is a novel concept, methods for evaluating it have not been developed yet. Although ROUGE (Lin and Hovy, 2003) is one of the most popular methods for evaluation of summaries, it may not be appropriate for the evaluation of the mediatory summary because the scoring based on N-gram in this method cannot be used to consider the fairness described in Section 2. Therefore, we evaluate the methods through the binary judgment of three human assessors, If the top summaries produced by each method are deemed to be appropriate by the three human assessors, we will be able to facilitate users' assessments of the contradictory opinions that are relevant to the given query.

Because we consider that filling a passage with all the information necessary to facilitate users' assessments is more important than shortening the passage under conditions for generation of mediatory summary, we imposed no limitation on the length of passages but the resultant penalty is obtained using Equations (6) and (7). The average length of all summaries generated by the proposed method and $KWtf$ was 288.4 characters, and none of the summaries exceeded 500 characters. Therefore, we allowed Lin_{TSU} and Lin_{scFIN} to generate summaries as long as 500 characters, which is about 200 characters longer than summaries generated by the proposed method and $KWtf$. We instructed the assessors to not judge the appropriateness of the summaries on the basis of their length.

For the experiment, we prepared the following six queries: "Are diesel engines harmful to the environment?," "Is safety of LASIK operation high?," "Are whales endangered species?," "Does asbestos have toxics?," "Is catch and release a better way of fishing?," and "Does carbon dioxide cause global warming?" We used the Japanese morphological analyzer, MeCab.[6]

[6]http://mecab.sourceforge.net/ (in Japanese)

Table 3: Average precision of assessors in terms of appropriateness of overall summaries.

	Top 3	Top 5	Top 10
Proposed	42.6%	30.0%	27.2%
KWtf	5.6%	3.3%	6.1%
Lin$_{TSU}$	37.0%	25.6%	21.7%
Lin$_{scFIN}$	9.3%	12.2%	13.9%

4.2 Result and Consideration

The kappa values between each pair of assessors' judgments on the appropriateness of the summaries were 0.79, 0.77, and 0.76, respectively; these values indicate a high level of agreement among assessors' judgments.

Table 2 shows the average precision[7] of the assessors in terms of appropriateness of summaries on the basis of responses to each query, and Table 3 shows the overall precision. The columns in Tables 2 and 3 show the precision of appropriateness for the top 3, top 5, and top 10 summaries produced by each method. It should be noted that there are only a few passages suitable for mediatory summary in all of the retrieved documents, and therefore a method for placing such suitable passages at a higher rank is more effective. We confirmed that the proposed method provided the best overall results among all the compared methods.

The difference between the proposed method and KWtf shows that classification of frequent words into positive keywords, negative ones, and others, in other words, the fairness described in Section 2 contributed to generation of appropriate mediatory summaries.

The difference between Lin$_{TSU}$ and Lin$_{scFIN}$ indicates that the order of the score $sc_{FIN}()$ described in Section 3.5 was different from that of the score of TSUBAKI. Lingua::JA::Summarize::Extract could not extract the appropriate passages from document sets on the basis of $sc_{FIN}()$, even though the document sets contained the same appropriate passages that were extracted by the proposed method. Therefore, summarization for a general purpose is insufficient for generation of mediatory summaries, and the proposed method can provide more appropriate mediatory summaries.

However, the results of the queries "Is catch and release a better way of fishing?" and "Does carbon dioxide cause global warming?" in Table 2 show that the proposed method could not extract all the appropriate passages that were extracted by Lin$_{TSU}$. We aim to improve the proposed method in future research.

[7]We use precision, which represents *#correct outputs/#total outputs*, as an evaluation measure because it is difficult to calculate the recall of the mediatory summaries that are dynamically generated from Web documents and because users tend to read just a few of the summaries generated by the system.

5 Conclusion

We proposed a method for automated generation of mediatory summaries in order to facilitate users' assessment of the credibility of information on the Web. A mediatory summary is generated by extracting a passage from Web documents on the basis of their relevance to a given query, fairness, and density of keywords, which are features of the summaries constructed to determine the credibility of information on the Web. We demonstrated the effectiveness of the generated mediatory summary in comparison with the summaries of Web documents produced by Web search engines.

Abstract

Document keywords are associated to documents as summarized versions of the documents' content. Considering that the number of documents is quickly growing every day, the availability of these keywords is very important. Although, usually keywords are manually written. This motivated us to work on an approach to change this manual procedure for an automatic one.

This paper presents a language independent approach that extracts the most relevant Multiword Expressions and single words from documents and propose them to describe the core content of each document.

1 Introduction

Keywords provide efficient and sharp access to documents concerning their main topics, that is, their core content. Keywords are semantically relevant terms, usually being relevant noun-phrases rather than long full phrases. Full phrases such as "John F Kennedy's speechwriter hails Obama's address" can be extracted by summarization approaches, but it wouldn't be appropriate if used as keywords since it doesn't mean any main topic/subtopic. On the other hand, by using LocalMaxs algorithm (Silva and Lopes, 1999) it is possible to extract Multiword Expressions (MWEs) from documents and, some of the most relevant ones relatively to each document can be used as that document's descriptor, if properly selected. In this paper we will show that MWEs having 2, 3 our 4 words, that is, (2-4)-gram MWEs, are the most appropriate ones to fit the typical keywords' semantic sharpness, as would be the case of "climate change", "American Red Cross", "social and economic policy", etc., rather than (5-7)-grams and larger MWEs addressing more specific meanings, such as "skills for lifelong learning process report" or "Assessment of the use of Magnetic Resonans Tomography".

On the other hand, although MWEs extracted by LocalMaxs algorithm are usually relevant, some of them are semantically vague or simply not relevant, such as "general use" or "Annex I", not having the semantic relevance and sharpness required to form keywords. Other MWEs such as "in case of" or "as soon as possible" may be useful for lexicon enrichment to improve Natural Language Processing, but they are not relevant MWEs to be taken as keywords.

During our investigation, we discovered that the median of the words' length in each MWE has a strong influence in the MWE relevance. Thus, combining this and other factors that influence relevance, a metric, Mk, is proposed to better evaluate the relevance of each MWE under the purpose of obtaining keywords, and consequently its relevance score in each document.

Although most document keywords are multiwords, there are some single words , that is, 1-grams, whose strong and sharp meaning make them good keywords, such as "Agriculture", "salmonella", among others. Then, since we wanted to include single words in the set of the main keywords of each document, and because LocalMaxs algorithm does not extracts 1-grams, we had to select the most informative single words

Coling 2008: Poster Volume, pages 1149–1157,
Beijing, August 2010

from documents using another metric, Sk, also presented in this paper.

This paper proposes a statistical and language-independent approach to generate document descriptors based on the automatic extraction of the most informative MWEs and single words, in terms of document summarization, under the purpose of keywords, taken from each document. Next section analyzes related work. A brief explanation of the LocalMaxs algorithm is presented in section 3. In section 4 we propose the metrics Mk and Sk and consider other measures. Results are presented in section 5 and conclusion are made in the last section.

2 Related Work

In (Cigarrán et al., 2005; Liu et al., 2009; Hulth, 2004) authors propose extraction of noun phases and keywords. However, these are not language-independent approaches, since they use some language-dependent tools such as stop-words removing, lemmatization, part-of-speech tagging or syntactic pattern recognition.

In (Delort et al., 2003), authors address the issue of Web document summarization by context. They consider the context of a Web document by the textual content of all documents linking to it. According to the authors, the efficiency of this approach depends on the size of the content and context of the target document. However, its efficiency also depends on the existence of links to the target documents.

In (Aliguliyev, 2006) a generic summarization method is proposed. It extracts the most relevance sentences from the source document to form a summary. The summary can contain the main contents of different topics. This approach is based on clustering of sentences and, although results are not shown, it does not use language-dependent tools.

Other Information Extraction methods rely on predefined linguistic rules and templates to identify certain entities in text documents (Yangarber and Grishman, 2000; Jacquemin, 2001). Again, these are not language-independent approaches, despite the good results that they give rise to.

Some approaches address specific-domain problems. In (Alani et al., 2003), authors propose a method to extract artist information, such as name and date of birth from documents and then generate his or her biography. It works with meta-data triples such as (subject-relation-object), using ontology-relation declarations and lexical information. Clearly, this approach is not language-independent. In (Velardi et al., 2001), a method to extract a domain terminology from available documents such as the Web pages is proposed. The method is based on two measures: Domain Relevance and Domain Consensus that give the specificity of a terminological candidate. In (Martínez-Fernández et al., 2004) the News specific-domain is addressed. Again, this approach is not language-independent.

A supervised approach (Ercan and Cicekli, 2007) extracts keywords by using lexical chains built from the WordNet ontology (Miller, 1991), a tool which is not available for every language.

Rather than being dependent on specific languages, structured data or domain, we try to find out more general and language-independent features from free text data.

In (Silva and Lopes, 2009), a MWEs extractor and a metric, $LeastRvar$, extracts keywords from documents. However, single words are ignored as possible keywords and their global results are outperformed by our proposal.

3 Using LocalMaxs Algorithm to Extract Keyword Candidates

We used the SCP_f cohesion metric and the LocalMaxs algorithm to extract MWEs from document *corpora*. Although details about these tools are given in (Silva and Lopes, 1999; Silva et al., 1999), here follows a brief description for paper self-containment. Thus, LocalMaxs is based on the idea that each n-gram[1] has a kind of *glue* or cohesion sticking the words together within the n-gram. Different n-grams usually have different cohesion values. One can intuitively accept that there is a strong cohesion within the n-gram "Giscard d'Estaing" i.e. between the words "Giscard" and "d'Estaing". However, one cannot say that there is a strong cohesion within the 2-grams "or given" or within the "of two". Thus, in order to

[1] $w_1 \dots w_n$ or $(w_1 \dots w_n)$ are also used to denote an n-gram of length n.

measure the cohesion value not only of 2-grams, but also for every n-gram of any size in the corpus, we used the $SCP\_f(.)$ metric:

$$SCP\_f(w_1 \dots w_n) = \frac{p(w_1 \dots w_n)^2}{Avp} \quad (1)$$

$$Avp = \frac{1}{n-1} \sum_{i=1}^{n-1} p(w_1 \dots w_i) \,.\, p(w_{i+1} \dots w_n) \quad (2)$$

where $p(w_1 \dots w_n)$ is the probability of the n-gram $w_1 \dots w_n$ in the corpus. This way, any size n-gram is *transformed* in a pseudo-bigram that reflects the *average cohesion* between any two adjacent contiguous sub-n-gram of the original n-gram. Now it is possible to compare cohesions from n-grams of different sizes.

3.1 LocalMaxs Algorithm

LocalMaxs is a language independent algorithm to filter out cohesive n-grams of text elements (words, tags or characters), requiring no threshold arbitrarily assigned.

Definition 1. *Let $W = w_1 \dots w_n$ be an n-gram and $g(.)$ a cohesion generic function. And let: $\Omega_{n-1}(W)$ be the set of $g(.)$ values for all contiguous $(n-1)$-grams contained in the n-gram W; $\Omega_{n+1}(W)$ be the set of $g(.)$ values for all contiguous $(n+1)$-grams which contain the n-gram W, and let $len(W)$ be the length (number of elements) of n-gram W. So, it is stated that*

W is a Multi Element Unit (MEU) if and only if,
for $\forall x \in \Omega_{n-1}(W), \forall y \in \Omega_{n+1}(W)$
$(len(W) = 2 \wedge g(W) > y) \quad \vee$
$(len(W) > 2 \wedge g(W) > \frac{x+y}{2})$.

Then, for n-grams with $n \geq 3$, LocalMaxs algorithm elects every n-gram whose cohesion value is greater than the average of two maxima: the greatest cohesion value found in the contiguous $(n-1)$-grams contained in the n-gram, and the greatest cohesion found in the contiguous $(n+1)$-grams containing the n-gram. Thus, in the present approach we used LocalMaxs as a MWEs extractor — MWEs are MEUs where the elements are words — and used $SCP\_f(.)$ cohesion measure as the $g(.)$ function referred in the algorithm definition above.

4 Selecting Keywords from MWEs

Not every MWE extracted by LocalMaxs has equal relevance or semantic sharpness. Some MWEs are vague in terms of semantic sharpness, such as “important meeting” or “general use”; other ones are very specific in terms of the topic they point to, for example “Assessment of the use of Magnetic Resonans Tomografy”; some others are (2-4)-gram strongly informative MWEs, fitting the semantic sharpness of typical keywords such as “computer science” or ”Food and Agriculture Organization”, and will be privileged by the metric we present in subsection 4.4.

Some single words have adequate semantic sharpness to be included as keywords, such as ”Algebra” or ”Agriculture”, among others. However, most single words are not informative enough for that purpose.

As a consequence, we felt the need to work on adequate metrics to value and privilege the strongly informative MWEs and single words in order to find keywords in documents.

4.1 The *Tf-Idf* Metric

$Tf{-}Idf$ (Term frequency−Inverse document frequency) is a statistical metric often used in IR and text mining. Usually, it is used to evaluate how important a word is to a document in a *corpus*. The importance increases proportionally to the number of times a word/multiword appears in the document but it is offset by its frequency in the *corpus*. Thus, this is one of the metrics with which we will try to privilege the most informative MWEs and 1-grams in each document.

$$Tf{-}Idf(W, d_j) = p(W, d_j) \,.\, Idf(W, d_j) \quad (3)$$

$$p(W, d_j) = \frac{f(W, d_j)}{N_{d_j}} \quad (4)$$

$$Idf(W, d_j) = \log \frac{\|\mathcal{D}\|}{\|\{d_j : W \in d_j\}\|} \quad (5)$$

where $f(W, d_j)$ if the frequency of word/multiword W in document d_j and N_{d_j} stands for the number of words of d_j; $\|\mathcal{D}\|$ is the number of documents of the *corpus*. So, $Tf{-}Idf(W, d_j)$ will give a measure of the importance of W, that is a MWE or a single word, within the particular document d_j. By the structure of term Idf we can see

that it privileges MWEs and single words occurring in less documents, particularly those occurring in just one document.

4.2 The *LeastRvar* Metric

Most weakly relevant MWE and errors extracted by LocalMaxs begin or end with a so called stopword, that is a highly frequent word appearing in most documents. However, stop-words may exist in the middle of a relevant MWE, for example "United States of America" or "Life on Mars"; but usually not in the leftmost or rightmost word of the MWEs. By considering this, $LeastRvar$ was proposed in (Silva and Lopes, 2009):

$$LeastRvar(MWE_i) = least(Lrv, Rrv) \quad (6)$$

where $Lrv = Rvar(leftmostw(MWE_i))$,
$Rrv = Rvar(rightmostw(MWE_i))$

and

$$Rvar(W) = \frac{1}{\|\mathcal{D}\|} \sum_{d_i \in \mathcal{D}} \Big(\frac{p(W,d_i) - p(W,.)}{p(W,.)} \Big)^2 \ . \quad (7)$$

$p(W,.)$ means the average probability of the word W considering all documents. $Rvar(.)$ is applied to the leftmost and the rightmost word of the MWE:

$$p(W,.) = \frac{1}{\|\mathcal{D}\|} \sum_{d_i \in \mathcal{D}} p(W,d_i). \quad (8)$$

$Rvar(W)$ measures the variation of the probability of the word W along all documents. Apparently the usual formula of the variance (the second moment about the mean), would measure that variation; however, it would wrongly benefit the very frequent words such as "of", "the" or "and", among others. This happens because the absolute differences between the occurrence probabilities of any of those frequent words along all documents is high, regardless of the fact that they usually occur in every document. These differences are captured and over-valued by the variance since it measures the average value of the quantity $(distance\, from\, mean)^2$, ignoring the *order of magnitude* of the individual probabilities. Then, $Rvar(.)$ divides each *individual distance*, in the original formula of the variance, by the order of magnitude of these probabilities, that is, the mean probability, given by $p(W,.)$; see equations 7 and 8.

Then, $LeastRvar(MWE_i)$ is given by the least $Rvar(.)$ values considering the leftmost word and the rightmost word of MWE_i. This way, $LeastRvar(.)$ tends to privilege informative MWEs and penalize those multiword expressions having semantically meaningless words in the begin or in the end of it.

4.3 The *LeastCv* metric

In oder to try to obtain better results than those produced by *LeastRvar*, we changed $Rvar(.)$ to an alternative to measure the relative variation of the probability of the leftmost and rightmost words in MWEs. Then we defined:

$$LeastCv(MWE_i) = least(Lcv, Rcv) \quad (9)$$

where $Lcv = Cv(leftmostw(MWE_i))$,
$Rcv = Cv(rightmostw(MWE_i))$,

$$Cv(W) = \sigma(W)/\mu(W) \ , \quad (10)$$

$$\sigma(W) = \sqrt{\frac{1}{\|\mathcal{D}\|} \sum_{d_i \in \mathcal{D}} (p(W,d_i) - p(W,.))^2} \ , \quad (11)$$

and

$$\mu(W) = p(W,.) \ ; \quad (12)$$

$p(W,d_i)$ and $p(W,.)$ have the same meaning as in equation 7. The reader may recognize $Cv(.)$ as the *coefficient of variation*, which is given by the ratio of the standard deviation σ to the mean μ. Results in section 5 will show that $LeastCv$ also tends to privilege informative MWEs.

4.4 Two New Metrics to Find Keywords

Considering the results obtained for *LeastRvar* and *LeastCv*, as we will see in section 5, we wanted to develop a better metric to find MWE keywords and another one for single word keywords. They were built by combining some important factors that we present next.

The Median of the MWE Words' Length: Since most of the semantically meaningless words

are small and long words usually have sharp meaning, we considered the median length of the words in each MWE to help on selecting the most informative MWEs. By comparison, median length showed better results than average length. For example, MWE "Language Institute" has an average word length of 8.5 characters, but the semantically equivalent "Institute of Languages" has a different average length of 6.66. On the contrary, the median length for both MWEs presents more close values: $((8+9)/2 = 8.5)$ for "Language Institute" and 9 for "Institute of languages" (the middle number after sorting the MWE words length: 2, 9 and 9). Thus, because the median values is more robust to outliers than the average value, the length of the meaningless word "of" was, say, *ignored* in the median calculation. In fact, those equivalent meaning MWEs have similar median length values (8.5 and 9), but not so similar average length values (8.5 and 6.66). Furthermore, the robustness of the median length enables more similar values when considering MWEs in English and other equivalent MWEs in other languages where stop words are more used; for example "écoles de conduite" (driving schools), "producción de batata" (potato production), etc..

How Many Words for a Keyword? As the reader may check in documents having associated keywords, we noticed that the main document keywords are usually (2-4)-grams. So, we defined a factor, $Ckl(MWE_i)$, to measure how similar is the *pseudo number of words* of MWE_i to the *typical* number of words of keywords. We define the *pseudo number of words* of a MWE:

$$Pnw(MWE_i) = \frac{NumChars(MWE_i)}{Med(MWE_i)} \ . \tag{13}$$

$NumChars(MWE_i)$ stands for the number of characters of MWE_i and $Med(MWE_i)$ is the median length of its words. $Pnw(MWE_i)$ gives a value close to the number of meaningful words of MWE_i. For example, Pnw("Institute of Languages") $= 20/9 = 2.2$ (close to 2); Pnw("European Council") $= 15/7.5 = 2$, etc.. Now, $Ckl(.)$ is given by:

$$Ckl(MWE_i) = \frac{1}{|Pnw(MWE_i) - T| + 1} \ , \tag{14}$$

where T is the *typical* number of words of the keywords. Maximum value for $CkLen(MWE_i)$ is 1; it happens if $Pnw(MWE_i)$ equals to T. As we will see by the results in section 5, we tried two T values: 2.5 and 3.5; and compared results.

The *Mk* Metric for MWE Keywords: We built $Mk(.)$ metric by improving $LeastRvar(.)$:

$$Mk(M) = LeastRvar(M).Med(M).Ckl(M) \tag{15}$$

Thus, $Mk(.)$ privileges MWEs having not only informative leftmost and rightmost words, but also having long words and a *pseudo number of words* close to the number of words of typical keywords – for reasons of lack of space, we used M instead of MWE_i in equation 15 –.

The *Sk* Metric for *Single Word* Keywords: We built $Sk(.)$ from $Rvar(.)$ – see equation 7 – to measure how meaningful is each single word:

$$Sk(W_i) = Rvar(W_i).Len(W_i) \ . \tag{16}$$

$Len(W_i)$ means the length of words W_i. Thus, $Sk(.)$ privileges single words having, not only a high relative variation of their probabilities along all documents, but also being long words.

5 Results

We analyze the quality of the document descriptors after applying the LocalMaxs extractor followed by each of the six different metrics to three different document *corpora*, each one for a different language: English, French and Spanish. Metrics applied to MWEs were $Tf{-}Idf$, $LeastCv$, $LeastRvar$, $Mk\,[2.5]$ – that is $T = 2.5$ in equation 14; and $Mk\,[3.5]$. Metrics applied to single words were $Tf{-}Idf$ and Sk.

5.1 The Document Descriptor

We decided to represent the core content of each document by using its 15 most informative terms, in the sense of keywords: 11 MWEs and 4 single words. An independent evaluation criteria were

defined by Prof. Francisca Xavier from the Linguistics Department of *Universidade Nova de Lisboa*. It was considered that, for example, "aim of mission" and "16 December 2003" are wrong keywords, as the first one is a too vague noun phrase and the second one, just a simple date. Relevant MWEs such as "nuclear weapons" and "financial crisis" were evaluated as keywords. However, although some proposed multi-word expressions are not keywords, they are informative in the context of the descriptor and correspond to well formed morphosyntactic tags, for example, "56% of GDP" or "comfort zone": these *near-miss* cases were classified as half-correct half-wrong terms; the same classification was given to single words such as "macro-economic" – see table 7 – which, although it's not a noun, it's an informative adjective.

Thus, for each document, the extracted MWEs are sorted according to each metric and the top 11 MWEs are taken as the document's MWEs descriptor. The single words of the document are also sorted according to one of the two applied metrics ($Tf{-}Idf$ or Sk). By ignoring the rest of the MWEs and single words, there is document information which will be *lost* by these descriptors, but they must be taken as core content descriptors, not as complete/detailed reports of the documents. Although descriptors are composed by MWEs and single words, for better comparison of the metrics, tables separately show MWE descriptors or *single word* descriptors. Table 1 shows an example of a document MWE descriptor resulting from the application of one of the metrics (Mk) to the document's MWEs extracted by LocalMaxs algorithm:

Table 1: Example of an English Document MWE Descriptor – Application of the $Mk\,[2.5]$ Metric.

enterprise profits
comfort zone
medium-sized enterprises
brain drain
cold war
Balance of Payment
56% of GDP
excessive deficit
looking ahead
exports and imports
Stability and Growth Pact

5.2 The Multi-Language *Corpora* Test

We used the *EUR-Lex corpora*, http://eur-lex.europa.eu/en/, containing European Union law documents about several topics in several European languages. We took 60 documents written in each language, English, French and Spanish to form three different *sub-corpora*. These are unstructured row text documents.

To evaluate the approach's performance, we used Precision and Recall concepts. Precision was given by the number of keywords in the set of the 11 most scored MWEs proposed as descriptor, by the combination LocalMaxs$-$metric used, divided by 11. Recall was given by the number of keywords that are simultaneously in the document's descriptor proposed and in the set made of the 11 most informative keywords of the document, divided by 11.

According to the criteria mentioned above, this is the evaluation of the descriptor shown in table 1, considering Precision: 8 MWEs can be accepted as keywords (1st, 3rd, 4th, 5th, 6th, 8th, 10th and 11th); 2 near-miss MWEs (2nd and 7th); and 1 weak or wrong MWE (9th). So, precision is $(8 + 2 * 0.5)/11 = 0.818$. Concerning the document this descriptor represents, there are 3 strong keywords that should be in the descriptor, but they weren't: "financial crisis", "structural reforms" and "macroeconomic imbalances". Thus, Recall is $8/11 = 72.7$ for this case.

5.3 Results for Different Metrics and Languages

By table 2 we may see that for the same metric, Precision or Recall values are similar for English, French and Spanish. So, this approach does not seem to privilege any of these languages, and we believe that probably this happens for many other languages, as no specific morphosyntactic information was used. Even the difference between Recall values for Spanish and English produced by $LeastRvar$ (0.61 and 0.63) would probably decrease if the test *corpora* had more documents. Table 2 also shows that $Tf{-}Idf$ presents the poor-

Table 2: Precision and Recall Average Values for the Document MWE Descriptors.

Language	Metric	Precision	Recall
English	$Tf–Idf$	0.51	0.35
	$LeastCv$	0.62	0.61
	$LeastRvar$	0.65	0.63
	$Mk\,[2.5]$	**0.76**	**0.72**
	$Mk\,[3.5]$	0.74	0.68
French	$Tf–Idf$	0.50	0.35
	$LeastCv$	0.62	0.60
	$LeastRvar$	0.64	0.63
	$Mk\,[2.5]$	**0.75**	**0.71**
	$Mk\,[3.5]$	0.73	0.68
Spanish	$Tf–Idf$	0.51	0.34
	$LeastCv$	0.61	0.60
	$LeastRvar$	0.64	0.61
	$Mk\,[2.5]$	**0.75**	**0.72**
	$Mk\,[3.5]$	0.74	0.67

est results. In fact, due to its structure — see equation 3 — we can see that MWEs that occur many times in just one document are the most valued/privileged ones. This explains why the descriptors made by this measure tend to include too specific/local MWEs, regardless of some important ones. Table 3 shows a document descriptor generated by the combination LocalMaxs$–Tf–Idf$: for example MWE "new Members" occurs in just one document, 10 times; however, "new Members" is not a keyword. This is the descriptor of the same document from where other descriptors were generated by the combinations including $LeastRvar$ and $Mk\,[2.5]$, and shown in tables 4 and 1.

For reasons of space limitation we don't show descriptors produced by $LeastCv$ and $MK\,[3.5]$ metrics. However, table 2 shows that $LeastCv$ was outperformed by $LeastRvar$. This table also shows that $Mk\,[2.5]$ metric presents the highest Precision (0.76, 0.75 and 0.75 for English, French and Spanish). The highest Recall values are also obtained for the same metric: 0.72, 0.71 and 0.72 for the same languages.

Tables 5 and 6 show examples of MWE descriptors of French and Spanish documents, by the application of $Mk\,[2.5]$ as it produced the best results.

brain drain

Tables 7 and 8 show examples of *single word* descriptors for the same document described in table 1. As we could expect, Precision and Recall values for *single word* descriptors are lower than the values for MWEs descriptors, since singles words are usually semantically less sharp than multiwords: see table 9. Sk shows better performance than $Tf–Idf$, specially for Recall.

6 Conclusions

Keywords are semantic tags associated to documents, usually declared manually by users. These tags form small document descriptors and enable applications to access to the summarized documents' core content. This paper proposes an approach to automatically generate document de-

scriptors, as a language-independent and domain-independent alternative to related work from other authors. This approach uses LocalMaxs algorithm to extract MWEs, and two new statistical metrics, Mk and Sk, to select the 15 most relevant MWEs and single words from each document in order to form document descriptors.

Comparing the results produced by Mk with the second best metric, $LeastRvar$, we may conclude that the introduction of the median of the words' length of each MWE and the preference for (2-4)-grams, improve the quality of document descriptors by about 11% and 9% for Precision and Recall, respectively. Furthermore, by comparison of $Mk\,[2.5]$ and $Mk\,[3.5]$ results we conclude that keywords are mostly (2-3)-grams, rather than (3-4)-grams or longer n-grams.

Results also showed that Precision and Recall values are similar for the three languages tested (English, French and Spanish), which enable us to expect similar performance to other languages. Apart from the Precision and Recall values, document descriptors made by this approach does indeed capture the core content of each document. We believe this may contribute to improve document summarization. Future work will include tests in other languages and we will work to improve results, specially for single words.

Abstract

We study a novel shallow information extraction problem that involves extracting sentences of a given set of topic categories from medical forum data. Given a corpus of medical forum documents, our goal is to extract two related types of sentences that describe a biomedical case (i.e., medical problem descriptions and medical treatment descriptions). Such an extraction task directly generates medical case descriptions that can be useful in many applications. We solve the problem using two popular machine learning methods Support Vector Machines (SVM) and Conditional Random Fields (CRF). We propose novel features to improve the accuracy of extraction. Experiment results show that we can obtain an accuracy of up to 75%.

1 Introduction

Conventional information extraction tasks generally aim at extracting finer granularity semantic information units such as entities and relations. While such detailed information is no doubt very useful, extraction of such information also tends to be difficult especially when the mentions of the entities to be extracted do not conform to regular syntactic patterns.

In this paper, we relax this conventional goal of extraction and study an easier extraction task where we aim at extracting sentences that belong to a set of predefined semantic categories. That is, we take a sentence as a unit for extraction. Specifically, we study this problem in the context of extracting medical case description from medical forums.

A variety of medical health forums exist online. People use them to post their problems, get advices from experienced patients, get second opinions from other doctors, or merely to vent out their frustration.

Compared with well-structured sources such as Wikipedia, forums are more valuable in the sense that they contain first hand patient experiences with richer information in terms of what treatments are better than others and why. Besides this, on forums, patients explain their symptoms much more freely than those mentioned on relatively formal sources like Wikipedia. And hence, forums are much more easier to understand for a naïve user.

However, even on targeted forums (which focus on a single disease), data is quite unstructured. There is therefore a need to structure out this information and present it in a form that can directly be used for a variety of other information extraction applications like the collecting of medical case studies pertaining to a particular disease, mining frequently discussed symptoms, identifying correlation between symptoms and treatments, etc.

A typical medical case description tends to consist of two aspects:

- **Physical Examination/Symptoms (PE)**: This covers current conditions and includes any condition that is the focus of current discussion. Note that if a drug causes an allergy, then we consider it as a PE and not a medication. Any condition that is the focus of conversation, i.e. around which

Coling 2008: Poster Volume, pages 1158–1166,
Beijing, August 2010

treatments are being proposed or questions are being asked is considered PE even if the user is recounting their past experience.

- **Medications (MED)**: Includes medications the person is currently taking, or is intending to take, or any medication on which the question is targeted. Medications do not necessarily mean drugs. Any measures (including avoiding of substances) taken to treat or avoid the symptoms are considered as medication. Sometimes, users also mention other things like constituents of the drug, how much of the drug to consume at a time, how to get access to a medication, how much it costs, side effects of medications, other qualities of medications etc.

Figure 1 shows an example of PE and MED labelings.

<MED>i was told hot peppers ie in salsa,
mexican,spicy,szechuan/polynesian type foods are great treatments.</MED>
<PE>They help against nasal/sinusitis/rhinitis conditions.</PE>
<PE>ie allergies/colds</PE>
<MED>also,i believe zyrtec and antihistimines can be and should be
taken before bedtime to eliminate daytime drowsiness.</MED>
<MED>Try vitamin c drops (also aids throat dryness) as a supplement.
Vitamin C can also be found in red peppers.
Peppers can clear passageways i heard in an article recently.</MED>

Figure 1: Example of PE and MED labelings

We thus frame the problem of extracting medical case descriptions as extracting sentences that describe any of these two aspects. Specifically, the task is to identify sentences in each of the two related categories (i.e., PE and MED) from forum posts. As an extraction task, this task is "shallower" than conventional information extraction tasks such as entity extraction in the sense that we extract a sentence as a unit, which makes the extraction task more tractable. Indeed, the task is more similar to sentence categorization. However, it also differs from a regular sentence categorization task (e.g., sentiment analysis) in that the multiple categories are usually closely related and categorization of multiple sentences may be dependent in the sense that knowing the category of one sentence may influence our decision about the category of another sentence nearby. For example, knowing that a sentence is in the category PE should increase our belief that the next sentence is of category of PE or MED.

We solve the problem using two popular machine learning methods, Support Vector Machines (SVM) and Conditional Random Fields (CRF). We define and study a large set of features, including two kinds of novel features: (1) novel features based on semantic generalization of terms, and (2) novel features specific to forums.

Since this is a novel task, there is no existing data set that we can use for evaluation. We thus create a new data set for evaluation. Experiment results show that both groups of novel features are effective and can improve extraction accuracy. With the best configurations, we can obtain an accuracy of up to 75%, demonstrating feasibility of automatic extraction of medical case descriptions from forums.

2 Related work

Medical data mining has been looked atleast since the early 2000s. Cios and Moore (2002) emphasize the uniqueness of medical data mining. They stress that data mining in medicine is distinct from that in other fields, because the data are heterogeneous, and special ethical, legal, and social constraints apply to private medical information. Treatment recommendation systems have been built that use the structured data to diagnose based on symptoms (Lazarus et al., 2001) and recommend treatments. Holt et al.(2005) provide references to medical systems that use case based reasoning methodologies for medical diagnosis. Huge amounts of medical data stored in clinical data warehouses can be used to detect patterns and relationships, which could provide new medical knowledge (Lazarus et al., 2001). In contrast, we look at the problem of converting some of the unstructured medical text data present in forum threads into structured symptoms and treatments. This data can then be used by all of the above mentioned applications.

Structuring of unstructured text has been studied by many works in the literature. Automatic information extraction (Aone and Ramos-Santacruz, 2000; Buttler et al., 2001) and wrapper induction techniques have been used for structuring web data. Sarawagi (2008) and Laen-

der et al. (2002) offer comprehensive overviews of information extraction and wrapper induction techniques respectively. The main difference between our work and main stream work on extraction is that we extract sentences as units, which is shallower but presumably more robust. Heinze et al. (2002) state that the current state-of-the-art in NLP is suitable for mining information of moderate content depth across a diverse collection of medical settings and specialties. Zhou et al. (2006), the authors perform information extraction from clinical medical records using a decision tree based classifier using resources such as WordNet [1], UMLS [2] etc. They extract past medical history and social behaviour from the records.

In other related works, sentiment classification (Pang et al., 2002; Prabowo and Thelwall, 2009; Cui et al., 2006; Dave et al., 2003) attempts to categorize text based on polarity of sentiments and is often applied at the sentence level (Kim and Zhai, 2009). Some work has also been done on extracting content from forum data. This includes finding question answer pairs (Cong et al., 2008) from online forums, auto-answering queries on a technical forum (Feng et al., 2006), ranking answers (Harabagiu and Hickl, 2006) etc. To the best of our knowledge, this is the first work on shallow extraction from medical forum data.

3 Problem formulation

Let $P = (s_1, ...s_n)$ be a sequence of sentences in a forum post. Given a set of interesting categories $C = \{c_1, ..., c_k\}$ that describe a medical case, our task is to extract sentences in each category from the post P. That is, we would like to classify each sentence s_i into one of the categories c_i or *Background*, which we treat as a special category meaning that the sentence is irrelevant to our extraction task. Depending on specific applications, a sentence may belong to more than one category.

In this paper, we focus on extracting sentences of two related categories describing a medical case: (1) Physical Examination (PE), which includes sentences describing the condition of a patient (i.e., roughly symptoms) (2) Medications (MED), which includes sentences mentioning medications (i.e., roughly treatment). These sentences provide a basic description of a medical case and can already be very useful if we can extract them.

We chose to analyze at the sentence level because a sentence provides enough context to detect the category accurately. For example, detecting the categories at word level will not help us to mark a sentence like *"I get very uncomfortable after eating cheese"* as PE or mark a sentence like *"It's best to avoid cheese in that case"* as MED. Here the problem is loosely represented by a combination of *"uncomfortable eating cheese"* and the solution is represented loosely by *"avoid cheese"*. Indeed, in preliminary analysis, we found that most of the times, the postings consist of PE and MED type sentences.

4 Methods

We use SVMs and CRFs to learn classifiers to solve our problem. SVMs represent approaches that solve the problem as a classification/categorization task while CRFs solve the problem as a sequence labeling task. In this section, we provide the basics of SVMs and CRFs.

4.1 Support Vector Machines

SVM first introduced in (Boser et al., 1992), are a binary classifier that constructs a hyperplane which separates the training instances belonging to the two classes. SVMs maximize the separation margin between this hyperplane and the nearest training datapoints of any class. The larger the margin, the lower the generalization error of the classifier. SVMs have been used to classify both linearly and non-linearly seperable data, and have been shown to outperform other popular classifiers like decision trees, Naïve Bayes classifiers, k-nearest neighbor classifiers, etc. We use SVMs as a representative classifier that does not consider dependencies between the predictions on multiple sentences.

4.2 Conditional Random Fields

Each of the sentences in the postings can itself contain features which help us to categorize it.

[1] http://wordnet.princeton.edu/

[2] http://www.nlm.nih.gov/research/umls

Besides this, statistical dependencies exist between sentences. Intuitively, a MED sentence will follow a PE sentence with high probability, but the probability of a PE sentence following an MED sentence would be low. Conditional random fields are graphical models that can capture such dependencies among input sentences. A CRF model defines a conditional distribution $p(y|x)$ where y is the predicted category (label) and x is the set of sentences (observations). CRF is an undirected graphical model in which each vertex represents a random variable whose distribution is to be inferred, and each edge represents a dependency between two random variables. The observation x can be dependent on the current hidden label y, previous n hidden labels and on any of the other observations in a n order CRF. CRFs have been shown to outperform other probabilistic graphical models like Hidden Markov Models (HMMs) and Maximum Entropy Markov Models (MeMMs). Sutton and McCallum (2006) provide an excellent tutorial on CRFs.

5 Features

To perform our categorization task, we use the following features.

- **Word based features**: This includes unigrams, bigrams and trigrams in the current sentence. Each of the n-grams is mapped to a separate boolean feature per sentence where value is 1 if it appears in sentence and 0 otherwise.
- **Semantic features**: This includes Unified Medical Language System (UMLS[3]) semantic groups of words in the current sentence. UMLS is a prominent bio-medical domain ontology. It contains approximately a million bio-medical concepts grouped under 135 semantic groups. MMTX[4] is a tool that allows mapping of free text into UMLS concepts and groups. We use these 135 semantic groups as our semantic features. In order to generate these features, we first process this sentence through MMTX API which provides all the semantic groups that were found in the sentence. Each of the semantic groups becomes a boolean feature.
- **Position based features**: We define two types of position based features: position of the current sentence in the post and position of the current post in the thread. These features are specific to the forum data. We include these features based on the observations that first post usually contains condition related sentences while subsequent posts often contain treatment measures for the corresponding condition. Each of the position number of a sentence in a post and a post in a thread is mapped to a boolean feature which gets fired for a sentence at a particular position. E.g. For a sentence at position i in a post, POSITION_IN_POST_i would be set to 1 while other features POSITION_IN_POST_j where $j \neq i$ would be set to 0.
- **User based features**: We include a boolean feature which gets fired when the sentence is a part of a post by the thread creator. This feature is important because most of the posts by a thread creator have a high probability of being a PE.
- **Tag based features(Edge features)**: We define features on tags (PE/MED/Backgnd) of previous two sentences to capture local dependencies between sentences. E.g., a set of medication related tags often follow a description of a condition. We use these features only for CRF based experiments.
- **Morphological features**: These include one boolean feature each for presence of
  - a capitalized word in the sentence
  - an abbreviation in the sentence
  - a number in the sentence
  - a question mark in the sentence
  - an exclamation mark in the sentence
- Length based features: We also consider the number of words in a sentence as a separate type of feature. Feature LENGTH_i becomes true for a sentence containing i words.

Table 1: Labeling results

6 Experiments

6.1 Dataset

Evaluation of this new extraction task is challenging as no test set is available. To solve this problem, we opted to created our own test set. HealthBoards[5] is a medical forum web portal that allows patients to discuss their ailments. We scraped 175 posts contained in 50 threads on allergy i.e., an average of 3.5 posts per thread and around 2 posts per user with a maximum of 9 posts by a particular user. Two humans were asked to tag this corpus as conditions (i.e., PE category) or treatments (i.e., MED category) or none on a per sentence basis. The corpus consists of 1494 sentences. Table 1 shows the labeling results. The data set is available at (http://timan.cs.uiuc.edu/downloads.html). Also the labeling results match quite well (82.86%) with a Kappa statistic value of 0.73. Occasionally (around 3%) PE and MED both occur in the same sentence and the labelers chose to mark such sentences as PE. In the case when the two labelers disagree, we manually analyzed the results and further chose one of them for our experiments.

6.2 Evaluation methodology

For evaluation, we use 5-fold cross validation. For CRFs, we used the Mallet[6] toolkit and for SVM, we used SVM-Light[7]. We experimented by varying the size of the training set, with different feature sets, using two machine learning models: SVMs and CRFs. Our aim is to accurately classify any sentence in a post as PE or MED or background. First we explore and identify the feature sets that help us in attaining higher accuracy. Next, we identify the setting (sequence labeling by CRFs or independent classification by SVMs) that works better to model our problem. We present most of our results using four metrics: precision, recall, F1 measure and average accuracy which is the ratio of correctly labeled sentences to the total sentences.

We considered the following features: all the 2647 words in the vocabulary (no stop-word removal or any other type of selection), 10858 bigrams, 135 semantic groups from UMLS, two position based features, one user based feature, two tag based features, four morphological features and one length based feature as described in the previous section. Thus our feature set is quite rich. Note that other than the usual features, semantic, position-based and user-based features are specific to the medical domain or to forum data.

6.3 Basic Results

First we considered word features, and learned a linear chain CRF model. We added other sets of features one by one, and observed variations in accuracy. Table 2 shows the accuracy in terms of precision, recall and F1. Note that these results are for an Order 1 linear-chain CRF. Accuracy is measured as ratio of the number of correct labelings of PE, MED and background to the total number of sentences in our dataset. Notice that the MED accuracy values are in general quite low compared to those of PE. As we will discuss later, accuracy is low for MED because our word-based features are not discriminative enough for the MED category.

From Table 2, we see that the accuracy keeps increasing as we add semantic UMLS based features, position based features and morphological features. However, length based features (word count), user-based faetures, and bigrams do not result in any improvements. We also tried trigrams, but did not observe any accuracy gains. Thus we find that semantic features and position-based features which are specific to the medical domain and the forum data respectively are helpful when added on top of word features, while generic features such as length-based features tend to not add value.

We also trained an order 2 CRF using the same set of features. Results obtained were similar to order 1 CRFs and so we do not report them here. This shows that local dependencies are more im-

Table 2: Order 1 Linear Chain CRF. †Improvement over only word features significant at 0.05-level, using Wilcoxon's signed-rank test

portant in medical forum data and global dependencies do not add further signal.

Further, we perform experiments using SVMs using the same set of features. Table 3 shows accuracy results on SVM. Again PE is detected with higher accuracy compared to MED. Unlike CRFs, SVMs do not incorporate the notion of local dependencies between sentences. However, we observe that SVMs outperform CRFs, as is evident from the results in Table 3. This is interesting, since it suggests that the SVM accuracy can potentially be further enhanced by incorporating such dependency information (e.g. in the form of new features). We leave this as part of future work.

Figure 2 shows an example of a forum post (which talks about allergy to dogs) being tagged using our CRF model.

<BKG>lori-lynn , </BKG>
<PE>you said he does well with the poms , but you also said he takes shots, so i wondered if the shots were for dog allergies</PE>
<PE>a lot of his friends have dogs , though , and he ' s so very allergic that he has trouble at their homes .</PE>
<MED>we opted not to go with the shots . </MED>
<BKG>i ' m still a little leary about adopting a dog . </BKG>
<BKG>i would just hate it if we did have reactions , because i know we ' d bond with the dog very quickly . </BKG>

Figure 2: Tagging example of a forum post

6.4 Feature selection

Incremental addition of different feature types did not lead to substantial improvement in performance. This suggests that none of the feature classes contains all "good" features. We therefore perform feature selection based on information gain and choose the top 4253 features from among all the features discussed earlier, based on a threshold for the gain. This results in improvement in the accuracy values over the previous best results (Table 4).

Among the word feature set, we found that important features were *allergy, alergies, food, hives, allergic, sinus, bread.* Among bigrams, *allergic_to, ear_infections, my_throat, are_allergic, to_gluten, food_allergies* have high information gain values. Among the UMLS based semantic groups, we found that *patf (Pathologic Function), dsyn (Disease or Syndrome), orch (Organic Chemical), phsu (Pharmacologic Substance), sosy (Sign or Symptom)* have high information gain values. Also looking at the word count feature, we notice that background sentences are generally short sentences. All these features are clearly highly discriminative.

6.5 Variation in training data size

We varied the amount of training data used for learning the models to observe the variation in performance with size of training data. Table 5 shows the variation in accuracy (PE F1, MED F1 and average accuracy) for different sizes of training data using CRFs. In general, we observe that accuracy improves as we increase the training data, but the degree varies with the feature sets used. We see similar trends in SVM also. These results show that it is possible to further improve prediction accuracy by obtaining additional training data.

6.6 Probing into the low MED accuracy

As observed in Tables 2 and 3, MED accuracy is quite low compared to PE accuracy. We wish to gain a deeper insight into why the MED accuracy suffers. Therefore, we plot the frequency of words in sentences marked as PE or MED versus the rank of the word as shown in the figure 3. We removed the stop words. Observe that for PE the curve is quite steep. This indicates that there

Feature set	PE Prec	MED Prec	PE Recall	MED Recall	PE F1	MED F1	Accuracy %
Word	0.65	0.52	0.71	0.28	0.68	0.36	66.13
+Semantic	0.73	0.54	0.73	0.38	0.73	0.45	71.02†
+Position	0.71	0.52	0.71	0.35	0.71	0.42	69.61
+Morphological	0.72	0.53	0.72	0.38	0.72	0.44	70.28
+WordCount	0.74	0.54	0.72	0.37	0.73	0.44	71.55
+Thread Creator	0.74	0.56	0.72	0.39	0.73	0.46	72.02
+Bigrams	0.75	0.54	0.72	0.40	0.74	0.46	71.69

Table 3: SVM results. †Improvement over only word features significant at 0.05-level, using Wilcoxon's signed-rank test

Classifier	PE Prec	PE Recall	PE F1	MED Prec	MED Recall	MED F1	Accuracy %
SVM (all* features)	0.72	0.53	0.72	0.38	0.72	0.44	70.28
SVM (selected features)	0.75	0.75	0.75	0.61	0.33	0.44	75.08†
CRF (all* features)	0.64	0.52	0.69	0.36	0.66	0.42	65.70
CRF (selected features)	0.60	0.77	0.67	0.58	0.37	0.45	65.93†

Table 4: Accuracy using the best feature set. (*Word +Semantic +Position +Morphological features). †Improvement over all* features significant at 0.05-level, using Wilcoxon's signed-rank test

are some discriminative words which have very high frequency and so the word features observed in the training set also get fired for sentences in the test set with high probability. While for MED, we observe that most of the words have very low frequencies. This basically means that discriminative words for MED may not occur with good enough frequency. So, many of the word features that show up in the training set may not appear in the test data. Hence, MED accuracy suffers.

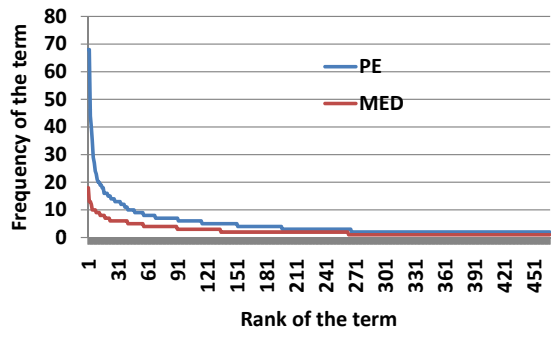

Figure 3: Freq of words vs rank for PE and MED

6.7 Multi-class vs Single class categorization

Note that our task is quite different from plain sentence categorization task. We observe that there is a dependence between the categories (PE/MED) that we are trying to predict per sentence. For example, considering 100% training data, Table 6 compares the precision, recall and F1 values when

	PE	MED	Backgnd	EOP
PE	0.54	0.13	0.28	0.05
MED	0.15	0.51	0.30	0.04
Backgnd	0.18	0.08	0.54	0.20
BOP	0.40	0.07	0.53	0.0

Table 7: Transition probability values

SVM and CRF are trained as single class classifiers using word+semantic features with the multi-class results obtained previously. Results are generally better when we do multi-class categorization versus single-class categorization. This trend was reflected for other featuresets also.

6.8 Analysis of transition probabilities

Table 7 shows the transition probabilities from one category to another as calculated based on our labelled dataset. BOP is beginning of posting and EOP is end of posting. Note that posts often start with a PE or a background sentence and often end with a background sentence. Also, consecutive sentences within a posting tend to belong to the same category.

6.9 Error analysis

We also perform some error analysis on results using the best feature set. Table 8 shows the confusion matrix for CRF/SVM. We observe many of the MED errors are because an MED sentence often gets marked as PE. This basically happens because some sentences contain both PE and MED.

Feature set	25%	50%	75%	100%
Word	0.59/0.21/0.57	0.6/0.36/0.60	0.61/0.39/0.62	0.62/0.42/0.63
+Semantic	0.61/0.17/0.59	0.63/0.32/0.61	0.64/0.38/0.63	0.64/0.43/0.65
+Position	0.59/0.18/0.56	0.64/0.29/0.60	0.65/0.33/0.62	0.66/0.42/0.65
+Morphological	0.6/0.19/0.57	0.64/0.32/0.61	0.65/0.37/0.63	0.66/0.42/0.65
Best	0.61/0.18/0.65	0.66/0.28/0.64	0.66/0.38/0.66	0.69/0.43/0.68

Table 5: Precision, recall, and F value for various sizes of training data set.

Classifier Type	PE Prec	PE Recall	PE F1	MED Prec	MED Recall	MED F1
SVM PE vs BKG	0.79	0.64	0.71	-	-	-
SVM MED vs BKG	-	-	-	0.6	0.28	0.39
SVM Multi-class	0.73	0.73	0.73	0.54	0.38	0.45
CRF PE vs BKG	0.68	0.64	0.66	-	-	-
CRF MED vs BKG	-	-	-	0.53	0.3	0.39
CRF Multi-class	0.61	0.68	0.64	0.52	0.37	0.43

Table 6: Multi-class vs Single-class categorization with word+semantic features

	PE	MED	Backgnd
PE	424/404	37/37	81/101
MED	102/70	107/95	81/125
Backgnd	164/62	55/21	618/754

Table 8: Confusion matrix showing counts of actual vs predicted labels for (Best CRF Classifier/Best SVM Classifier)

Other than that some of the PE keywords are also present in MED sentences, and since the few discriminative MED keywords are quite low in frequency, MED accuracy suffers. E.g. The sentence *"i'm still on antibiotics for the infection but they don't seem to be doing any good anymore."* was labeled as MED but marked as PE by the CRF. The sentence clearly talks about a medication. However, the keyword *"infection"* is often observed in PE sentences and so the CRF marks the sentence as PE.

7 Conclusion

In this paper, we studied a novel shallow information extraction task where the goal is to extract relevant sentences to a predefined set of categories that describe a medical case. We proposed to solve the problem using supervised learning and explored two representative approaches (i.e., CRF and SVM). We proposed and studied two different types of novel features for this task, including generalized terms and forum structure features. We also created the first test set for evaluating this problem. Our experiment results show that (1) the proposed new features are effective for improving the extraction accuracy, and (2) it is feasible to automatically extract medical cases in this way, with the best prediction accuracy above 75%.

Our work can be further extended in several ways. First, since constructing a test set is labor-intensive, we could only afford experimenting with a relatively small data set. It would be interesting to further test the proposed features on larger data set. Second, while in CRF, we have shown adding dependency features improves performance, it is unclear how to evaluate this potential benefit with SVM. Since SVM generally outperforms CRF for this task, it would be very interesting to further explore how we can extend SVM to incorporate dependency.

Abstract

This work presents a study to bridge topic modeling and personalized search. A probabilistic topic model is used to extract topics from user search history. These topics can be seen as a roughly summary of user preferences and further treated as feedback within the KL-Divergence retrieval model to estimate a more accurate query model. The topics more relevant to current query contribute more in updating the query model which helps to distinguish between relevant and irrelevant parts and filter out noise in user search history. We designed task oriented user study and the results show that: (1) The extracted topics can be used to cluster queries according to topics. (2) The proposed approach improves ranking quality consistently for queries matching user past interests and is robust for queries not matching past interests.

1 Introduction

The majority of queries submitted to search engines are short and ambiguous and the users of search engines often have different search intents even when they submit the same query (Janse and Saracevic, 2000)(Silverstein and Moricz, 1999). The "one size fits all" approach fails to optimize each individual's specific information need. Personalized search has be viewed as a promising direction to solve the "data overload" problem, and aims to provide different search results according to the specific preference of an individual(Pitkow and Breuel, 2002). Information retrieval (IR) communities have developed models for context sensitive search and related applications (Shen and Zhai, 2005a)(White and Chen, 2009).

The search context includes a broad range of information types such as a user's background, his personal desktop index, browser history and even the context information of a group of similar users (Teevan, 2009). In this paper, we exploit the user search history of an individual which contains the past submitted queries, results returned and the click through information. As described in (Tan and Zhai, 2006), search history is one of the most important forms of search context. When dealing with search history, distinguishing between relevant and irrelevant parts is important. The search history may contain a lot of noisy information which can harm the performance of personalization (Dou and Wen, 2007). Hence, we need to sort out relevant and irrelevant parts to optimize search personalization.

In this paper, we propose a topic model based approach to study users' preferences. The main contribution of this work is modeling user search history with topics for personalized search. Our approach mainly consists of two steps: topic extraction and relevance feedback. We assume that a user's search history is governed by the underlying hidden properties and apply probabilistic Latent Semantic Indexing (pLSI) (Hofmann, 1999) to extract topics from user search history. Each topic indexes a unigram language model. We model these extracted topics as feedback in the KL-Divergence retrieval framework. The task is to estimate a more accurate query model based on the evidence from user feedback. We distin-

Coling 2008: Poster Volume, pages 1167–1175,
Beijing, August 2010

guish relevant parts from irrelevant parts in search history by focusing on the relevance between topics and query. The closer a topic is to the current query, the more it contributes in updating the query model, which in turn is used to rerank the documents in results set.

2 Related Work

2.1 Personalized IR

Personalized search is an active ongoing research direction. Based on different representations of user profile, we classify approaches as follows:

Taxonomy based methods: this approach maps user interests to an existing taxonomy. ODP[1] is widely used for this purpose. For example, by exploiting the user search history, (Speretta and Gauch, 2005) modeled user interest as a weighted concept hierarchy created from the top 3 level of ODP. (Havelivala, 2002) proposed the "topic sensitive pagerank" algorithm by calculating a set of PageRanks for each web page on the top 16 ODP categories. (Qiu and Cho, 2006) further improved this approach by building user models from user click history. In recent studies, (Xu S. and Yu, 2008) used ODP categories for exploring folksonomy for personalized search. (Dou and Wen, 2007) proposed a method that represent user profile as a weighting vector of 67 predefined topic categories provided by KDD Cup-2005. Taxonomy based methods rely on a predefined taxonomy and may suffer from the granularity problem.

Content based methods: this category of methods use traditional text presentation model such as vector space model and language model to express user preference. Rich content information such as user search history, browser history and indexes of desktop documents are explored. The user profiles are built in the forms of term vectors or term probability distributions. For example, (Sugiyama and M., 2004) represented user profiles as vectors of distinct terms and accumulated past preferences. (Teevan and Horvitz, 2005) constructed a rich user model based on both search-related information, such as previously issued queries, and other information such as documents and emails a user had read and created. (Shen and Zhai, 2005b) used browsing histories and query sessions to construct short term individual models for personalized search.

Learning to rank methods: (Eugene and Susan, 2005) and (Eugene and Zheng, 2006) incorporated user feedback into the ranking process in a *learning to rank* framework. They leveraged millions of past user interaction with web search engine to construct implicit feedback features. However, this approach aims to satisfy majority of users rather than individuals.

2.2 Probabilistic Topic Models

Probabilistic topic models have become popular tools for unsupervised analysis of document collection. Topic models are based upon the idea that documents are mixtures of topics, where a topic is a probability distribution over words (Steyvers and Griffiths, 2007). These topics are interpretable to a certain degree. In fact, one of the most important applications of topic models is to find out semantic lexicons from a corpus. One of the most popular topic models, the probabilistic Latent Semantic Indexing Model (pLSI), was introduced by Hofmann (Hofmann, 1999) and quickly gained acceptance in a number of text modeling applications. In this study, pLSI is used to discover the underlying topics in user search history. Though pLSI is argued that it is not a complete generative model, we used it because it does not need to generate unseen documents in our case and the model is much easier to be estimated compared with sophisticated models such as LDA(David M. Blei and Jordan, 2003).

2.3 Model based Relevance Feedback

Our work is also related to language model based (pseudo) relevance feedback (Zhai and Lafferty, 2001b) and shares the similar idea with (Tan B. and Zhai, 2007). The differences are: (1) The feedback source is user search history rather than top ranked documents for a query. (2) We make use of user implicit feedback rather than explicit feedback. (3) The topics in search history could be extracted offline and updated periodically. Additionally, these topics provide an informative picture of user search history.

3 Proposed Approach

3.1 Main Idea

A user's search history usually covers multiple topics. It is crucial to distinguish between relevant and irrelevant parts for optimizing personalization. We propose a topic model based method to achieve that goal. First, we construct a document collection revealing user intents according to the user's past activities. A probabilistic topic model is applied on this collection to extract latent topics. Then the extracted topics are used as feedback. The query model is updated by highlighting the topics highly relevant to current query. Finally, the search results are reranked according to the relevance to the updated query model. Table 1 shows 4 topics extracted from a user's search history. Each topic is a unigram language model. The terms with higher probabilities belonging to each topic are listed. We can predict that the user has interests in both *movie* and *football*. However, when the user submits a query about *world cup*, the topic 16 is given higher preference for estimating a more accurate query model.

3.2 Topic Extraction from Search History

Individual's search history consists of all the past query units. Each query unit includes query text, returned search results (with title, snippets and URLs) and click through information. Here, we concatenated the title and snippet of each search result to form a document being considered as a whole. The whole search history can be seen as a collection of documents. Obviously, many documents in the collection may fail to satisfy the user's information need and are uncertain for discovering the user's preferences. Therefore, the first task is to select proper documents in search history as the preference collection for topic discovery.

3.2.1 Preference Collection

An intuitive solution is to use the documents that are clicked by the user. The assumption is that a user clicks on a result only if he is interested in the document. However, user click is sparse in real search environments and the documents not clicked by the user may also be relevant to the user's information need. We assumed that the user had only one search intent for a submitted query. To enhance this coherence within a query unit, we created only one super-document for a query unit as follows: if a query unit had clicked documents, then we concatenated these document to form a preferred document. Otherwise, we selected the top *n* documents from the search results and concatenated them as a preferred document. That is motivated by the idea of pseudo relevance feedback (Lavrenko and Croft, 2001) and used here for alleviating data sparsity. Pseudo relevance feedback is sensitive to the number of feedback documents. In this work, *n* is set to 3, because the average clicks for a query is not more than 3. By this way, we got a preference collection whose size is the same as the number of past queries.

3.2.2 Topic Extraction

Given the collection of preferred documents, we applied pLSI on this collection to extract underlying topics. We define the collection as $C=\{d_1,d_2,\ldots,d_M\}$, where d_i corresponds to the ith query unit, and M is the size of the collection. Each query unit is viewed as a mixture of different topics. It is reasonable in reality. For example, a news document about "*play basketball with obama*" might be seen as a mixture of topics "*politics*" and "*sports*".

Modeling: The basic idea of pLSI is to treat the words in each document as being generated from a mixture model where the component models are topic word distributions. Let k be the num-

ber of topics which is assumed known and fixed. θ_j is the word distribution for topic *j*. We extract topics from collection *C* using a simple probabilistic mixture model as described in (Zhai and Yu, 2004). A word *w* within document *d* can be viewed as generated from a mixture model:

$$p_d(w) = \lambda_B p(w|\theta_B) + (1-\lambda_B)\sum_{j=1}^{k}\pi_{d,j}p(w|\theta_j) \quad (1)$$

where θ_B is the background model for all the documents. The background model is used to draw common words across all the documents and lead to more discriminative and informative topic models, since θ_B gives high weights to non-topical words. λ_B is the probability that a term is generated from the background model which is set to be a constant. To draw more discriminative topic models, we set λ_B to 0.95. Parameter $\pi_{d,j}$ indicates the probability that topic *j* is assigned to the specific document *d*, where $\sum_{j=1}^{k}\pi_{d,j}$=1.

Parameter estimation: The parameters we have to estimate including the background model θ_B, $\{\theta_j\}$ and $\{\pi_{d,j}\}$. θ_B is maximum likelihood estimated (MLE) using all available text in our data set so that it is a fixed distribution. The other parameters to be estimated are $\{\theta_j\}$ and $\{\pi_{d,j}\}$. The log-likelihood of document *d* is:

$$\log p(d) = \sum_{w\in V} c(w,d)\log[\lambda_B p(w|\theta_B) + (1-\lambda_B)\sum_{j=1}^{k}\pi_{d,j}p(w|\theta_j)] \quad (2)$$

The log-likelihood of the whole collection *C* is:

$$\log(C) = \sum_{d\in C}\sum_{w\in V} c(w,d)\log[\lambda_B p(w|\theta_B) + (1-\lambda_B)\sum_{j=1}^{k}\pi_{d,j}p(w|\theta_j)] \quad (3)$$

The Expectation-Maximization (EM) algorithm (Dempster and Rubin, 1977) is used to find a group of parameters maximizing equation (3). The updating formulas are:

E-Step:

$$p(z_{d,w}=B) = \frac{\lambda_B p(w|\theta_B)}{\lambda_B p(w|\theta_B) + (1-\lambda_B)\sum_{j=1}^{k}\pi_{d,j}p(w|\theta_j)}$$

$$p(z_{d,w}=j) = \frac{\pi_{d,j}^{(m)} p^{(m)}(w|\theta_j)}{\sum_{j'=1}^{k}\pi_{d,j'}^{(m)} p^{(m)}(w|\theta_{j'})}$$

M-Step:

$$\pi_{d,j}^{(m+1)} = \frac{\sum_{w\in V} c(w,d)(1-p(z_{d,w}=B))\,p(z_{d,w}=j)}{\sum_{j'=1}^{k}\sum_{w\in V} c(w,d)(1-p(z_{d,w}=B))\,p(z_{d,w}=j')}$$

$$p^{(m+1)}(w|\theta_j) = \frac{\sum_{d\in C} c(w,d)(1-p(z_{d,w}=B))\,p(z_{d,w}=j)}{\sum_{d\in C}\sum_{w'\in V} c(w',d)(1-p(z_{d,w'}=B))\,p(z_{d,w'}=j)}$$

where $c(w,d)$ denotes the number of times *w* occurs in *d*. A hidden variable $z_{d,w}$ is introduced for the identity of each word. $p(z_{d,w}=B)$ is the probability that the word *w* in document *d* is generated by the background model. $p(z_{d,w}=j)$ denotes the probability that the word *w* in document *d* is generated using topic *j* given that *w* is not generated from the background model. Informally, the EM algorithm starts with randomly assigning values to the parameters to be estimated and then alternates between E-Step and M-Step iteratively until it yields a local maximum of the log likelihood.

Interpretation: As shown in equation (1), a word can be viewed as a mixture of topics. From the updating formulas, we can see that the dominant topic of a word depends on both itself and the context. The word tends to have the same topic with the document containing it. While the probability of assigning topic *j* to document *d* is estimated by aggregating all the fractions of words generated by topic *j* in document *d*. We can explain it in a more intuitive way with in our application. As we know, the queries are usually ambiguous. A classic example is *"apple"* which may refer to a kind of fruit, apple Inc, apple electric products, etc. Therefore, it is reasonable to assume that each word belongs to multiple latent semantic properties. If a returned result contains *"apple"* and other words like *"computer"*, *"ipod"* , etc. The word *"apple"* in this result tends to have the same topic distributions with *"computer"* and

'ipod". If the user clicks the result, we can predict that the user's real preference about query *"apple"* is related to electric products having a high probability. Further, if *"apple"* occurs frequently in many documents related to electric products, it obtains a higher probability in this topic. As a result, we not only know user's interest in electric products, but also find a preference to *"apple"* brand.

Since a document's topic depends on the words it contains, two documents with similar word distributions have similar topic distributions. In other words, each topic is like a bridge connecting queries with similar intents. In summary, the topic extraction process plays a role in our application for finding user preference, highlighting discriminative words and connecting queries with similar intents.

3.3 Topics as Feedback

The topics extracted from search history are considered as a kind of feedback. Since topic models actually are extensions of language models, we use such feedback within the KL-Divergence retrieval model (Xu and Croft, 1999)(Zhai and Lafferty, 2001b) that is a principled framework to model feedback in the language modeling approach. In this framework, feedback is treated as updating the query language model based on extra evidence obtained from the feedback sources. The information retrieval task is to rank documents according to the KL divergence $D(\theta_q||\theta_d)$ between a query language model θ_q and a document language model θ_d. The KL divergence is defined as:

$$D(\theta_q||\theta_d) = \sum_{w \in V} p(w|\theta_q) \log \frac{p(w|\theta_q)}{p(w|\theta_d)} \quad (4)$$

where *V* denotes the vocabulary. We estimate the document model θ_d using Dirichlet estimation (Zhai and Lafferty, 2001a):

$$p(w|\theta_d) = \frac{c(w,d) + \mu p(w|\theta_C)}{|d| + \mu} \quad (5)$$

where $|d|$ is document length, $p(w|\theta_C)$ is collection language model which is estimated using the whole data collection. μ is the Dirichlet prior that is set to 20 in this work. The updated query model is defined as:

$$\begin{aligned} p(w|\theta_q) &= \lambda p_{ml}(w|\theta_q) \\ &+ (1-\lambda) \sum_{j=1}^{k} p(w|\theta_j) p(z=j|q) \end{aligned} \quad (6)$$

where $p_{ml}(w|\theta_q)$ is the MLE query model. $\{\theta_j\}$ represents a set of extracted topics each of which is a unigram language model. λ is used to balance the two components. z is a hidden variable over topics. The task is to estimate the multinomial topic distribution $p(z|q)$ for query *q*. Since pLSI does not properly provide a prior, we estimate $p(z=j|q)$ as:

$$\begin{aligned} p(z=j|q) &= \frac{p(q, z=j)}{\sum_{j'=1}^{k} p(q, z=j')} \\ &\propto \frac{sim(\theta_q, \theta_j)}{\sum_{j'=1}^{k} sim(\theta_q, \theta_{j'})} \end{aligned} \quad (7)$$

Since the query text is usually very short, it is not easy to make a decision based on query text alone. Instead, we concatenate all the available documents in returned result set to form a superdocument. A language model is estimated for it. We convert both the document language model and topic models into weighted term vectors and use cosine similarity as the *sim* function. $p(z|q)$ plays an import role here as it determines the contribution of topics. The topics with higher similarity with current query contributes more in updating query model. This scheme helps to filter out noisy information in search history.

4 Evaluation and Discussion

4.1 Data Collection

To the best of our knowledge, there is no public collection with enough content information and user implicit feedback. We decided to carry out a data collection. Due to the difficulty to describe and evaluate user interests implicitly, we predefined some user interests and implemented a search system to collect user interactions.

The predefined interests belong to 5 big categories namely *Entertainment*, *Computer* & *Internet*, *Sports*, *Health* and *Social life*. Each interest is a kind of user preference such as "movies"

Table 2: An example of predefined user interests and tasks

category	Enterntainment
interest	movies
task1	search for a brief introduction of your favorite movie
task2	search for an introduction of an actor or actress you like
task3	search for movies about "artificial intelligence"

Table 3: Statistics of the data collection

user	1	2	3	4	5
#queries	218	256	177	206	311
#big category	5	5	5	5	5
#interest	25	25	25	25	25
#tasks	100	100	100	100	100
avg.#relevant results	4.17	4.22	3.89	4.12	3.24
avg.#clicked results	2.37	2.21	2.71	1.98	2.42

and "outdoor sports". For each interest, we designed several tasks each of which had a goal. Table 2 illustrates an example of a predefined user interest and related tasks. The volunteers were asked to find out the information need according to the tasks. Though we defined these interests and tasks, we did not impose any constraint on the queries. The volunteers could choose and reformulate any query they thought good for finding the desired information. But we did try to increase the possibility that a user might issue ambiguous queries by designing tasks like "search for movies about artificial intelligence" which was categorized to interest "movies", but also related to computer science.

To collect the user interaction with search engine, we implemented a Lucene based search system on Tianwang terabyte corpus(Yan and Peng, 2005). Five volunteers were asked to submit queries to this system to find information satisfying the tasks of each interest. The system recorded users' activities including submitted queries, returned search results (with title, snippet and URL) and users' click through information. When the user finished a task, he clicked a button to tell the system termination of the session containing all the queries and activities related to this task. After finishing all the tasks, the volunteers were asked to judge the top 20 results' relevance (relevant or not relevant) for each query according to the search target. Each volunteer submitted 233 queries on average. Table 3 presents some statistics of this collection.

4.2 Evaluating Topic Extraction

It is not easy to assess the quality of topics, because topic extraction is an unsupervised process and difficult to give a standard answer. Therefore, we view the topic extraction as a clustering problem that is to organize queries into clusters. To group queries into clusters through extracted topics, we use $\hat{j} = \arg\max_j \pi_{d,j}$ to assign a query to the $\hat{j}$th topic. Each topic corresponds to a cluster. All the queries are divided into *k* clusters. Based on the data collection, we setup the golden answers according to the predefined interests. We view all the queries belonging to a predefined interest(which includes multiple tasks) form a cluster which helps us to build a golden answer with 25 clusters in tatal.

One purpose of making use of topics in search history is to find more relevant parts and reduce the noise. We hope that the extracted topics are coherent. That is, a cluster should contain as many queries as possible belonging to a single interest. To evaluate coherence, we adopt *purity* (Zhao and Karypis, 2001), a commonly used metric for evaluating clustering. The higher the purity is, the better the system performs. We compare our method (denoted as PLSI) against the k-means algorithm(denoted as K-Means) on the preference collection.

Figure 1 shows the overall purity with different number of topics. Our method gained better performance than k-means algorithm consistently. It is effective to discover and organize user interests. Besides, as illustrated in Table 1, our method is able to give higher probability to discriminative words of each topic that provides a clear picture of user search history. This leads to an emergence of novel approaches for personalized browsing.

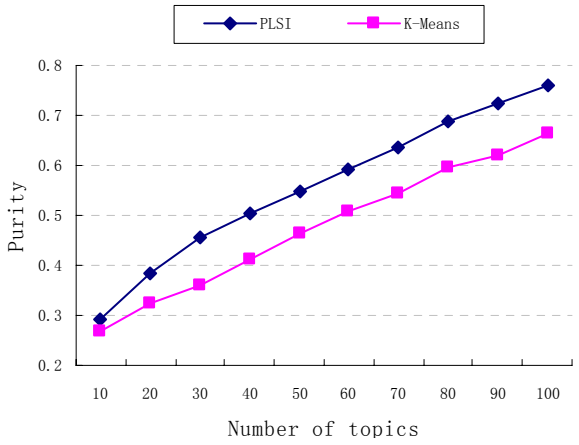

Figure 1: Average purity over 5 users gained by both PLSI and K-Means with different number of topics(clusters).

4.3 Evaluating Result Reranking

4.3.1 Metric

To quantify the ranking quality, the Discounted Cumulative Gain (DCG) (Jarvelin and Kekakainen, 2000) is used. DCG is a metric that gives higher weights to highly ranked documents and incorporates different relevance levels by giving them different gain values.

$$DCG(i) = \begin{cases} G(1), & \text{if } i = 1 \\ DCG(i-1) + \frac{G(i)}{\log(i)}, & \text{otherwise} \end{cases}$$

In our work, we use $G(i) = 1$ for the results labeled as relevant by a user and $G(i) = 0$ for the results that are not relevant. The average normalized DCG (NDCG)over all the test queries is selected to show the performance.

4.3.2 Systems

We evaluated the performance of following systems:

PLSI: The proposed method. The history model was a weighted interpolation over topics extracted from the preference collection described in session 3.2.1.

PSEUDO: From each query unit, we selected top n documents as pseudo feedback. The language history model was estimated on all these documents.

PLSI-PSEUDO: Top n documents from each query unit were concatenated to form a preferred document. The history model was constructed based on topics extracted from these preferred documents.

HISTORY: The history language model was estimated based on all the documents in search history.

TB: It was based on(Tan and Zhai, 2006)which built a unit language model for every past query and the history model was a weighted interpolation of past unit language models.

ORIGINAL: The default search system.

The first 5 systems provided schemes to smooth the query model. They estimated the query models by utilizing different types of feedback (implicit feedback or pseudo feedback) and weighting methods (topic modeling or simple language modeling). The updated query model was an interpolation between MLE query model and history language model. The interpolation parameter was set to 0.5, and n was set to 3.

4.3.3 Performance Comparison

To evaluate the performance on a test query, we focus on two conditions:

1. the test query matches some past interests. We want to check the ability of systems to find relevant information from noisy data.

2. the test query does not match any of past interests. We are interested in the robustness of the systems.

For the first case, the users were asked to select at most 2 queries they submitted for each task. These queries were used as test queries. The other queries were used to simulate the users' search history. In total we got 400 queries for testing. Figure 2 demonstrates the performance of these systems over all test queries. PLSI outperformed all other systems consistently that shows topic model based methods help to estimate a more accurate query model and the user implicit feedback is better evidence. The PLSI-PSEUDO also performed well that indicates the top documents is useful for revealing the topic of queries, even though they do not satisfy user need on occasion. TB also gained better performance than PSEUDO and HISTORY. It indicates

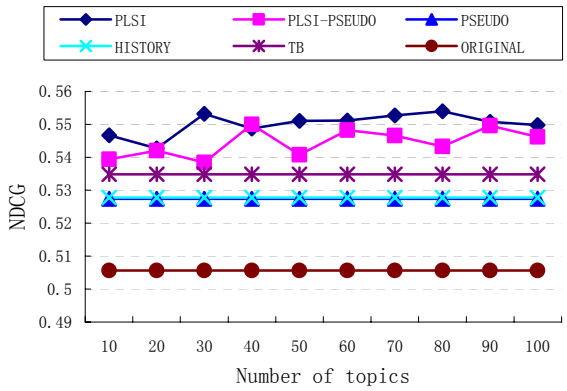

Figure 2: The overall average performance of systems, when each test query matches some user past interests

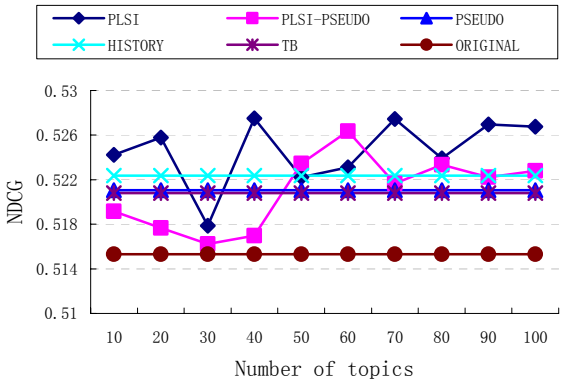

Figure 3: The overall average performance of systems, when each test query does not match any user past interest.

highlighting relevant parts in search history helps to improve the retrieval performance, when the query matches some of user past interests. Compared with default system, both HISTORY and PSEUDO improved a lot which proves that the context in search history is reliable feedback.

For the second case, each user was asked to hold out 5 interests from his collection for testing and the other interests were used as search history. The users selected queries from the held out interests as test queries. These queries did not match each user's past interests. We got 244 test queries. As figure 3 shows, though systems still performed better against ORIGINAL, the improvements were not significant. PLSI still gained the best performance. It has better ability to alleviate the effect of noise. HISTORY and PLSI are more robust than PLSI-PSEUDO which seems sensitive to the number of topics in this case.

In both cases, HISTORY gained moderate performance but quite robust. It is still a very strong baseline, though noisy information is not filtered out. PLSI performed best in both cases. PLSI-PSEUDO outperformed PSEUDO when the test queries matched user past interests and gained comparable results in second case. It shows that modeling user search history as a mixture of topics and weighting topics according to relevance between topics and query help to update a better query model. However, it is necessary to determine if a query matches past interests that helps to optimize personalized search strategies.

5 Conclusion and Future Work

In this paper, we have proposed a topic model based method for personalized search. This approach has some advantages: first, it provides a principled way to combine topic modeling and personalized search; second, it is able to find user preferences in an unsupervised way and gives an informative summary of user search history; third, it explores the underlying relationship between different query units via topics that helps to filter out the noise and improve ranking quality.

In future, we plan to do a large scale study by leveraging the already built search system or business search engines. Also, we will try to add more information to extend the existing model. Besides, it is necessary to design methods for determining whether a submitted query matches the user past interests that is crucial to apply our algorithm adaptively and selectively.

Notes on the Evaluation of Dependency Parsers Obtained Through Cross-Lingual Projection

Kathrin Spreyer
Department of Linguistics
University of Potsdam
spreyer@uni-potsdam.de

Abstract

In this paper we address methodological issues in the evaluation of a projection-based framework for dependency parsing in which annotations for a source language are transfered to a target language using word alignments in a parallel corpus. The projected trees then constitute the training data for a data-driven parser in the target language. We discuss two problems that arise in the evaluation of such cross-lingual approaches. First, the annotation scheme underlying the source language annotations – and hence the projected target annotations and predictions of the parser derived from them – is likely to differ from previously existing gold standard test sets devised specifically for the target language. Second, the standard procedure of cross-validation cannot be performed in the absence of parallel gold standard annotations, so an alternative method has to be used to assess the generalization capabilities of the projected parsers.

1 Introduction

The manual annotation of treebanks for natural language parsing is time-consuming and expensive, but the availability of such resources is crucial for data-driven parsers, which require large amounts of training examples. A technique known as *annotation projection* (Yarowsky and Ngai, 2001) provides a means to relax this resource bottleneck to some extent: In a word-aligned parallel corpus, the text of one language (*source language*, SL), say English, is annotated with an existing parser, and the word alignments are then used to transfer (or *project*) the resulting annotations to the other language (*target language*, TL). The projected trees, albeit noisy, can then constitute the training data for data-driven TL parsers (Hwa et al., 2005; Spreyer and Kuhn, 2009). Finally, in order to assess the quality of the projected parser, its output needs to be compared to held-out TL test data.

Two problems arise in the evaluation of such approaches. First, the annotations projected from the SL usually differ stylistically from those found in the TL test data, rendering any immediate comparison between the predictions of the projected parser and the gold standard meaningless. We discuss the use of tree transformations for evaluation purposes, namely to consolidate discrepancies between the annotation schemes. We then present experiments that investigate the influence of the annotation scheme used in training on the generalization capabilities of the resulting parser. We also briefly address the interaction between annotation style and parsing algorithm (transition-based vs. graph-based).

The second problem addressed here is the assessment of variance in the training data, and hence in parser quality. The standard procedure for this purpose would be *cross-validation*. However, the popular data sets used for benchmarking parsers, such as those that emerged

Coling 2008: Poster Volume, pages 1176–1184,
Beijing, August 2010

from the CoNLL-X shared task on dependency parsing (Buchholz and Marsi, 2006), are typically based on monolingual text. This means that cross-validation is unavailable for projection-based frameworks, because no projection can be performed for the training splits in the absence of a translation in the SL. We therefore propose a validation scheme which accounts for training data variance by training a parser multiple times, on random samples drawn from the projected training data. Each of the obtained parsers can subsequently be evaluated against a fixed, held-out test set independent of the projection step, and the array of accuracy measurements thus obtained can be further subjected to significance testing to verify that observed performance differences are not merely random effects.

The paper is structured as follows. Section 2 describes the projection framework we are assuming. Section 3 summarizes and contrasts the characteristics of four different annotation schemes underlying our SL parsers (English, German) and TL test data (Dutch, Italian). Experiments with different annotation schemes and parsing algorithms are presented in Section 4. In Section 5 we discuss variance assessment in more detail. Section 6 concludes.

2 The Projection Framework

This section briefly describes how we obtain dependency parsers for new languages via annotation projection in a parallel corpus. A detailed discussion can be found in Spreyer and Kuhn (2009).

We use the Europarl corpus (Koehn, 2005) as our parallel corpus. It comprises parallel data from 11 languages; in this paper, we present experiments with English and German as SLs, and Dutch and Italian as TLs.

First, the bitexts for the language pairs under consideration (English-Dutch, English-Italian, German-Dutch, and German-Italian) are word-aligned using Giza++ (Och and Ney, 2003), and all texts are part-of-speech tagged with the TreeTagger (Schmid, 1994) according to pre-trained models.[1]

[1]Available from `http://www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger/DecisionTreeTagger.html`.

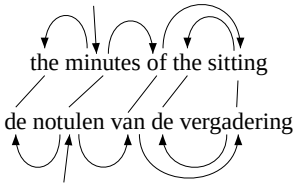

Figure 1: Dependency tree projection from English to Dutch.

Second, we annotate the SL portions, i.e., the German and English texts, with MaltParser dependency parsers (Nivre et al., 2006) trained on standard data sets for the two languages; specifically, we are using the baseline parsers of Øvrelid et al. (2010). The English training data consists of the Wall Street Journal sections 2–24 of the Penn Treebank (Marcus et al., 1993), converted to dependencies (Johansson and Nugues, 2007). The treebank data used to train the German parser is the Tiger Treebank (Brants et al., 2002), in the version released with the CoNLL-X shared task (Buchholz and Marsi, 2006).

Given the SL dependency trees, we project the dependencies to the corresponding (i.e., aligned) TL elements as shown in Figure 1. The links between the English and Dutch words indicate the word alignment. We postulate edges between TL words (e.g., *de* and *notulen*) if there is an edge between their respective SL counterparts (*the* and *minutes*).

The projected dependencies are then used as training data for TL (Dutch and Italian) dependency parsers. In order to account for the fact that many of the projected dependency structures are incomplete due to missing alignments or non-parallelism of the translation, we employ fMalt (Spreyer and Kuhn, 2009), a modified version of the MaltParser which handles fragmented training data. We restrict the admissible fragmentation to three fragments per sentence, for sentences with four or more words, based on early experiments with automatically labeled Dutch data. Sentences that receive more fragmented analyses are discarded.

Finally, we evaluate the projected TL parsers against gold standard test sets by parsing the TL test data and comparing the parser output to

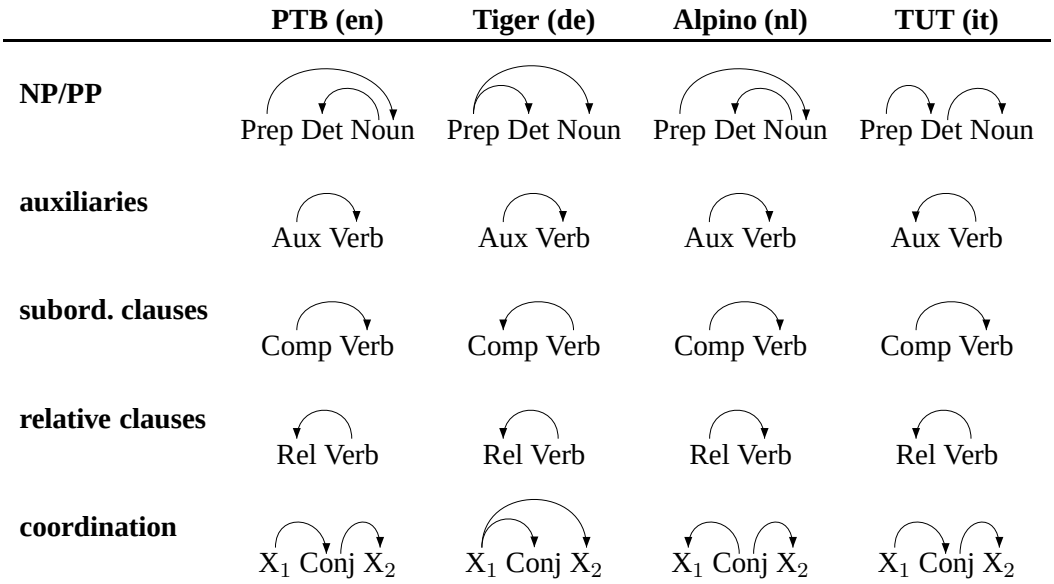

Table 1: Different annotation schemes in dependency-converted treebanks.

the reference annotations. However, we discuss below how differences in annotation style prohibit a direct comparison, and how the annotation schemes affect the learnability of the grammar and therefore the accuracy of the derived parsers.

3 Annotation Schemes

In a projection setting like the one described above, we deal with two sets of annotations: those projected from the SL, and those marked up in the TL gold standard. The four annotation schemes we compare here are those used in the Penn Treebank (PTB; WSJ sections) (Marcus et al., 1993) for English, the Tiger Treebank (Brants et al., 2002) for German, the Alpino Treebank (van der Beek et al., 2002) for Dutch, and the Turin University Treebank[2] (TUT) for Italian.

Table 1 illustrates the most obvious differences among the annotation schemes. Note that we compare annotations in the dependency-converted format. This restricts the comparison to attachment decisions and eliminates the bracket bias inherent to constituent-based comparisons (Carroll et al., 1998; Rehbein and van Genabith, 2007). Again, we use the dependency-converted data sets of the CoNLL-X shared task.

As shown in the table, both the English and the Dutch treebank annotate prepositional phrases hierarchically, with an embedded NP. The flat annotation scheme of the German treebank, on the other hand, makes every word in the PP a dependent of the preposition (with some exceptions). The Italian annotation scheme assumes a hierarchical structure like English and Dutch, but declares the determiner rather than the noun as the head of nominal phrases. Another idiosyncrasy of the Italian annotation scheme is the treatment of fused prepositions such as *della* which incorporate the determiner of the embedded NP: In the dependency-converted TUT, these fused prepositions are represented as two separate tokens, one tagged as a preposition, the other as a determiner.

Next, auxiliaries take the lexical verb as their dependent in all treebanks except the Italian TUT, which inverts the dependency, resulting in a flat structure with the lexical verb as its head. The structure of subordinate clauses is hierarchical according to the English, Dutch and Italian annotation schemes, but flat in Tiger, with the complementizer as a dependent of the embedded verb. Relative clauses, on the other hand, are assigned a flat structure in all but the Dutch scheme, where the relativizer is the head of the embedded verb. Finally, coordination is annotated in three different ways: While the treebanks for English and Italian implement a strictly right-branching strat-

[2] http://www.di.unito.it/~tutreeb

egy, the German annotation scheme attaches both the conjunction and the second conjunct to the first conjunct. The Dutch treebank annotates coordinations as flat structures, with all conjuncts depending on the conjunction.

In order to evaluate projected parsers, any differences in the source and target annotations need to be consolidated. A straightforward way of doing so is by means of tree transformations. Naturally, this begs the question of where such transformations should take place: One could transform the projected annotations to conform to the reference annotations encountered in the test set; alternatively, one can manipulate the test set to reflect the annotation decisions adopted in the source annotations. A variant of the former approach has been implemented by Hwa et al. (2005). They apply post-projection transformations to Chinese training data projected from English in order to infuse TL-specific information which has no counterpart in the source language.

We argue in favor of the alternative, since in a practical application scenario, where rapid, inexpensive development plays a prominent role, it is conceivable that the SL annotation scheme would be adopted unaltered for the TL parser. Consider, for instance, an architecture for multilingual syntax-based information retrieval which is based on parsers for various TLs, all to be derived from a single SL. Devising a tailored annotation scheme for each of the TLs would require linguistically trained personnel with extensive knowledge of the languages at hand. By contrast, adhering to the SL annotation scheme results in homogeneous parser output across the TLs and thus facilitates streamlined higher-level processing.

In Section 4 we present experiments that involve the language pairs English–Dutch, German–Dutch, English–Italian, and German–Italian. For each of the TLs Dutch and Italian, we therefore derive transformed test sets for each SL: one version according to the English PTB annotation style to evaluate the parsers projected from English, and another version according to the German Tiger-style annotations to evaluate parsers projected from German. As an example, Table 2 illustrates the transformations performed on the Italian test set for the parser projected from English.

TUT (it) ⇒ PTB (en)

English.

4 Annotation Scheme Experiments

4.1 Learnability

If the annotation style is carried over from the source language as we suggest above, we may ask: Is one annotation scheme more appropriate than the other? When more than one source language (annotation scheme) is available, will one produce more "learnable" TL annotations than the other? We explore these questions experimentally. Table 3a shows the performance of Dutch ('nl') and Italian ('it') MaltParsers trained on annotations projected from English ('PTB') and German ('Tiger'), as evaluated against the respective transformed Dutch and Italian gold standards.

Looking at the results for Dutch, we find that there is indeed a significant difference between the parser projected from English and the one projected from German. The former, generating PTB-style dependencies, achieves 69.21% unla-

lang.	words/sent	words/frag	frags/sent
en→nl	27.83	1.95	14.25

		PTB > *orig* > *Tiger*	

Table 5: UAS of the Dutch MST parsers trained on gold standard dependencies. (MaltParser results repeated from Table 3b.)

beled attachment score (UAS). According to a t-test (cf. Section 5), this is significantly ($p<0.01$) better than the parser projected from German Tiger-style annotations, which achieves 67.38%.

Turning to Italian, the parser projected from the English PTB-style annotations again performs better. However, the huge difference of 13.35% UAS suggests a more fundamental underlying problem with the word alignment between the German and Italian sentences. And indeed, inspection of the degree of fragmentation in the Italian projected dependencies (Table 4) confirms that considerably more edges are missing in the dependencies projected from German than from English. Missing edges are an indication of missing word alignment links.

In order to control such factors and focus only on the learnability of the different annotation schemes, we report in Table 3b the results of training on gold standard monolingual treebank data (distinct from the test data), transformed – like the test sets – to conform with the English and German annotation scheme, respectively.[3] In addition, the column labeled 'orig' shows the performance obtained when the original (dependency-converted) Alpino/TUT annotation scheme is used. For Italian, the results corroborate those obtained with the projected parsers: training on the PTB-transformed treebank is significantly[4] ($p<0.01$) more effective than training on the Tiger-transformed treebank. The original TUT scheme is even more effective ($p<0.01$), which comes as no surprise given that the TUT guidelines were tailored to the traits of the Italian language.

The Dutch parser, too, responds better to the hierarchical PTB-based annotation scheme than to the flat Tiger scheme ($p<0.01$). In fact, it also outperforms the parser trained with the original Alpino annotations ($p<0.01$). This demands for further investigation, reported in the following section.

4.2 Interaction with Parsing Algorithms

The results in Table 3 affirm that the performance of a parser hinges on the annotation scheme that it is trained on. However, the learnability of a given scheme depends not only on the annotation decisions, but also on the parsing algorithm implemented by the parser. For instance, it has been noted (Joakim Nivre, p.c. 2008) that flat coordination structures like those in the Alpino Treebank generally pose a challenge to incremental, deterministic parsers like MaltParser.

In order to see to what extent our results are influenced by characteristics of the MaltParser, we repeated the experiments with the MST parser (McDonald et al., 2005), focusing on Dutch parsers from gold standard training data.[5]

The MST parser is a graph-based dependency parser which considers all possible edges to find the globally optimal tree. The results of the MST experiments are given in Table 5, together with the corresponding Malt results repeated from Table 3b. We observe that the relative learnability ranking among the three annotation schemes is indeed different with MST. While in the transition-based paradigm the original Alpino annotations still appeared more adequate for training than the

[3] We did not attempt parameter optimization, so the figures reported here do *not* represent the state-of-the-art in dependency parsing for either language.

[4] According to Dan Bikel's Randomized Parsing Evaluation Comparator: `http://www.cis.upenn.edu/~dbikel/software.html#comparator`

[5] With projected training data for Dutch, and in all experiments with Italian, MST produced the same pattern of relative performance as Malt.

all_{de}	79.19	**83.87**

Table 6: Impact of individual transformations on Dutch treebank parsers. Significant improvements ($p<0.01$) over original Alpino annotation ('none') are in bold face.

Tiger trees, it is now outperformed by both the PTB and the Tiger trees under the graph-based approach. There is no significant difference between the Tiger-based and the PTB-based parser.

To shed some light on the unexpected ranking of the Alpino annotation scheme, we look at the impact of the individual transformations separately in Table 6. The upper part of the table shows how the transformations of the Alpino data towards PTB-style annotations affects learnability. We find that both the MaltParser and the MST parser benefit from the right-branching coordination markup of the PTB scheme. The attachment of relativizers in relative clauses seems to play only a minor role and makes no significant difference.

Turning to the Tiger-style transformations, first note that the semi-flat coordination adopted in the German treebank does not seem to be superior to the flat annotations in Alpino: no significant improvement is achieved for either parser by using the former ('$\text{coordination}_{\text{de}}$'). Surprisingly, both parsers benefit from the flat annotation of prepositional phrases ('np/pp_{de}'). The MST parser, but not the MaltParser, further takes advantage of the flat subordination structure annotated in Tiger. As mentioned earlier, this is in line with the fundamentally different parsing paradigms represented by Malt and MST.

We tentatively conclude that the MST parser is in fact better at exploiting the flat aspects of the Tiger annotations, while both parsers largely benefit from the highly hierarchical coordination structure of the PTB annotation scheme. A more detailed exploration of these issues is clearly in order, and subject to future research.

4.3 Discussion

Kübler et al. (2008) present an extensive comparison of two German treebanks: the Tiger treebank with its rather flat annotation scheme, and the TüBa/DZ treebank with more hierarchical structures. They find that the flat Tiger annotation scheme is more easily learned by constituent-based (PCFG) parsers when evaluated on a dependency level. Our results suggest the opposite, but this may well be due to the differences in the experimental setup: Our training data represent dependency trees directly, and we learn incremental, deterministic dependency parsers rather than PCFGs.

5 Variance Assessment

The second question we address in this paper is the assessment of variance in the training data, and hence in parser quality. The standard procedure for this purpose would be *cross-validation*. To perform k-fold cross-validation, the data is partitioned into k splits of equal size, and one of the splits is used as test data, while the remaining k-1 splits serve as training data. The train–test cycle is repeated until each of the k subsamples has been used as test data exactly once.

However, the popular data sets used for benchmarking parsers, such as the CoNLL-X shared task data used here, are typically based on monolingual text. This means that cross-validation is unavailable for projection-based frameworks, because no projection can be performed for the training splits in the absence of a translation in the SL.

Moreover, the expected noise level in the projected dependencies requires that there be a considerable amount of training data for an evaluation to be meaningful. So even if parallel test data is available, the data partitioning performed in cross-validation may compromise the results.

We therefore propose a validation scheme which (i) does not reduce the amount of test data by partitioning (this may be a problem when only a small number of gold standard annotations is

	nl_{ptb}	nl_{tig}	it_{ptb}	it_{tig}
	68.51	67.25	66.56	54.01
	70.07	66.79	66.45	54.21
	69.21	68.13	66.07	53.37
	69.45	68.29	66.47	52.77
	68.47	67.31	66.74	52.55
	69.07	66.97	66.20	53.66
	69.99	67.87	66.56	52.70
	69.71	66.43	66.37	52.70
	68.77	67.11	66.05	52.08
	68.83	67.67	66.96	52.82
mean	69.21	67.38	66.44	53.09
sd	0.58	0.60	0.29	0.69

Table 7: Intra-system variance assessment.

available), (ii) does not require parallel test data and is independent of the projection step, and (iii) takes advantage of the fact that training data is cheap and therefore abundant in projection-based settings. Specifically, given that we have plenty of training data, we can train a particular parser multiple (say, k) times, each time sampling a fixed number of training examples from the pool of training data. The k parsers can then each parse the unseen test set, and subsequent comparison against the gold standard annotations yields k values of the performance metric at hand (here, UAS). As in conventional cross-validation, these k values are then averaged to provide an aggregated score, and they can be used to derive standard deviations etc. The arrays of measurements for different systems can further be subjected to significance tests such as the two-sample t-test to verify that observed performance differences are not merely random effects.

5.1 Experiments

We use the validation procedure just described (with k=10) to investigate the variance in the projected parsers discussed in the previous section (Table 3a). Table 7 lists the scores obtained by the individual parsers, each trained on a different random sample of 100,000 words, drawn from the pool of all projected annotations. We also show the standard deviation and repeat the mean UAS. We observe that, for a given language, standard deviation seems to correlate negatively with mean UAS; in other words, the better parsers also seem to be more robust towards variance in the training data.

5.2 Discussion

Classical cross-validation and the validation method described here do measure slightly different things. First, in cross-validation it is not only the training data that is varied, but the test data as well. Second, when two systems are compared under the cross-validation regime, the k rounds can usually be considered *paired* samples because both systems are trained and evaluated on identical partitionings of the data. In contrast, projection-based settings typically involve some form of filtering on the basis of the projected annotations; in our case, the filter restricts the degree of fragmentation in the projected dependency tree. This filtering makes it all but impossible to pair the training samples without seriously diminishing the pool from which the samples are drawn. For instance, when comparing the Italian parser projected from English (it_{ptb}) and the one projected from German (it_{tig}), a training sentence may receive a complete analysis from the English translation, and hence be included in the training pool for it_{ptb}; but the same (Italian) sentence may receive a highly fragmented analysis under projection from German (e.g., due to missing alignment links) and be discarded from the training pool for it_{tig}.

With samples that cannot be paired, it is also not obvious how evaluation strategies like the randomized comparison mentioned above (fn. 4) could be employed in a sound way (by non-statisticians).

6 Conclusions

We have discussed two issues that arise in the evaluation of frameworks that involve cross-lingual projection of annotations. We focused on the projection of dependency trees from German and English to Dutch and Italian, and presented experiments that compare parsers trained on the projected dependencies. The parsers differ in the annotation scheme they follow: When they are projected from German, they employ the flat Tiger annotation scheme of the source language; pro-

jected from English, they learn the more hierarchical PTB structures. In order to evaluate the projected parsers against target language (Dutch, Italian) gold standard annotations, we convert the test sets to the annotation scheme employed in the respective source language.

While our experiments with gold standard treebank data affirm that the annotation scheme that is being learned has some influence on the performance of the parser, one should bear in mind that in a projection scenario, the quality of the word alignment plays at least an equally important role when it comes to chosing a suitable source language and annotation scheme.

We have further proposed a validation scheme which unlike cross-validation does not require parallel test data. Instead, it exploits the fact that training data is usually available in abundance in projection scenarios, so parsers can be trained on multiple random samples and evaluated against a single, independent test set which need not be further partitioned.

Abstract

In this paper, we propose a novel *dependency-based bracketing transduction grammar* for statistical machine translation, which converts a source sentence into a target dependency tree. Different from conventional bracketing transduction grammar models, we encode target dependency information into our lexical rules directly, and then we employ two different maximum entropy models to determine the reordering and combination of partial dependency structures, when we merge two neighboring blocks. By incorporating dependency language model further, large-scale experiments on Chinese-English task show that our system achieves significant improvements over the baseline system on various test sets even with fewer phrases.

1 Introduction

Bracketing transduction grammar (BTG) (Wu, 1995) is an important subclass of synchronous context free grammar, which employs a special synchronous rewriting mechanism to parse parallel sentence of both languages.

Due to the prominent advantages such as the simplicity of grammar and the good coverage of syntactic diversities in different language pairs, BTG has attracted increasing attention in statistical machine translation (SMT). In flat reordering model (Wu, 1996; Zens et al., 2004), which assigns constant reordering probabilities depending on the language pairs, BTG constraint proves to be very effective for reducing the search space of phrase reordering. To pursue a better method to predict the order between two neighboring blocks[1], Xiong et al. (2006) present an enhanced BTG with a maximum entropy (ME) based reordering model. Along this line, source-side syntactic knowledge is introduced into the reordering model to improve BTG-based translation (Setiawan et al., 2007; Zhang et al., 2007; Xiong et al., 2008; Zhang and Li, 2009). However, these methods mainly focus on the utilization of source syntactic knowledge, while ignoring the modeling of the target-side syntax that directly influences the translation quality. As a result, how to obtain better translation by exploiting target syntactic knowledge is somehow neglected. Thus, we argue that it is important to model the target-side syntax in BTG-based translation.

Recently, modeling syntactic information on the target side has progressed significantly. Depending on the type of output, these models can be divided into two categories: the *constituent-output* systems (Galley et al., 2006; Zhang et al., 2008; Liu et al., 2009) and *dependency-output* systems (Eisner, 2003; Lin, 2004; Ding and Palmer, 2005; Quirk et al., 2005; Shen et al., 2008). Compared with the *constituent-output* systems, the *dependency-output* systems provide a simpler platform to capture the target-side syntactic information, while also having the best interlingual phrasal cohesion properties (Fox, 2002). Typically, Shen et al. (2008) propose a string-to-dependency model, which integrates the target-side well-formed dependency structure into translation rules. With the dependency structure, this system employs a dependency language model (LM) to exploit long distance word relations, and achieves a significant improvement over the hierarchical phrase-based system (Chiang, 2007). So

[1] A block is a bilingual phrase without maximum length limitation.

Coling 2008: Poster Volume, pages 1185–1193,
Beijing, August 2010

we think it will be a promising way to integrate the target-side dependency structure into BTG-based translation.

In this paper, we propose a novel dependency-based BTG (DepBTG) for SMT, which represents translation in the form of dependency tree. Extended from BTG, our grammars operate on two neighboring blocks with target dependency structure. We integrate target syntax into bilingual phrases and restrict target phrases to the well-formed structures inspired by (Shen et al., 2008). Then, we adopt two ME models to predict how to reorder and combine partial structures into a target dependency tree, which gives us access to capturing the target-side syntactic information. To the best of our knowledge, this is the first effort to combine the translation generation with the modeling of target syntactic structure in BTG-based translation.

The remainder of this paper is structured as follows: In Section 2, we give brief introductions to the bases of our research: BTG and dependency tree. In Section 3, we introduce DepBTG in detail. In Section 4, we further illustrate how to create two ME models to predict the reordering and dependency combination between two neighboring blocks. Section 5 describes the implementation of our decoder. Section 6 shows our experiments on Chinese-English task. Finally, we end with a summary and future research in Section 7.

2 Background

2.1 BTG

BTG is a special case of synchronous context free grammar. There are three rules utilized in BTG:

$$A \rightarrow [A^1, A^2] \quad (1)$$

$$A \rightarrow \langle A^1, A^2 \rangle \quad (2)$$

$$A \rightarrow x/y \quad (3)$$

where the reordering rules (1) and (2) are used to merge two neighboring blocks A^1 and A^2 in a straight or inverted order, respectively. The lexical rule (3) is used to translate the source phrase x into the target phrase y.

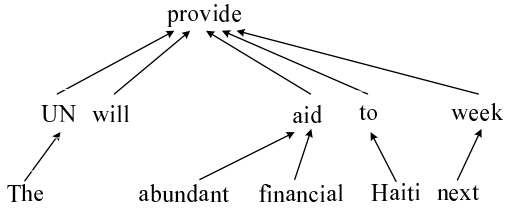

Figure 1: The dependency tree for sentence *The UN will provide abundant financial aid to Haiti next week.*

2.2 Dependency Tree

In a given sentence, each word depends on a parent word, except for the root word. The dependency tree for a given sentence reflects the long distance dependency and grammar relations between words. Figure 1 shows an example of a dependency tree, where a black arrow points from a child word to its parent word.

Compared with constituent tree, dependency tree directly models semantic structure of a sentence in a simpler form. Thus, it provides a desirable platform for us to utilize the target-side syntactic knowledge.

3 Dependency-based BTG

3.1 Grammars

In this section, we extend the original BTG into DepBTG. The rules of DepBTG, which derive from that of BTG, merge blocks with target dependency structure into a larger one. These rules take the following forms:

$$A_d \rightarrow [A_d^1, A_d^2]_{CC} \quad (4)$$

$$A_d \rightarrow [A_d^1, A_d^2]_{LA} \quad (5)$$

$$A_d \rightarrow [A_d^1, A_d^2]_{RA} \quad (6)$$

$$A_d \rightarrow \langle A_d^1, A_d^2 \rangle_{CC} \quad (7)$$

$$A_d \rightarrow \langle A_d^1, A_d^2 \rangle_{LA} \quad (8)$$

$$A_d \rightarrow \langle A_d^1, A_d^2 \rangle_{RA} \quad (9)$$

$$A_d \rightarrow x/y \quad (10)$$

where A_d^1 and A_d^2 represent two neighboring blocks with target dependency structure. Rules (4)$\sim$(9) are used to determine the reordering and combination of two dependency structures, when

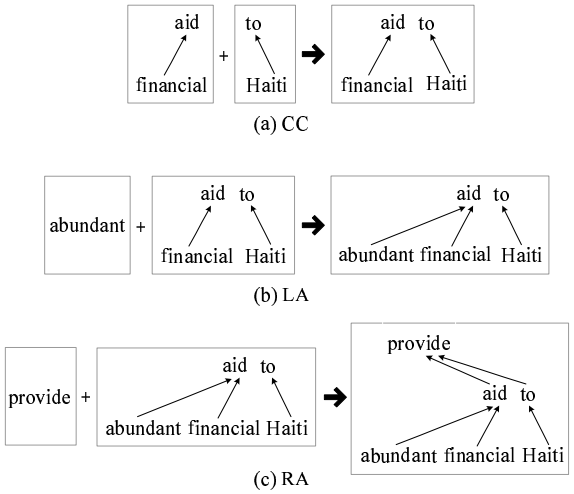

Figure 2: Dependency operations on the neighboring dependency structures. CC = coordinate concatenate, LA = left adjoining, and RA = right adjoining.

we merge two neighboring blocks. Rule (10) is applied to generate bilingual phrase (x, y) with target dependency structure learned from training corpus. To distinguish the rules with different functions, the rules (4)∼(9) and rule (10) are named as **merging rules** and **lexical rule**, respectively.

Specifically, we first merge the neighboring blocks in the straight order using rules (4)∼(6) or in the inverted order using rules (7)∼(9). Then, according to different merging rules, we conduct some operations to combine the corresponding dependency structures in the target order: coordinate concatenate (**CC**), left adjoining (**LA**) and right adjoining (**RA**).

To clearly illustrate our operations, we show the process of applying three dependency operations to build larger structures in Figure 2. Adopting rule (4), the dependency structures "*((financial) aid)*"[1] and "*(to (Haiti))*" can be combined into a larger one consisting of two sibling subtrees (see Figure 2(a)). Adopting rule (5), we can adjoin the left dependency structure "*(abundant)*" to the leftmost sub-root of the right dependency structure "*((financial) aid) (to (Haiti))*" (see Figure 2(b)). Adopting rule (6), we can include the right dependency structure "*((abundant) (financial) aid) (to (Haiti))*" as a child of the rightmost sub-root of the left dependency structure "*(provide)*" (see Figure 2(c)). In a similar way, rules (7)∼(9) are applied to deal with two partial structures in the inverted order.

[1]We use the lexicon dependency grammar (Hellwig, 2006) to express the projective dependency tree. Using this grammar, the words in the brackets are defined as the child words depending on the parent word outside the brackets.

3.2 Well-Formed Dependency Structures

As illustrated in the previous sub section, the rules of DepBTG operate on the blocks with target dependency structure. Following (Shen et al., 2008), we restrict the target phrases to the well-formed dependency structures. The main difference is that we use more relaxed constraints to extract more bilingual phrases with rational structure. Take a sentence $S = w_1 w_2 ... w_n$ for example, we denote the parent word ID of word w_i with d_i, and show the definitions of structures as follows.

Defination 1 *A dependency structure $d_{i...j}$ is* **fixed on head** *h, where $h \in [i, j]$, if and only if it meets the following conditions*

- $d_h \notin [i, j]$
- $\forall k \in [i, j]\ and\ k \neq h, d_k \in [i, j]$
- $\forall k \in [i, j],\ d_k = h\ or\ d_k \in [i, j]$

Defination 2 *A dependency structure $d_i ... d_j$ is* **floating with children** C, *for a non-empty set $C \subseteq \{i...j\}$, if and only if it meets the following conditions*

- $\exists h \notin [i, j], s.t. \forall k \in C, d_k = h$
- $\forall k \in [i, j]\ and\ k \notin C, d_k \in [i, j]$
- $\forall k \notin [i, j],\ d_k \notin [i, j]$ $\underline{or\ d_k = c_l}$ $\underline{or\ d_k = c_r}$

where c_l and c_r represent the IDs of the leftmost and rightmost words in the set *C*, respectively. Note that the underline indicates the difference between our definition and that of (Shen et al., 2008). In our model, we regard the floating structure, which is not complete on its boundary sub-roots, as an useful structure, since it will become a complete constituent by combining it with other partial structures. For example, the dependency

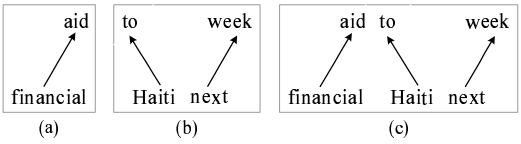

Figure 3: (a) A fixed structure and (b) (c) two floating structures. Note that (c) is ill-formed in (Shen et al., 2008).

structures shown in Figure 3 are all well-formed structures. However, according to the definitions of (Shen et al., 2008), 3(c) is ill-formed because *aid* does not include its leftmost child word *abundant* in the structure.

4 ME Models for Merging Rules

4.1 The Models

A simple way to estimate the probabilities of the merging rules is to adopt maximum likelihood estimation to obtain the conditional probabilities. However, this method is not applicable to merging rules because the dependency structures become larger and larger during decoding, which are very sparse in the corpus.

Inspired by MEBTG translation (Xiong et al., 2006), which considers phrase reordering as a classification problem, we model the reordering and combination of two neighboring dependency structures based on the ME principle. Owing to data sparseness and the complexity of multi-class classification, we establish two ME models rather than an unified ME model: one for the reordering between blocks, called **reordering model**; the other for the dependency operations on the corresponding dependency structures, called **operation model**.

Thus, according to the ME scheme, we decompose the probability Ω of each merging rule into

$$\begin{aligned}\Omega &= p_{\theta_1}(o|A_d^1, A_d^2) \cdot p_{\theta_2}(d|A_d^1, A_d^2) \\ &= \frac{\exp(\Sigma_i \theta_{1i} h_{1i}(o, A_d^1, A_d^2))}{\Sigma_o \exp(\Sigma_i \theta_{1i} h_{1i}(o, A_d^1, A_d^2))} \cdot \\ &\quad \frac{\exp(\Sigma_j \theta_{2j} h_{2j}(d, A_d^1, A_d^2))}{\Sigma_d \exp(\Sigma_j \theta_{2j} h_{2j}(d, A_d^1, A_d^2))}\end{aligned}$$

where the functions $h_{1i} \in \{0, 1\}$ are the features of the ME-based reordering model, θ_{1i} are the corresponding weights, and $o \in \{straight, inverted\}$. Similarly, the functions $h_{2j} \in \{0, 1\}$ and the weights θ_{2j} are trained for the ME-based operation model, and $d \in \{CC, LA, RA\}$.

4.2 Example Extraction

To train the ME models, we extract examples from a string-to-dependency word-aligned corpus during the process of bilingual phrases extraction (Koehn et al., 2005), and then collect various features for the models.

For the reordering model, we adopt the method of (Xiong et al., 2006) to extract reordering examples. Due to the limit of space, we skip the details of this method.

For the operation model, given an operation training example consisting of two neighboring dependency structures: the left structure d_l and the right structure d_r, we firstly classify it into different categories by the dependency relation between d_l and d_r:

- if d_l and d_r have the same parent, the category of the example is CC;
- if d_l depends on the leftmost sub-root of d_r, the category of the example is LA;
- if d_r depends on the rightmost sub-root of d_l, the category of the example is RA.

For instance, Figure 4 shows an operation example with RA operation, where the sub-root word *week* of d_r depends on the rightmost sub-root word *provide* of d_l.

Then, we collect various features from the following nodes: the rightmost sub-root of d_l, and its rightmost child node; the leftmost sub-root of d_r, and its leftmost child node. Here, we speculate that these nodes may carry useful information for the dependency combination of the two structures, since they locate nicely at the boundary subtrees of d_l and d_r. For simplicity, we refer to these nodes as the *feature nodes* of the example. Let's revisit Figure 4, the feature nodes of the example are marked with dashed ellipses. The rightmost sub-root word of d_l is *provide*, and its rightmost child word is *to*; The leftmost sub-root word of d_r is *week*, and its leftmost child word is *next*.

Type	Name	Description
Lexical Features	$W_{lh}(d_r)$	The leftmost sub-root word of d_r
	$W_{rh}(d_l)$	The rightmost sub-root word of d_l

	$W_{rrc}(d_l)\_W_{lh}(d_r)$ = to_week $W_{rrc}(d_l)\_P_{lh}(d_r)$ = to_NN $P_{rrc}(d_l)\_W_{lh}(d_r)$ = TO_week $P_{rrc}(d_l)\_P_{lh}(d_r)$ = TO_NN

Table 2: ME operation features and instances of the example shown in Figure 4.

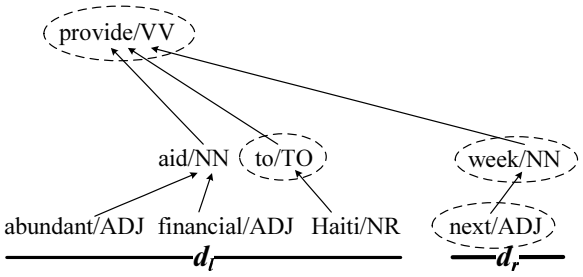

Figure 4: An example with RA category consisting of the neighboring dependency structures d_l and d_r. The dashed ellipses denote the *feature nodes* of the example, and each node consists of one word and its corresponding POS tag.

In addition, to keep the number of operation examples acceptable, we follow (Xiong et al., 2006) to only extract the smallest one from the examples with the same *feature nodes* in each sentence.

4.3 Features

To capture reordering information, we use the boundary words of bilingual blocks as features, which are proved to be very effective in (Xiong et al., 2006).

To capture dependency operation information, we design two kinds of features on the *feature nodes*: the Lexical features and Parts-of-speech (POS) features. With the POS features, the operation ME model will do exact predicating to the best of its ability, and then can back off to approximately predicating if exact predicating fails. Table 1 shows these feature categories in detail.

Furthermore, we also use some bigram features, since it is generally admitted that the combination of different features can lead to better performance than unigram features. To better understand our operation features, we continue with the example shown in Figure 4, listing features and instances in Table 2.

5 Implementation Details

5.1 Decoder

We develop a CKY-style decoder which uses the following features: (1) Phrase translation probabilities in two directions, (2) Lexical translation probabilities in two directions, (3) N-gram LM

score, (4) ME-based reordering model score, (5) Number of phrases, (6) Number of target words, (7) ME-based operation model score, (8) Dependency LM scores at word level and POS level separately, and (9) Discount on ill-formed dependency structures. Here, the former six features are also used in MEBTG translation.

5.2 Dependency Language Model

Following (Shen et al., 2008), we apply different tri-gram dependency LMs at word level and POS level separately to DepBTG translation.

Given a dependency structure, where w_h is the parent word, $w_L = w_{l_1}...w_{l_n}$ and $w_R = w_{r_1}...w_{r_m}$ are child word sequences on the left side and right side respectively, the probability of a tri-gram is computed as follows:

$$\begin{aligned} & P(w_L, w_R|w_h\text{-as-head}) \\ = \; & P(w_L|w_h\text{-as-head}) \cdot P(w_R|w_h\text{-as-head}) \end{aligned}$$

Here $P(w_L|w_h\text{-as-head})$ can be decomposed into:

$$\begin{aligned} & P(w_L|w_h\text{-as-head}) \\ = \; & P(w_{l_1}|w_h\text{-as-head}) \cdot P(w_{l_2}|w_{l_1}, w_h\text{-as-head}) \\ & ... \cdot P(w_{l_n}|w_{l_{n-1}}, w_{l_{n-2}}) \end{aligned}$$

where '-as-head' is used to distinguish the head word from child word in the language model. In like manner, $P(w_R|w_h\text{-as-head})$ has a similar calculation method.

5.3 Ill-Formed Dependency Structure

To preserve the good coverage of bilingual phrases, we keep some bilingual phrases with the special ill-formed dependency structure. Different from the well-formed structures, where all the children of the sub-roots are complete, these ill-formed structures are not complete on the children of the boundary sub-roots, lacking a well-formed sub structure on the boundary. We consider them as useful structures with gaps, each of which can be combined with some well-formed structures into a larger well-formed one. To reduce the search space, we constrain the number of gap to one on each boundary. During decoding, we directly substitute the gap in a structure with another well-formed structure which has the same direction.

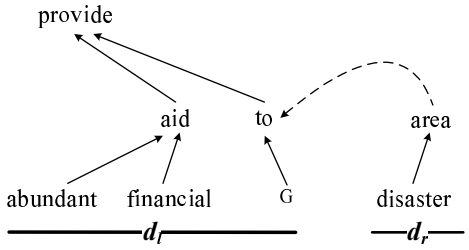

Figure 5: Dependency combination of the ill-formed dependency structure d_l with the right well-formed dependency structure d_r. G denotes gap and the dotted line denotes the substitution of the gap G with d_r.

For example, there are two dependency structures in Figure 5: d_l is an ill-formed structure with a right gap, and d_r is a well-formed one. Instead of investigating three operations to combine these structures, we fill the gap of d_l with d_r, and then compute the corresponding score of the RA operation on the sub structures "*(to)*" and "*((disaster) area)*" in the ME-based operation model.

6 Experiment

6.1 Setup

The training corpus[1] comes from LDC with 1.54M bilingual sentences (41M Chinese words and 48M English words). We run GIZA++ (Och and Ney, 2000) to obtain word alignments with the heuristic method "grow-diag-final-and". Then we parse the English sentences to generate a string-to-dependency word-aligned corpus using the parser (Huang et al., 2009). From this corpus, we extract bilingual phrases with dependency structure. Here, the maximum length of the source phrase is set to 7. For the n-gram LM, we use SRILM Toolkits (Stolcke, 2002) to train a 4-gram LM on the Xinhua portion of the Gigaword corpus. For the dependency LM, we train different 3-gram dependency LMs at word level and POS level separately on the English side of the training corpus.

During the process of bilingual phrase extraction, we collect the neighboring blocks without

[1]The training corpus consists of six LDC corpora: LDC2002E18, LDC2003E07, LDC2003E14, Hansards part of LDC2004T07, LDC2004T08 , LDC2005T06.

any length limitation to obtain examples for two ME models. For the reordering model, we obtain about $22.6M$ examples with monotone order and $4.8M$ examples with inverted order. For the operation model, we obtain about $5.9M$ examples with CC operation, $14.8M$ examples with LA operation, and $9.7M$ examples with RA operation. After collecting various features from the examples, we use the ME training toolkit developed by Zhang (2004) to train ME models with the following parameters: iteration number i=200 and Gaussian prior g=1.0.

The 2002 NIST MT Evaluation test set is used as the development set. The 2003 and 2005 NIST MT Evaluation test sets are our test sets. We perform the MERT training (Och, 2003) to tune the optimal feature weights on the development set. To run the decoder, we prune the phrase table with b = 100, prune the chart with n = 50, α = 0.1. See (Xiong et al., 2006) for the meanings of these parameters. The translation quality is evaluated by case-insensitive BLEU-4 metric (Papineni et al., 2002), as calculated by mteval-v11b.pl.

6.2 Results

Since (Xiong et al., 2006) has made a deep investigation on the ME-based reordering model, we mainly focus on the study of the ME-based operation model. To explore the utility of the various features in the operation model, we randomly select about $10K$ examples from all the operation examples as held-out data, and use the rest examples as training data. Then, we train the operation models on different feature sets and investigate the performance of models on the held-out data.

Table 3 shows the accuracy rates of the ME operation models using different feature sets. We find that the bigram feature set provides the most persuasive evidences and achieves best performance than other feature sets.

To investigate the influences of various factors on the system performance, we carried out experiments on the NIST Chinese-English task with the following systems:

- MEBTG + all: an MEBTG translation system, which uses all bilingual phrases. It is our baseline system;
- MEBTG + filter1: a baseline system, which uses the bilingual phrases consistent to the well-formed dependency structures by (Shen et al., 2008);
- MEBTG + filter2: a baseline system, which uses the bilingual phrases consistent to our well-formed dependency structures;
- MEBTG + filter3: a baseline system, which uses the bilingual phrases consistent to our well-formed dependency structures and the special ill-formed dependency structures;
- DepBTG + unigram features: a DepBTG system which only uses the unigram features in the ME-based operation model;
- DepBTG + bigram features: a DepBTG system which only uses the bigram features in the ME-based operation model;
- DepBTG + all features: a DepBTG system which uses all features in the ME-based operation model;
- DepBTG + unigram features + dep LMs: a DepBTG system with dependency LMs, where only the unigram features are adopted in the ME-based operation model;
- DepBTG + bigram features + dep LMs: a DepBTG system with dependency LMs, where only the bigram features are adopted in the ME-based operation model;
- DepBTG + all features + dep LMs: a DepBTG system with dependency LMs, where all features are adopted in the ME-based operation model.

Model	Accuracy Rate
lexical features	87.614%
POS features	88.232%
unigram features	90.024%
bigram features	$\mathbf{93.907}\%$
all features	93.290%

Table 3: The accuracy rates of the ME-based operation models on the held-out data set using different feature sets. Unigram features include lexical features and POS features, and bigram features are the combinations of different unigram features.

System	Type	#Bp	MT03	MT05
MEBTG	all(baseline)	$81.4M$	33.41	32.65
	filter1	$27.8M$	32.17($\downarrow$ 1.24)	31.26($\downarrow$ 1.39)
	filter2	$33.7M$	32.77($\downarrow$ 0.64)	31.93($\downarrow$ 0.72)
	filter3	$58.5M$	33.29($\downarrow$ 0.12)	32.71($\uparrow$ 0.06)
DepBTG	unigram features	$59.9M$	33.46($\uparrow$ 0.05)	32.67($\uparrow$ 0.02)
	bigram features	$59.9M$	33.57($\uparrow$ 0.16)	32.89($\uparrow$ 0.24)
	all features	$59.9M$	33.59($\uparrow$ 0.18)	32.86($\uparrow$ 0.21)
	unigram features + dep LMs	$59.9M$	33.90($\uparrow$ 0.49)	33.29($\uparrow$ 0.64)
	bigram features + dep LMs	$59.9M$	**34.18**($\uparrow$ 0.77)	**33.58**($\uparrow$ 0.93)
	all features + dep LMs	$59.9M$	34.10($\uparrow$ 0.69)	33.55($\uparrow$ 0.90)

Table 4: Experimental results on Chinese-English NIST Task.

Experiment results are summarized in Table 4. Our baseline system extracts $81.4M$ bilingual phrases and achieves the BLEU scores of 33.41 and 32.65 on two test sets separately. Adopting the constraint of the well-formed structures by (Shen et al., 2008), we extract $27.8M$ bilingual phrases, which lead to great drops in BLEU score: 1.24 points and 1.39 points on two test sets separately(see Row 3). Using the constraint of our well-formed structures, the number of extracted bilingual phrases is $33.7M$. We observe the similar results that the performance drops 0.64 points and 0.72 points over the baseline system on two test sets, respectively (see Row 4). Furthermore, we add some bilingual phrases with the special ill-formed structure into our phrase table, and the number of the bilingual phrases in use is 58.5M accounting up 71.9% of the full phrases. For two test sets, our system achieves the BLEU scores of 33.29 and 32.71 (see Row 5), which are very close to the scores of baseline system. Those experimental results demonstrate that phrase coverage has a great effect on the system performance and our definitions of the allowed dependency structures are useful to retain rational bilingual phrases.

Then, by employing the ME-based operation model and two 3-gram dependency LMs, the DepBTG system outperforms the MEBTG system in almost all cases. The experimental results indicate that the dependency LMs are more effective than the ME-based operation model for DepBTG system. Especially, using bigram features and dependency LMs, the DepBTG system obtains absolute improvements on two test sets: $\mathbf{0.77}$ BLEU points on NIST03 test set and $\mathbf{0.93}$ BLEU points on NIST05 test set (see Row 10), which are both statistically significant at $p < 0.05$ using the significance tester developed by Zhang et al. (2004).

7 Conclusion and Future Work

In this paper, we propose a novel dependency-based BTG to directly model the syntactic structure of the translation. Using the bilingual phrases with target dependency structure, our system employs two ME models to generate the translation in line with dependency structure. Based on the target dependency structure, our system filters 26.4% bilingual phrases (from $81.4M$ to $59.9M$), captures the target-side syntactic knowledge by dependency language models, and achieves significant improvements over the baseline system.

There is some work to be done in the future. To better utilize the syntactic information, we will put more effort on the study of the dependency LM with deeper syntactic knowledge. Moreover, we believe that modeling the syntax of both sides is a promising method to further improve BTG-based translation and this will become a study emphasis in our future research. Finally, inspired by (Tu et al., 2010), we will replace 1-best dependency trees with dependency forests to further increase the phrase coverage.

Abstract

We present a simple algorithm for clustering semantic patterns based on distributional similarity and use cluster memberships to guide semi-supervised pattern discovery. We apply this approach to the task of relation extraction. The evaluation results demonstrate that our novel bootstrapping procedure significantly outperforms a standard bootstrapping. Most importantly, our algorithm can effectively prevent semantic drift and provide semi-supervised learning with a natural stopping criterion.

1 Introduction

The Natural Language Processing (NLP) community faces new tasks and new domains all the time. Without enough labeled data of a new task or a new domain to conduct supervised learning, semi-supervised learning (SSL) is particularly attractive to NLP researchers since it only requires a handful of labeled examples, known as seeds. SSL starts with these seeds to train an initial model; it then applies this model to a large volume of unlabeled data to get more labeled examples and adds the most confident ones as new seeds to re-train the model. This iterative procedure has been successfully applied to a variety of NLP tasks, such as hypernym/hyponym extraction (Hearst, 1992), word sense disambiguation (Yarowsky, 1995), question answering (Ravichandran and Hovy, 2002), and information extraction (Brin, 1998; Collins and Singer, 1999; Riloff and Jones, 1999; Agichtein and Gravano, 2000; Yangarber et al., 2000; Chen and Ji, 2009).

While SSL can give good performance for many tasks, it is a procedure born with two defects. One is semantic drift. When SSL is under-constrained, the semantics of newly promoted examples might stray away from the original meaning of seed examples as discussed in (Brin, 1998; Curran et al., 2007; Carlson et al., 2010). For example, a SSL procedure to learn semantic patterns for the *LocatedIn* relation (PERSON in LOCATION/GPE[1]) might accept patterns for the *Employment* relation (employee of GPE / ORGANIZATION) because many unlabeled pairs of names are connected by patterns belonging to multiple relations. Patterns connecting <*Bill Clinton, Arkansas*> include *LocatedIn* patterns such as "*visit*", "*arrive in*" and "*fly to*", but also patterns indicating other relations such as "*governor of*", "*born in*", and "*campaign in*". Similar analyses can be applied to many other examples such as <*Bush, Texas*> and <*Schwarzenegger, California*>. Without careful design, SSL procedures usually accept bogus examples during certain iterations and hence the learning quality degrades.

The other shortcoming of SSL is its lack of natural stopping criteria. Most SSL algorithms either run a fixed number of iterations (Agichtein and Gravano, 2000) or run against a separate labeled test set to find the best stopping criterion (Abney, 2008). The former solution needs a human to keep eyeballing the learning quality of different iterations and set ad-hoc thresholds accordingly. The latter requires a

[1] These are the types of relations and names used in the NIST-sponsored ACE evaluation. http://www.itl.nist.gov/iad/mig//tests/ace/. GPE represents a Geo-Political Entity — an entity with land and a government.

Coling 2008: Poster Volume, pages 1194–1202,
Beijing, August 2010

separate labeled test set for each new task or domain. They make SSL less appealing than it could be since the intention of using SSL is to minimize supervision.

In this paper, we propose a novel learning framework which can automatically monitor the semantic drift and find a natural stopping criterion for SSL. Central to our idea is that instead of using unlabeled data directly in SSL, we first cluster the seeds and unlabeled data in an unsupervised way before conducting SSL. The semantics of unsupervised clusters are usually unknown. However, the cluster to which the seeds belong can serve as the target cluster. Then we guide the SSL procedure using the target cluster. Under such learning settings, semantic drift can be automatically detected and a stopping criterion can be found: stopping the SSL procedure when it tends to accept examples belonging to clusters other than the target cluster.

We demonstrate in this paper the above general idea by considering a bootstrapping procedure to discover semantic patterns for extracting relations between named entities (NE). Standard bootstrapping usually starts with some high-precision and high frequency seed patterns for a specific relation to match named entities, then it uses newly promoted entities to search for additional confident patterns connecting them. It is a procedure driven by the duality between patterns and entities: a good pattern can connect more than one pair of named entities and a pair of named entities is usually connected by more than one good pattern.

We present a new bootstrapping procedure in which we first cluster the seed and other patterns in a large corpus based on distributional similarity. We then guide the bootstrapping using the target cluster.

The next section describes our unsupervised pattern clusters. Section 3 presents the details of our novel bootstrapping procedure with guidance from pattern clusters. We evaluate our algorithms in Section 4 and present related work in Section 5. We draw conclusions and point to future work in Section 6.

2 Pattern Clusters

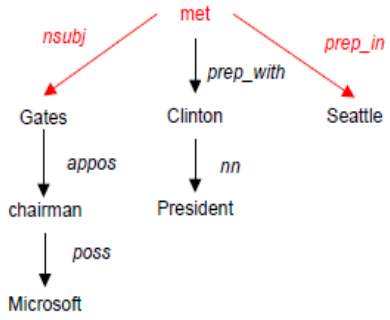
2.1 Distributional Hypothesis

The Distributional Hypothesis (Harris, 1954) states that words that tend to occur in similar contexts tend to have similar meanings. Lin and Pantel (2001) extended this hypothesis to cover patterns (dependency paths in their case). The idea of the extension is that if two patterns tend to occur in similar contexts then the meanings of the patterns tend to be similar. For example, in "*X solves Y*" and "*X finds a solution to Y*", "*solves*" and "*finds a solution to*" share many common *Xs* and *Ys* and hence are similar to each other. This extended distributional hypothesis serves as the basis on which we compute similarities for each pair of patterns.

2.2 Pattern Representation — Shortest Dependency Path

We adopt a shortest dependency path (SDP) representation of relation patterns. SDP has demonstrated its power in kernel methods for relation extraction (Bunescu and Mooney, 2005). Its capability in capturing most of the information of interest is also evidenced by a systematic comparison of effectiveness of different information extraction (IE) patterns in (Stevenson and Greenwood, 2006) [2] . For example, "*nsubj* ← met → *prep_in*" is able to represent *LocatedIn* between "*Gates*" and "*Seattle*" while a token-based pattern would be much less general because it would have to specify all the intervening tokens.

Figure 1. Stanford dependency tree for sentence *"Gates, Microsoft's chairman, met with President Clinton in Seattle".*



[2] SDP is equivalent to the linked chains described in Stevenson and Greenwood (2006) when the dependency of a sentence is represented as a tree not a graph.

2.3 Pre-processing

We tag and parse each sentence in our corpus with the NYU named entity tagger[3] and the Stanford dependency parser. Then for each pair of names in the dependency tree, we extract the SDP connecting them. Names in the path are replaced by their types. We require SDP to contain at least one verb or noun. We use the base form of words in SDP. We also require the length of the path (defined as the number of dependency relations and words in it) to be between 3 and 7. Short paths are more likely to be generic patterns such as "*of*" and can be handled separately as in (Pantel and Pennacchiotti, 2006). Very long paths are more likely to be non-relation patterns and too sparse to be useful even if they are relation patterns.

2.4 Clustering Algorithm

The basic idea of our clustering algorithm is to group all the paths (including the seed paths used later for SSL) in our corpus into different clusters based on distributional similarities. We first extract a variety of features from the named entities *X* and *Y* connected by a path *P* as shown in Table 1. We then compute an analogue of tf-idf for each feature *f* of *P* as follows: tf as the number of corpus instances of *P* having feature *f* divided by the number of instances of *P*; idf as the total number of paths in the corpus divided by the number of paths with at least one instance with feature *f*. Then we adopt a vector space model, i.e., we construct a tf-idf feature vector for each *P*. Now we compute the similarity between two vectors/paths using Cosine similarity and cluster all the paths using Complete Linkage.

Some technical details deserve more attention here.

Feature extraction: We extract more types of features than the DIRT paraphrase discovery procedure used in (Lin and Pantel, 2001). Lin and Pantel (2001) considered *X* and *Y* separately while we also use the conjunction of *X* and *Y*. We also extract named entity types as features since we are interested in discovering relations among different types of names. Some names are ambiguous such as *Jordan*. We hope coupling the type with the string of the name may alleviate the ambiguity.

Table 1. Sample features for "*X visited Y*" as in "*Jordan visited China*"

Feature Type	Example
Name Type of *X*	*LEFT_PERSON*
Name Type of *Y*	*RIGHT_GPE*
Combination of Types of X and *Y*	*PERSON_GPE*
Conjunction of String and Type of *X*	*LEFT_Jordan_PERSON*
Conjunction of String and Type of *Y*	*RIGHT_China_GPE*
Conjunction of Strings and Types of *X* and *Y*	*Jordan_PERSON_China_GPE*

Similarity measure and clustering method: There are many ways to compute the similarity/distance between two feature vectors, such as *Cosine*, *Euclidean*, *Hamming*, and *Jaccard coefficient*. There are also many standard clustering algorithms. A systematic comparison of the performance of different distance measures and clustering algorithms is beyond the scope of this paper.

3 Semi-supervised Relation Pattern Discovery

We first present a standard bootstrapping algorithm coupled with analyses of some of its shortcomings. Then we describe our new bootstrapping procedure which is guided by pattern clusters.

3.1 Bootstrapping without Guidance

The procedure associates a precision between 0 and 1 with each pattern, and a confidence between 0 and 1 with each name pair. Initially the seed patterns for a specific relation *R* have precision 1 and all other patterns 0. It consists of the following steps:

Step1: Use seed patterns to match new NE pairs and evaluate NE pairs.

Intuitively, for a newly matched NE pair N_i, if many of the *k* patterns connecting the two names are high-precision patterns then the name pair has a high confidence. The confidence is computed by the following formula.

$$Conf(N_i) = 1 - \prod_{j=1}^{k} (1 - \Pr ec(p_j)) \quad (1)$$

[3] Please refer to Grishman et al. (2005) and http://cs.nyu.edu/grishman/jet/license.html

Problem: While the intuition is correct, in practice this will over-rank NE pairs which are not only matched by patterns belonging to the target relation *R* but are also connected by patterns of many other relations. This is because of the initial settings used in many SSL systems: seeds are assigned high confidence. Thus all NE pairs matched by initial seed patterns will have very high confidence.

Suppose the target relation is *LocatedIn*, and "*visited*" is a seed pattern; then the <*Clinton*, *Arkansas*> example will be over-rated because we cannot take into account that it would also match patterns of other relations such as *PersonGovernorOfLocation* and *PersonBornInLocation* in a real corpus. This will cause a vicious circle, i.e., bogus NE pairs extract more bogus patterns which further extract more bogus NE pairs. We believe this flaw of the initial settings partially results in the semantic drift problem.

One can imagine that this is not a problem that can be solved by using a different formula to replace the one presented here. A possible solution is to study the structure of unlabeled data (NE pairs in our case) and integrate this structure information into the initial settings. Indeed, this is where pattern clusters come into play. We will demonstrate this in Section 3.2.

Step 2: Use NE pairs to search for new patterns and rank patterns.

Similar to the intuition in Step 1, for a pattern *p*, if many of the NE pairs it matches are very confident then *p* has many supporters and should have a high ranking. We can use formula (2) to estimate the confidence of patterns and rank them.

$$Conf(p) = \frac{Sup(p)}{|H|} \bullet \log Sup(p) \qquad (2)$$

Here $|H|$ is the number of unique NE pairs matched by *p* and *Sup(p)* is the sum of the support it can get from the $|H|$ pairs:

$$Sup(p) = \sum_{j=1}^{|H|} Conf(N_j) \qquad (3)$$

The precision of *p* is given by the average confidence of the NE pairs matched by *p*.

$$\Pr ec(p) = \frac{Sup(p)}{|H|} \qquad (4)$$

Formula (4) normalizes the precision to range from 0 to 1. As a result the confidence of each NE pair is also normalized to between 0 and 1.

Step 3: Accept patterns

Most systems accept the *K* top ranked patterns in Step 2 as new seeds, subject to some restrictions such as requiring the differences of confidence of the *K* patterns to be within a small range.

Step 4: Loop or stop

The procedure now decides whether to repeat from Step 1 or to terminate.

Most systems simply do not know when to stop. They either run a fixed number of iterations or use some held-out data to find one criterion that works the best for the held-out data.

3.2 Bootstrapping Guided by Clusters

Recall that our clustering algorithm in Section 2 provides us with *K* clusters, each of which contains *n* (*n* differs in different clusters) patterns. Every pattern in our corpus now has a cluster membership (the seed patterns have the same membership).

The most important benefit from our pattern clusters is that now we can measure how strongly a NE pair N_i is associated with our target cluster C_t (the one to which the seed patterns belong).

$$\Pr ob(N_i \in C_t) = \frac{\sum_{p \in C_t} freq(N_i, p)}{m} \qquad (5)$$

Here $freq(N_i, p)$ is the number of times *p* matches N_i and *m* is the total number of pattern instances matching N_i.

We integrate this prior cluster distribution of each NE pair into the initial settings of our new bootstrapping procedure.

Step1: Use seed patterns to match new NE pairs and evaluate NE pairs.

Assumption: A good NE pair must be strongly associated with the target cluster and can be matched by multiple high-precision patterns.

So we evaluate a NE pair by the harmonic mean of two confidence scores, namely the confidence as its association with the target cluster and the confidence given by the patterns matching it.

$$Conf(N_i) = 2 \bullet \frac{Semi\_Conf(N_i) \bullet Cluster\_Conf(N_i)}{Semi\_Conf(N_i) + Cluster\_Conf(N_i)} \quad (6)$$

$$Semi\_Conf(N_i) = 1 - \prod_{j=1}^{k} (1 - Prec(p_j)) \quad (7)$$

$$Cluster\_Conf(N_i) = \Pr ob(N_i \in C_t) \quad (8)$$

Under such settings, <*Clinton, Arkansas*> will be assigned a lower confidence score for the *LocatedIn* relation than it is in the standard bootstrapping. Even if we assign high precision to our seed patterns such as "*visited*" and consequently the *Semi_Conf* is very high, it can still be discounted by the *Cluster_Conf*[4].

Step 2: Use NE pairs to search for new patterns and rank patterns.

All the measurement functions are the same as those used in the standard bootstrapping. However, with better ranking of NE pairs in Step 1, the patterns are also ranked better than they are in the standard bootstrapping.

Step 3: Accept patterns

We also accept the *K* top ranked patterns.

Step 4: Loop or stop

Since each pattern in our corpus has a cluster membership, we can monitor the semantic drift easily and naturally stop: it drifts when the procedure tries to accept patterns which do not belong to the target cluster; we can stop when the procedure tends to accept more patterns outside of the target cluster.

If our clustering algorithm can give us perfect pattern clusters, we can stop bootstrapping immediately after it accepts the first pattern not belonging to the target cluster. Then the bootstrapping becomes redundant since all it does is to consume the patterns of the target cluster.

Facing the reality of the behavior of many clustering algorithms, we allow the procedure to occasionally accept patterns outside of the target cluster but we are not tolerant when it tries to accept more patterns outside of the target cluster than patterns in it. Note that when such patterns are accepted they will be moved to the target cluster and invoke the recomputation of *Cluster_Conf* of NE pairs connected by these patterns. The ranking functions in step 1 and 2 insure that the procedure will only accept patterns which can gain strong support from NE pairs that are strongly associated with the target cluster and are connected by many confident patterns.

4 Experiments

4.1 Corpus

Our corpora contain 37 years of news articles: TDT5, NYT(94-00), APW(98-00), XINHUA(96-00), WSJ(94-96), LATWP(94-97), REUFF(94-96), REUTE(94-96), and WSJSF(87-94). It contains roughly 65 million sentences and 1.3 billion tokens.

4.2 Seeds

Seeds of the 3 relations we are going to test are given in table 2. *LocatedIn* detects relation between PERSON and LOCATION/GPE; Social (*SOC*) detects social relations (either business or family) between PERSON and PERSON; Employment (*EMP*) detects employment relations between PERSON and ORGANIZATION.

Table 2. Seed Patterns

Relation	Seeds
Located-in	*nsubj'* visit *dobj* *nsubj'* travel *prep_to* *poss'* trip *prep_to*
SOC	*appos* friend/lawyer *poss* *appos* son/spokesman *prep_of/prep_for* *nsubj'* fire *dobj* *nsubjpass'* fire *agent*
EMP[5]	*appos* chairman/executive/founder *prep_of* *appos* editor *prep_of* *appos* director/head/officer/analyst *prep_at* *appos* manager *prep_with*

(*nsubj*, *dobj*, *prep*, *appos*, *poss*, *nsubjpass*, *agent* stand for subject, direct object, preposition, apposition, possessive, passive nominal subject and complement of passive verb. The quote marks in Table 2 and Table 3 denote inverse dependencies in the dependency path.)

We work on these three relations mainly because of the availability of benchmark evaluation data. These are the most frequent relations in our evaluation data.

[4] The *Cluster_Conf* of <*Clinton, Arkansas*> related to the *LocatedIn* relation is indeed very low (less than 0.1) in our experiments.

[5] We provide more seeds (executives and staff) for *EMP* because it has been pointed out in (Sun, 2009) that *EMP* contains a lot of job titles.

4.3 Unsupervised Experiments

We run the clustering algorithm described in Section 2 using all the 37 years' data. We require that a pattern match at least 7 distinct NE pairs and that an NE pair must be connected by at least 7 unique patterns. As a result, there are 635,128 patterns (22,225 unique ones) used in experiments. We use 0.005 as the cutoff threshold of complete linkage. The threshold is decided by trying a series of thresholds and searching for the maximal[6] one that is capable of placing the seed patterns for each relation into a single cluster. Table 3 shows the top 15 patterns (ranked by their corpus frequency) of the cluster into which our *LocatedIn* seeds fall.

Table 3. Top 15 patterns in the *LocatedIn* Cluster

Index	Pattern	Frequency
1	*nsubj'* said *prep_in*	2203
2	*nsubj'* visit *dobj*	1831
3	*poss'* visit *prep_to*	1522
4	*nsubj'* return *prep_to*	1394
5	*nsubj'* tell *prep_in*	1363
6	*nsubj'* be *prep_in*	1283
7	*nsubj'* arrive *prep_in*	1113
8	*nsubj'* leave *dobj*	1106
9	*nsubj'* go *prep_to*	926
10	*nsubj'* fly *prep_to*	700
11	*nsubj'* come *prep_to*	658
12	*appos* leader *poss*	454
13	*poss'* trip *prep_to*	442
14	*rcmod* be *prep_in*	419
15	*nsubj'* make *prep_in*	418

4.4 Semi-supervised Experiments

To provide strong statistical evidence, we divide our data into 10 folds (combinations of news articles from different years and different news resources). We then run both the standard and our new bootstrapping on the 10 folds. For both procedures, we accept n patterns in a single iteration (n is initialized to 2 and set to $n + 1$ after each iteration). We run 50 iterations in the standard bootstrapping and 1,325 patterns are accepted for each fold and each relation. Our new bootstrapping procedure stops when there are two consecutive iterations in which more than half of the newly accepted patterns do not belong to the target cluster. Thus the number of patterns accepted for each fold and each relation differs as the last iteration differs.

[6] We choose the maximal value because many clusters will be merged to a single one when the threshold is close to 0, making the clusters too general to be useful.

4.5 Evaluation

The output of our bootstrapping procedures is 60 sets of patterns (3 relations × 2 methods × 10 folds). We need a data set and evaluation method which can compare their effectiveness equally and consistently.

Evaluation data: ACE 2004 training data. ACE does not provide relation annotation between each pair of names. For example, in "*US President Clinton said that the United States …*" ACE annotates an *EMP* relation between the name "*US*" and nominal "*President*". There is no annotation between "*US*" and "*Clinton*". However, it provides entity co-reference information which connects "*President*" to "*Clinton*". So we take advantage of this entity co-reference information to automatically re-annotate the relations where possible to link a pair of names within a single sentence. The re-annotation yields an *EMP* relation between "*US*" and "*Clinton*". The re-annotation is reviewed by hand to avoid adding a relation linking "*Clinton*" and the more distant co-referent "*United States*", even though "*US*" and "*the United States*" refer to the same entity. This data set provides us with 412/3492 positive/negative relation instances between names. Among the 412 positive instances, there are 188/117/35 instances for *EMP/LocatedIn/SOC* relations.

Evaluation method: We adopt a direct evaluation method, i.e., use our sets of patterns to extract relations between names on ACE data. Applying patterns to a benchmark data set can provide us with better precision/recall analyses. We use a strict pattern match strategy. We can certainly take advantage of loose match or add patterns as additional features to feature-based relation extraction systems to boost our performance but we do not want these to complicate the comparison of the standard and our new bootstrapping procedures.

4.6 Results and Analyses

We average our results on the 10 folds. We plot precision against recall and semantic drift rate against iterations (Drift). We compute the semantic drift rate as the percentage of false

Figure 2. Performance for *EMP/LocatedIn/SOC*

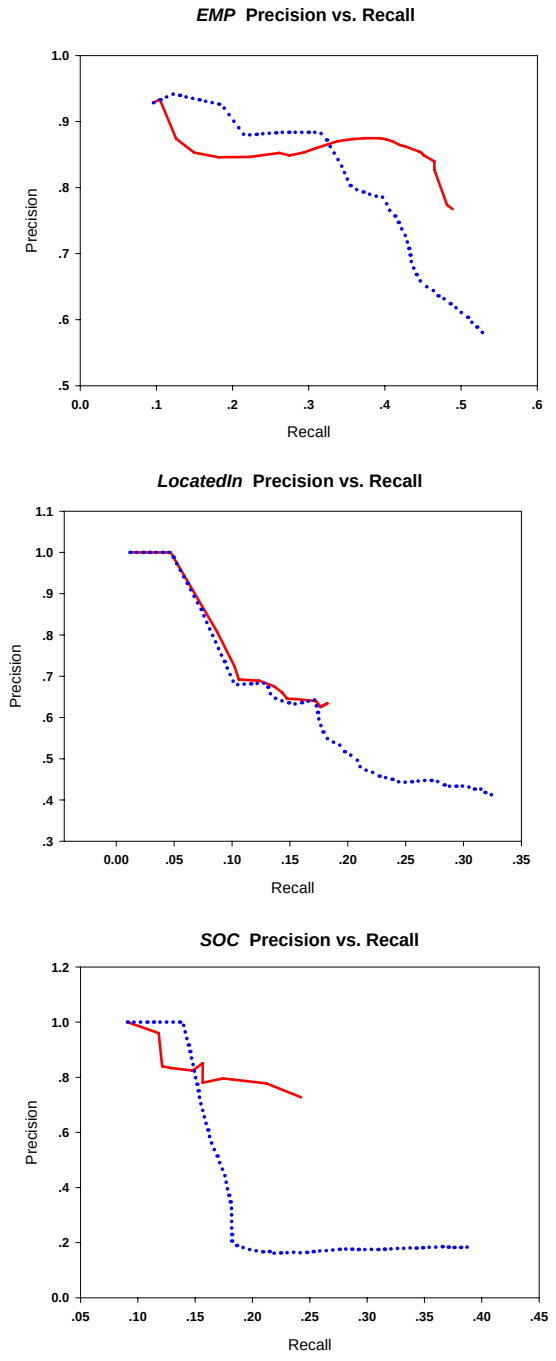


Figure 3. Drift for *EMP/LocatedIn/SOC*

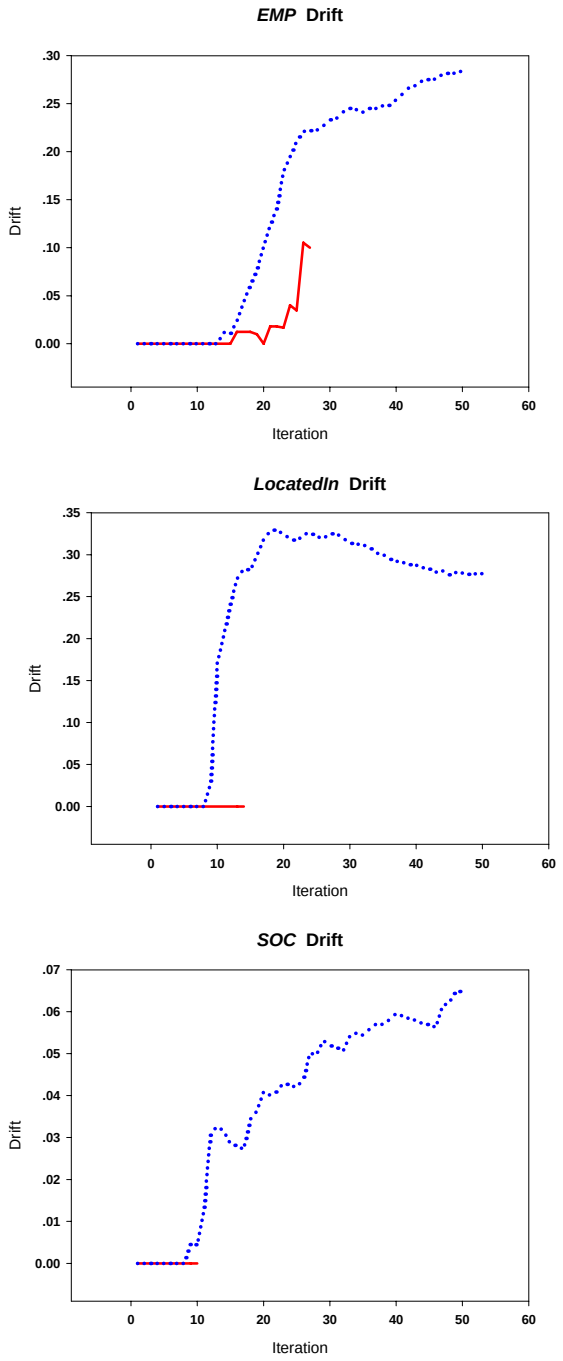

positive instances belonging to ACE relations other than the target relation. Take *EMP* for example, we compute how many of the false positive instances belonging to other relations such as *LocatedIn*, *SOC* and other ACE relations. In all plots, red solid lines represent bootstrapping with guidance from clusters and blue dotted lines standard bootstrapping.

There are a number of conclusions that can be drawn from these results. We are particularly interested in the following two questions: To what extent did we prevent semantic drift by the guidance of pattern clusters? Did we stop at the right point, i.e., can we keep high precision while maintaining near maximal recall?

1) It is obvious from the drift curves that our bootstrapping effectively prevents semantic drift. Indeed, there is no drift at all when *LocatedIn*

and *SOC* learners terminate. Although drift indeed occurs in the *EMP* relation, its curve is much lower than that of the standard bootstrapping.

2) Our new procedure terminates when the precision is still high while maintaining a reasonable recall. Our bootstrapping for *EMP/SOC/LocatedIn* terminates at F-measures of 60/37/28 (in percentage). We conducted the Wilcoxon Matched-Pairs Signed-Ranks Test on the 10 folds, comparing the F-measures of the last iteration of our bootstrapping guided by clusters and the iteration which provides the best average F-measure over the 3 relations of the standard bootstrapping. The results show that the improvement of using clusters to guide bootstrapping is significant at a 97% confidence level.

We hypothesize that when working on dozens or hundreds of relations the gain of our procedure will be even bigger since we can effectively prevent inter-class errors.

5 Related Work

Recent research starts exploring unlabeled data for discriminative learning. Miller et al., (2004) augmented name tagging training data with hierarchical word clusters and encoded cluster membership in features for improving name tagging. Lin and Wu (2009) further explored a two-stage cluster-based approach: first clustering phrases and then relying on a supervised learner to identify useful clusters and assign proper weights to cluster features. Other similar work includes (Wong and Ng, 2007) for name tagging, and (Koo et. al., 2008) for dependency parsing.

While similar in spirit, our supervision is minimal, i.e., we only use a few seeds while the above approaches rely on a large amount of labeled data. To the best of our knowledge, the theme explored in this paper is the first study of using pattern clusters for preventing semantic drift in semi-supervised pattern discovery.

Recent research also explored the idea of driving SSL with explicit constraints constructed by hand such as identifying mutual exclusion of different categories (i.e., people and sport are mutually exclusive). This is termed constraint-driven learning in (Chang et al., 2007), coupled learning in (Carlson et al., 2010) and counter-training in (Yangarber, 2003). The learning quality largely depends on the completeness of explicit constraints. While we share the same goal, i.e., to prevent semantic drift, we rely on unsupervised clusters to discover implicit constraints for us instead of generating constraints by hand.

Our research is also close to semi-supervised IE pattern learners including (Riloff and Jones, 1999), (Agichtein and Gravano, 2000), (Yangarber et al., 2000), and many others. While they conduct bootstrapping on unlabeled data directly, we first cluster unlabeled data and then bootstrap with help from clusters.

There are also clear connections to work on unsupervised relation discovery (Hasegawa et al., 2004; Zhang et al., 2005; Rosenfeld and Feldman, 2007). They group pairs of names into relation clusters based on the contexts between names while we group the contexts/patterns into clusters based on features extracted from names.

6 Conclusions and Future Work

We presented a simple algorithm for clustering patterns and used pattern clusters to guide semi-supervised semantic pattern discovery. The novel bootstrapping procedure can achieve the best F-1 score while maintaining a good trade-off between precision and recall. We also demonstrated that it can effectively prevent semantic drift and naturally terminate.

We plan to extend this idea to improve relation extraction performance with a richer model as used in (Zhang et al., 2004; Zhou et al., 2008) than a simple pattern learner. The feature space will be much larger than the one adopted in this paper. We will investigate how to overcome the memory bottleneck when we apply rich models to millions of instances.

Utilizing Variability of Time and Term Content, within and across Users in Session Detection

Abstract

In this paper, we describe a SVM classification framework of session detection task on both Chinese and English query logs. With eight features on the aspects of temporal and content information extracted from pairs of successive queries, the classification models achieve significantly superior performance than the stat-of-the-art method. Additionally, we find through ROC analysis that there exists great discrimination power variability among different features and within the same feature across different users. To fully utilize this variability, we build local models for individual users and combine their predictions with those from the global model. Experiments show that the local models do make significant improvements to the global model, although the amount is small.

1 Introduction

To provide users better experiences of search engines, inspecting users' activities and inferring users' interests are indispensible. Query logs recorded by search engines serves well for these purposes. Query log conveys the user interest information in the form of slices of the query stream. Thus the task of session detection consists in distinguishing slice that corresponds to a user interest from other ones, and thus this paper, we adopt the definition of a session following (Jansen et al., 2007):

(A session is) a series of interactions by the user toward addressing a single information need.

This definition is equivalent to that of the "search goal" proposed by Jones and Klinkner (2008), which corresponds to an *atomic* information need, resulting in one or more queries.

This paper adopts a classification point of view to the task of session detection (Jones and Klinkner, 2008). Given a pair of successive queries in a query log, we examine it in various viewpoints (i.e. features) such as time proximity and similarity of the content of the two queries to determine whether these two queries cross a border of a search session. In other words, we classify the gap between the two queries into two classes: session shift and session continuation. In practice, search goals in a search mission and different search missions could be intermingled, and increase the difficulty of correctly identifying them. In this paper, we do not take this issue into account and simply treat all boundaries between intermingled search goals as session shifts. The chief advantage in this choice is that we will have the opportunity to make classification model working online without caching user's queries that are pending to be assigned to a session.

Various studies built accurate models in predicting session boundaries and in distinguishing intermingled sessions, and they are summarized in Section 2. However, none of these works analyzed the contribution of individual features from a user-oriented viewpoint, or evaluated a feature's discrimination power in a general scenario independent of its usage, as this paper does by conducting ROC analyses. During these analyses, we found that the discrimination power of features varies dramatically, and for different users, the discrimination power of a particular feature also does not remain constant.

Thus, it is appealing to build local models for users with have sufficient size of training examples, and combine the local models' predictions with those made by the global model trained by the whole training data. However, few of previ-

Coling 2008: Poster Volume, pages 1203–1210,
Beijing, August 2010

ous works build user-specific models for the sake of characterizing the variability in user's search activities, except that of Murray et al. (2006). To fully make use of these two aspects of variability, inspired by Murray et al., we build users' local models based on a much broader range of evidences, and show that different local models vary to a great extent, and experiments show that the local models do make significant improvements to the global model, although the amount is small.

The remainder of this paper is organized as follows: Section 2 summarizes the related work of the session detection task. In Section 3, we first describe our classification framework as well as the features utilized. Then we conduct various evaluations on both English and Chinese query logs. Section 4 introduces the approaches to building local models based on an analysis of the variability of the discrimination power of features, and combine predictions of local models with those of the global model. Section 5 discusses the experimental results and concludes this paper.

2 Related Work

The simplest method in session detection is defining a timeout threshold and marking any time gaps of successive queries that exceed the threshold as session shifts. The thresholds adopted in different studies were significantly different, ranging from 5 minutes to 30 minutes (Silverstein et al., 1999; He and Göker, 2000; Radlinski and Joachims, 2005; Downey et al., 2007). Other study suggested adopting a dynamic timeout threshold. Murray et al. (2006) proposed a user-centered hierarchical agglomerative clustering algorithm to determine timeout threshold for each user dynamically, other than setting a fixed threshold. However, Jones and Klinkner (2008) pointed out that single timeout criterion is always of limited utility, whatever its length is, and incorporating timeout features with other various features achieved satisfactory classification accuracy.

An effective approach to combining the time out features with various evidences for session detection is machine learning. He et al. (2002) collected statistical information from human annotated query logs to predict the probability a "New" pattern indicates a session shift according to the time gap between successive queries. Özmutlu and colleagues re-examined He et al.'s work, and explored other machine learning techniques such as neural networks, multiple linear regression, Monte Carlo simulation, conditional probabilities (Gayo-Avello, 2009), and HMMs (Özmutlu, 2009).

In recent studies, Jones and Klinkner (2008) built logistic regression models to identify search goals and missions, and tackled the intermingled search goal/mission issue by examining arbitrary pairs of queries in the query log. Another contribution of Jones and Klinkner is that they made a thorough analysis of contributions of individual features. However, they explored the features' contributions from a feature selection point of view rather than from a user-oriented one, and thus failed to characterize the variability of the discrimination power of the features when applied to different users.

3 Learning to Detect Session Shifts

3.1 Feature Extraction

We adopt eight features covering both the temporal and the content aspect of pairs of successive queries. Most these features are commonly used by previous studies (He and Göker, 2000; Özmutlu, 2006; Jones and Klinkner, 2008). However, in this paper, we will analyze their contributions to the resulted model in a quite different way from that in previous works.

Let $Q = (q_1, q_2, \ldots, q_n)$ denote a query log. The features are extracted from every successive pair of queries (q_i, q_{i+1}). Table 1 summarizes the features we adopt. The normalization described in Table1 is done according to the type of the feature. Features describing characters are normalized by the average length of the two queries, while those describing character-n-grams are normalized by the average size of the n-gram sets of the two queries. Character-n-grams (e.g. bigrams "*ca*" and "*at*" in "*cat*") are robust to different representations of the same topic (e.g. "*IR*" as *Information Retrieval*) and typos (e.g. "*speling" as "spelling"*), and serve as a simple stemming method. In practice, character-*n*-grams are accumulative, which means they consist of all *m*-grams with $m \leq n$.

The feature "avg_ngram_distance", a variant of the "lexical distance" in (Gayo-Avello, 2009), is more complicated than to be described briefly.

Here we first define n-gram distance (*ND*) from q_i to q_j, which is formalized as follows:

$$ND(q_i \rightarrow q_j) = 1 - \frac{\#\text{ of char.-}n\text{-gram in } q_i \text{ occur in } q_j}{\#\text{ of char.-}n\text{-gram in } q_j}$$

Note that character-n-grams are accumulative and there could be multiple occurrences of a character-n-gram in a query, so the number of a character-*n*-gram is the sum of that of all *m*-grams with $m \leq n$, and multiple occurrences are all considered. At last, the average of character-n-gram distance (*ACD*) of the pair (q_i, q_{i+1}) is:

$$ACD(q_i, q_{i+1}) = \frac{ND(q_i \rightarrow q_{i+1}) + ND(q_{i+1} \rightarrow q_i)}{2}$$

There are seven features describing the content aspect of a query pair, and they are more or less overlapped (e.g. edit_distance vs. common_char). However, we show in the next subsection that all these features are beneficial to the final performance.

Feature	Description
time_interval	time interval between successive queries
avg_ngram_ distance	avg. of character-n-gram distances
edit_disance	normalized Levenshtein edit distance
common_prefix	normalized length of prefix shared
common_suffix	normalized length of suffix shared
common_char	normalized number of characters shared
common_ngram	normalized number of character-n-grams shared
Jaccard_ngram	Jaccard distance between character-n-gram sets

Table 1. Features used in classification models

3.2 Data Preparation

The query logs we explored include an English search log tracked by AOL from Mar 1, 2006 to May, 31 2006 (Pass et al., 2006), and a Chinese search log tracked by Sogou.com, which is one of the major Chinese Search Engines, from Mar 1, 2007 to Mar 31, 2007[1]. We applied systematic sampling over the user space on the two logs, which yielded 223 users and 2809 users, corresponding to 6407 and 6917 query instances respectively[2]. Sampling over the user space instead of over the query space avoids the bias to the most active users who submit much more queries than average users.

For each sampled dataset, we invited annotators who are familiar with IR and search process to determine each pair of successive queries of interest is across the border of a session. We made trivial pre-split process under two rules:

> Queries from different users are not in the same session.
>
> Queries from different days are not in the same session.

Table 2 shows some basic statistics of the annotated data set. During the annotation process, the annotators were guided to identify the user's information need at the finest granularity ever possible, because we focus on the atomic information needs as described in Section 1. Consequently, the average numbers of queries in a session in both query logs are lower than previous studies.

	AOL log	Sogou log
Queries	6407	6917
Sessions	4571	5726
Queries per session	1.40	1.21
Longest session	21	12

Table 2. Summary of the annotation results in both query logs

3.3 Learning Framework

In this section we seek to build accurate global classification model based on the whole training data obtained in the previous sub-subsection for both the query logs. We built the models within SVM framework. The implementation of SVM we used is libSVM (Chang and Lin, 2001). For the sake of evaluations and of model integration in the next section, we set the prediction of SVM to be *probability estimation* of the test example being positive. All features were pre-scaled into [0, 1] interval. We adopted the polynomial kernel, and for both datasets, we exhaustively tried each of the subset of the eight features using 5-fold cross validation. We found that using all the eight features yielded the best classification accuracy. Thus in the experiments in rest of this

[1] http://www.sogou.com/labs/resources.html

[2] The sampling schema and sample size was determined following (Gayo-Avello, 2009).

section and the next section, we adopt the entire feature set to build global classification models.

There is one parameter to be determined for feature extraction: the length of character-n-grams. The proper lengths on AOL log and Sogou log are different. We tried the length from 1 to 9, and according to cross validation accuracy, we found the best lengths for the two logs as 6 and 3 respectively.

3.4 Experimental Results

3.4.1 Baseline Methods

We provide two base line methods for comparisons. The first method is the commonly used timeout methods. We tried different timeout thresholds from 5 minutes to 30 minutes with a step of 5 minutes, and found that for both query logs the 5 minutes' threshold yield the best overall performance.

The second method achieved the best performance on the AOL log (Gayo-Avello, 2009), which addresses the session detection problem using a geometric interpolation method, in comparison to previous studies on this query log. We re-implemented this method and evaluated it on both the datasets. Similarly, the best parameters for the two query logs are different, such as the length of a character-n-gram. We only report the performance with the best parameter settings.

3.4.2 Analyzing the Performance

We analyze the performance of the SVM models according to precision, recall, F_1-mean and $F_{1.5}$-mean of predictions on session shift and continuation against human annotation data.

The F_β-mean is defined as:

$$F_\beta\text{-mean} = \frac{(1+\beta^2)PR}{\beta^2 P + R}$$

where P denotes precision and R denotes recall. He et al. (2002) regards recall more important than precision, and set the value of β in F_β-mean to 1.5. We also report performance under this measure.

In addition to traditional precision / recall based measures, we also perform ROC (Receiver Operating Characteristic) analysis to determine the discrimination power of different methods. The best merit of ROC analysis is that given a reference set, which is usually the human annotation results, it evaluates a set of indicator's discrimination power for arbitrary binary classification problem *independent* of the critical value with which the class predictions are made.

Specifically, in the context session detection, regardless of the critical value that splits the classifier outputs into positive ones and negative ones (e.g. the 5-minutes' timeout threshold and 50% probability in SVM's output), the ROC analysis provides the overall discrimination power evaluation of the output set of a certain method (by trying to set each output value as the critical value). For the baseline method by Gayo-Avello, the core of the decision heuristics also had a critical value to be determined. For details, readers could refer to (Gayo-Avello, 2009).

3.4.3 Precision, Recall, and F-means

Before we examine the discrimination power of each session detection method's output independent of the threshold value selected. In this sub-subsection, we begin with a more traditional evaluation schema: setting a proper threshold to produce binary predictions. It is straightforward to set the threshold for SVM method to 50%, and as described in sub-subsection 3.1.1, the threshold for timeout method is 5 minutes. The threshold of Gayo-Avello's method is implied in its heuristics.

Table 3 and Table 4 show the experimental results on AOL log and Sogou log respectively. For each dataset, we performed 1000-times bootstrap resampling, generating 1000 bootstrapped datasets with the same size as the original dataset. To test the statistical significance of performance differences, we adopted Wilcoxon signed-rank test on the performance measures computed from the 1000 bootstrapped dataset, and found comparisons between each pair of methods were all significant at 95% level.

The results show that SVM method clearly outperforms the baseline methods, and timeout method performs poorly. It may be argued that the poor performance of timeout method is due to the improper threshold value chosen. In this case, the ROC analysis, which assesses the discrimination power of a method's output set independent of the threshold value chosen, is more suitable for performance evaluation.

Gayo-Avello method significantly outperforms the timeout method. But due to its heuristic nature, it is less likely to do better than the supervised-learning methods, although it avoids the over fitting issue. The Gayo-Avello method's unstable performance in predicting session con-

tinuations implies that its heuristics did not generalize well to Chinese query logs.

3.4.4 ROC Analysis

By setting certain threshold value, we analyzed the three method's performance using precision / recall based measures. In this sub-subsection, we try to set each value in an output set as the threshold value, and evaluate the discrimination power of methods by the area under the ROC curve.

Figure 1 shows the ROC curves of the SVM method and the two baseline methods: timeout and Gayo-Avello, for predicting session shifts. ROC curves for predicting session continuations are symmetric with respect to the reference line, so we omit them in the rest of this paper for the sake of space limit.

The results show that SVM method clearly outperforms the baseline methods in the prospective of discrimination power, with ROC area 0.9562 on AOL dataset and 0.9154 on Sogou dataset. The curves of the two baseline methods are clearly under that of SVM method. This means baseline methods can never achieve accuracy as high as SVM method w.r.t. a fixed false alarm (classification error) rate, nor false alarm rate as low as SVM method w.r.t. a fixed accuracy rate. Again, Gayo-Avello method significantly outperforms timeout method, while underperforms the SVM method. For the question in the previous sub-subsection, coinciding with previous studies (Murray et al., 2006; Jones and Klinkner, 2008), applying single timeout threshold always yields limited discrimination power, wherever the operating point on ROC curve (i.e. threshold value) is set.

4 Making Use of the Variability of Discrimination Power

In this section, we first analyze the amount of contribution that each feature makes and show that the contribution, i.e. the discrimination power of each feature varies dramatically across different users. Then, we propose an approach to making use of this variability. Finally through experimental results, we show that the proposed approach makes small, yet significant improvements to the SVM method in Section 3.

4.1 Variability of Discrimination Power

The ROC analysis of individual feature provides adequate characterizations of the discrimination power of the feature. Another advantage of adopting ROC analysis is that the results are independent not only of the critical value, but also of the scale of the feature values.

Figure 2 shows the ROC curves of all the eight features in both datasets. Note that some features are with a higher value indicating session continuation rather than session shift, so their ROC curves are below the reference line. The feature "time_interval" behaves exactly the same as the timeout method in Figure 1. For the rest of the features, "avg_ngram_distance", "common_ngram" and "Jaccard_ngram" achieve the best discrimination powers, showing the character-n-gram representation is effective. The feature "common_char" performs significantly better in Sogou dataset than in AOL dataset, because Chinese characters convey much more information than English characters do. "common_suffix" performing worse than "common_prefix" reflects the custom of users. Users tend to add terms at the end of the query in a searching iteration, thus predicting session continuations by examining the common suffixes is problematic.

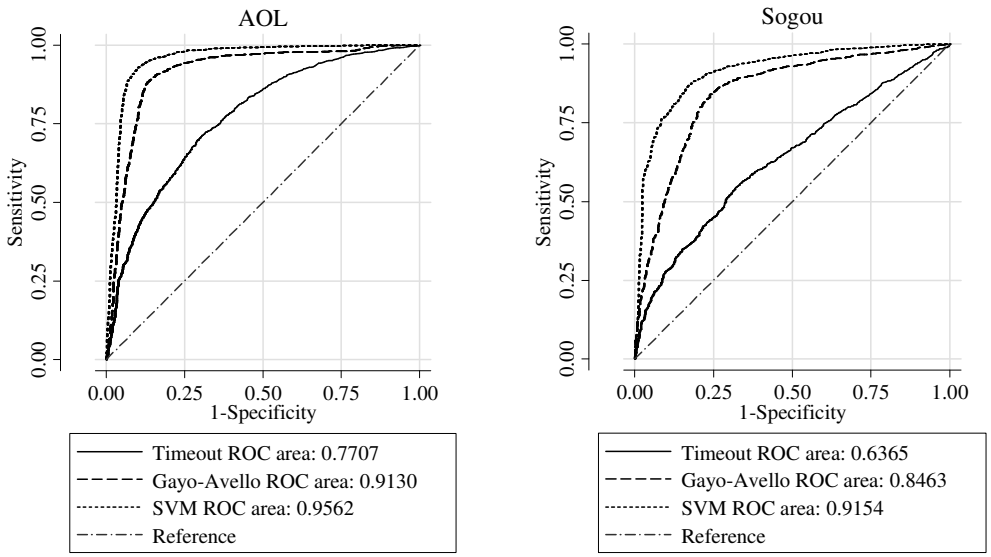

Figure 1. ROC analysis of SVM method and two baseline methods for predicting session shifts on both AOL and Sogou dataset. All comparisons between ROC areas within the same dataset are at least 95% statistically significant, because the corresponding confidence intervals do not overlap.

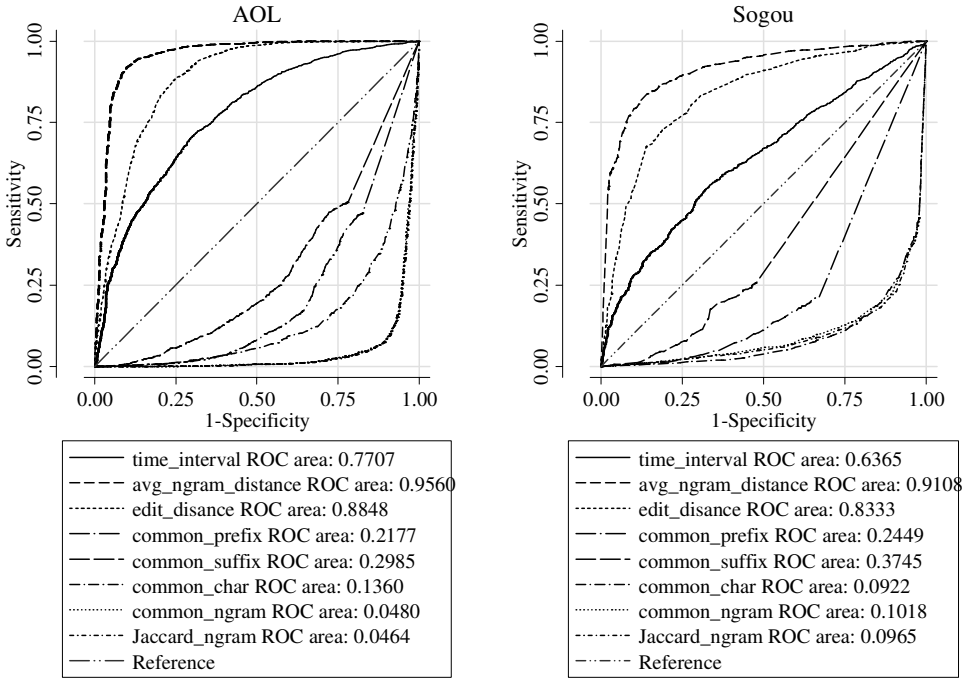

Figure 2. ROC analysis of individual features for predicting session shifts on both AOL and Sogou dataset. Note that some curves with similar ROC area values overlap each other.

In spite of the discrimination power a feature has, its behavior on different users is worthwhile to be examined. For selecting users that have sufficient data to draw stable conclusions, we consider only users who issued more than 50 queries in the datasets. Unfortunately, there are too few users (6 users) qualified in Sogou dataset, so we show only the statistics of ROC area values of each of the features in Table 5 based on 37 users in AOL dataset.

The statistics in Table 5 show that for different users. Recall that in sub-subsection 3.3.2, a 0.04 difference of ROC area make the performance of the SVM method significantly better

than that of the Gayo-Avello's method. Thus, the discrimination power of a feature is likely to vary significantly, because all the standard deviations are at 0.03 or even higher level. Especially, the minimum and maximum values show that for these users, some of the findings above from the whole dataset do not hold. This implies that it is likely more feasible to build specific local models for these users to make full use of the variability within the same feature.

Feature	avg.	sdev.	min.	max.
time_interval	0.780	0.088	0.476	0.912
avg_ngram_ distance	0.954	0.034	0.861	1.000
edit_disance	0.883	0.056	0.733	0.990
common_prefix	0.224	0.069	0.099	0.327
common_suffix	0.299	0.113	0.064	0.578
common_char	0.143	0.082	0.037	0.493
common_ngram	0.051	0.037	0.000	0.187
Jaccard_ngram	0.049	0.036	0.000	0.173

Table 5. Average, standard deviation, minimum, and maximum ROC areas of individual features

4.2 Building Local Models

We built individual local models for each user that issued more than 50 queries in AOL dataset. We also performed 5-fold cross validations and set the prediction to be the probability estimation of a test example being positive. The feature selection process showed again that all the eight features are beneficial, and none of them should be excluded.

In each fold of cross validation, we performed 90%-bagging on the training set 10 times to get the variance estimations of the local model. For each example in the test set, we set the final output on it to be the average of the 10 outputs, and recorded the standard deviation of the outputs on this example which is used during the model combination. We also conducted the same process for the global model for the sake of combination process described below.

4.3 Combing with the Global Model

Since the predictions of both the local and the global models are probability estimations, it is reasonable to combine them using linear combination. For each example, there are two outputs O_l and O_g coming from local and global models accordingly. For each example e of a user's sub dataset U, we have the outputs $O_l(e)$ and $O_g(e)$ as well as the normalized deviations $D_l(e)$ and $D_g(e)$ (by the largest deviation in U of the corresponding models). The final output $O(e)$ is defined as:

$$O(e) = \frac{D_l(e) \cdot O_g(e) + D_l(e) \cdot O_g(e)}{D_l(e) + D_g(e)}$$

		Global	Local	Combine
P	shift	**90.48**	88.53	90.43
	cont.	91.75	92.12	**92.52**
R	shift	93.94	94.44	**94.56**
	cont.	**87.20**	84.16	87.04
F_1	shift	92.18	91.39	**92.45**
	cont.	89.41	87.96	**89.69**
$F_{1.5}$	shift	92.85	92.54	**93.25**
	cont.	88.55	86.46	**88.65**

Table 6. Precision (P), recall (R), F_1-mean (F_1), and $F_{1.5}$-mean ($F_{1.5}$) of global model (bagging), local model (bagging) and combined model

This combination process is similar to (Osl et al., 2008). Note that the more the deviation of a model is, the less feasible the corresponding model is. We compared the performance of three models: global model, local model, and combined model. The results are summarized in Table 6. All comparisons between different models are statistically significant at 95% level, based on the same bootstrapping settings in subsubsection 3.4.3. The combined model shows slight (may due to the inferior performance of the local model), yet significant improvement to the global model. In spite of the amount of the improvement, the local model did correct some errors of the global model. It may be not acceptable to build such an expensive combined model for a limited improvement. Nevertheless, the results do show that the variability across different users is exploitable.

5 Discussion and Conclusion

In this paper, we built a learning framework of detecting sessions which corresponds to user's interest in a query log. We considered two aspect of a pair of successive queries: temporal aspect and content aspect, and designed eight features based on these two aspects, and the SVM models built with these features achieved satisfactory performance (92.37% F_1-mean on session shift, 90.25% F_1-mean on session continuation), significantly better than the best-ever approach on AOL query log.

The analysis of the features' discrimination power was conducted not only among different features, but also within the same feature when applied to different users in the query log. By analyzing the statistics of ROC area values of each of the features based on 37 users in AOL dataset, experimental results showed that there is considerable variability in both these aspects. To make full use of this variability, we built local models for individual user and combine the yielded predictions with those yielded by the global model. Experiments showed that the local model did make significant improvements to the global model, although the amount was small (92.45% vs. 92.18% F_1-mean on session shift, 89.69% vs. 89.41% F_1-mean on session continuation).

In future studies, we will explore other learning frameworks which better integrate the local model and the global model, and will try to acquire more data to build local models. We will also analyze more deeply the characteristics of ROC analysis in the feature selection process.

Word-Based and Character-Based Word Segmentation Models: Comparison and Combination

Weiwei Sun
Department of Computational Linguistics, Saarland University

Abstract

We present a theoretical and empirical comparative analysis of the two dominant categories of approaches in Chinese word segmentation: word-based models and character-based models. We show that, in spite of similar performance overall, the two models produce different distribution of segmentation errors, in a way that can be explained by theoretical properties of the two models. The analysis is further exploited to improve segmentation accuracy by integrating a word-based segmenter and a character-based segmenter. A *Bootstrap Aggregating* model is proposed. By letting multiple segmenters vote, our model improves segmentation consistently on the four different data sets from the second SIGHAN bakeoff.

1 Introduction

To find the basic language units, i.e. words, segmentation is a necessary initial step for Chinese language processing. There are two dominant models for Chinese word segmentation. The first one is what we call "word-based" approach, where the basic predicting units are words themselves. This kind of segmenters sequentially decides whether the local sequence of characters make up a word. This word-by-word approach ranges from naive maximum matching (Chen and Liu, 1992) to complex solution based on semi-Markov conditional random fields (CRF) (Andrew, 2006). The second is "character-based" approach, where basic processing units are characters which compose words. Segmentation is formulated as a classification problem to predict whether a character locates at the beginning of, inside or at the end of a word. This character-by-character method was first proposed in (Xue, 2003), and a number of sequence labeling algorithms have been exploited.

This paper is concerned with the behavior of different segmentation models in general. We present a theoretical and empirical comparative analysis of the two dominant approaches. Theoretically, these approaches are different. The word-based models do prediction on a dynamic sequence of possible words, while character-based models on a static character sequence. The former models have a stronger ability to represent word token features for disambiguation, while the latter models can better induce a word from its internal structure. For empirical analysis, we implement two segmenters, both using the *Passive-Aggressive* algorithm (Crammer et al., 2006) to estimate parameters. Our experiments indicate that despite similar performance in terms of overall F-score, the two models produce different types of errors, in a way that can be explained by theoretical properties. We will present a detailed analysis that reveals important differences of the two methods in Sec. 4.

The two types of approaches exhibit different behaviors, and each segmentation model has strengths and weaknesses. We further consider integrating word-based and character-based models in order to exploit their complementary strengths and thereby improve segmentation accuracy beyond what is possible by either model in isolation. We present a *Bootstrap Aggregating* model to combine multiple segmentation systems. By

Coling 2008: Poster Volume, pages 1211–1219,
Beijing, August 2010

letting multiple segmenters vote, our combination model improves accuracy consistently on all the four different segmentation data sets from the second SIGHAN bakeoff. We also compare our integrating system to the state-of-the-art segmentation systems. Our system obtains the highest reported F-scores on three data sets.

2 Two Methods for Word Segmentation

First of all, we distinguish two kinds of "words": (1) Words in dictionary are word types; (2) Words in sentences are word tokens. The goal of word segmentation is to identify word tokens in a running text, where a large dictionary (i.e. list of word types) and annotated corpora may be available. From the view of *token*, we divide segmentation models into two main categories: word-based models and character-based models. There are two key points of a segmentation model: (1) How to decide whether a local sequence of characters is a word? (2) How to do disambiguation if ambiguous segmentation occurs? For each model, we separately discuss the strategies for word prediction and segmentation disambiguation.

2.1 Word-Based Approach

It may be the most natural idea for segmentation to find word tokens one by one. This kind of segmenters read the input sentences from left to right, predict whether current piece of continuous characters is a word token. After one word is found, segmenters move on and search for next possible word. There are different strategies for the word prediction and disambiguation problems. Take for example maximum matching, which was a popular algorithm at the early stage of research (Chen and Liu, 1992). For word prediction, if a sequence of characters appears in a dictionary, it is taken as a word candidate. For segmentation disambiguation, if more than one word types are matched, the algorithm chooses the longest one.

In the last several years, machine learning techniques are employed to improve word-based segmentation, where the above two problems are solved in a uniform model. Given a sequence of characters $\mathbf{c} \in \mathcal{C}^n$ (n is the number of characters), denote a segmented sequence of words $\mathbf{w} \in \mathcal{W}^m$ (m is the number of words, i.e. m varies with $\mathbf{w}$), and a function GEN that enumerates a set of segmentation candidates $\mathrm{GEN}(\mathbf{c})$ for $\mathbf{c}$. In general, a segmenter solves the following "argmax" problem:

$$\hat{\mathbf{w}} = \arg \max_{\mathbf{w} \in \mathrm{GEN}(\mathbf{c})} \theta^\top \Phi(\mathbf{c}, \mathbf{w}) \quad (1)$$

$$= \arg \max_{\mathbf{w} \in \mathrm{GEN}(\mathbf{c})} \theta^\top \sum_{i=1}^{|\mathbf{w}|} \phi(\mathbf{c}, w_{[1:i]}) \quad (2)$$

where Φ and ϕ are global and local feature maps and θ is the parameter vector to learn. The inner product $\theta^\top \phi(\mathbf{c}, w_{[1:i]})$ can been seen as the confidence score of whether w_i is a word. The disambiguation takes into account confidence score of each word, by using the sum of local scores as its criteria. Markov assumption is necessary for computation, so ϕ is usually defined on a limited history. Perceptron and semi-Markov CRFs were used to estimate θ in previous work (Zhang and Clark, 2007; Andrew, 2006).

2.2 Character-Based Approach

Most previous data-driven segmentation solutions took an alternative, character-based view. This approach observes that by classifying characters as different positions in words, segmentation can be treated as a sequence labeling problem, assigning labels to the characters in a sentence indicating whether a character c_i is a single character word (*S*) or the begin (*B*), middle (*I*) or end (*E*) of a multi-character word. For word prediction, word tokens are inferred based on the character classes. The main difficulty of this model is character ambiguity that most Chinese characters can occur in different positions within different words. Linear models are also popular for character disambiguation (i.e. segmentation disambiguation). Denote a sequence of character labels $\mathbf{y} \in \mathcal{Y}^n$, a linear model is defined as:

$$\hat{\mathbf{y}} = \arg \max_{\mathbf{y} \in \mathcal{Y}^{|\mathbf{c}|}} \theta^\top \Psi(\mathbf{c}, \mathbf{y}) \quad (3)$$

$$= \arg \max_{\mathbf{y} \in \mathcal{Y}^{|\mathbf{c}|}} \theta^\top \sum_{i=1}^{|\mathbf{c}|} \psi(\mathbf{c}, y_{[1:i]}) \quad (4)$$

Note that local feature map ψ is defined only on the sequence of characters and their labels.

Several discriminative models have been exploited for parameter estimation, including perceptron, CRFs, and discriminative latent variable CRFs (Jiang et al., 2009; Tseng, 2005; Sun et al., 2009b).

2.3 Theoretical Comparison

Theoretically, the two types of models are different. We compare them from four aspects.

2.3.1 Internal Structure of Words

Chinese words have internal structures. In most cases, Chinese character is a morpheme which is the smallest meaningful unit of the language. Though we cannot exactly infer the meaning of a word from its character components, the character structure is still meaningful. Partially characterizing the internal structures of words, one advantage of character-based models is the ability to induce new words. E.g., character "者/person" is usually used as a suffix meaning "one kind of people". If a segmenter never sees "工作者/worker" in training data, it may still rightly recognize this word by analyzing the prefix "工作/work" with label *BI* and the suffix "者" with label *E*. In contrast, current word-based models only utilize the weighted features as word prediction criteria, and thus word formation information is not well explored. For more details about Chinese word fomation, see (Sun et al., 2009a).

2.3.2 Linearity and Nonlinearity

A majority of structured prediction models are linear models in the sense that the score functions are linear combination of parameters. Both previous solutions for word-based and character-based systems utilize linear models. However, both "linear" models incur nonlinearity to some extent. In general, a sequence classification itself involves nonlinearity in a way that the features of current token usually encode previous state information which is linear combination of features of previous tokens. The interested readers may consult (Liang et al., 2008) for preliminary discussion about the nonlinearity in structured models. This kind of nonlinearity exists in both word-based and character-based models. In addition, in most character-based models, a word should take a *S* label or start with a *B* label, end with *E* label, and only have *I* label inside. This inductive way for word prediction actually behaves nonlinearly.

2.3.3 Dynamic Tokens or Static Tokens

Since word-based models take the sum of part score of each individual word token, it increases the upper bound of the whole score to segment more words. As a result, word-based segmenter tends to segment words into smaller pieces. A difficult case occurs when a word token w consists of some word types which could be separated as words on their own. In such cases a word-based segmenter more easily splits the word into individual words. For example, in the phrase "四千三百/4300 米/meter (4300 meters)", the numeral "四千三百" consists of two individual numeral types "四千 (4000)" and "三百(300)". A word-based segmenter more easily made a mistake to segment two word tokens. This phenomenon is very common in named entities.

2.3.4 Word Token or Word Type Features

In character-based models, features are usually defined by the character information in the neighboring n-character window. Despite a large set of valuable features that could be expressed, it is slightly less natural to encode predicted word token information. On the contrary, taking words as dynamic tokens, it is very easy to define word token features in a word-based model. Word-based segmenters hence have greater representational power. Despite of the lack of word token representation ability, character-based segmenters can use word type features by looking up a dictionary. For example, if a local sequence of characters following current token matches a word in a dictionary; these word types can be used as features. If a string matches a word type, it has a very high probability (ca. 90%) to be a word token. So word type features are good approximation of word token features.

3 Baseline Systems

For empirical analysis, we implement segmenters in word-based and character-based architectures respectively. We introduce them from three aspects: basic models, parameter estimation and feature selection.

Algorithm 1: The *PA* learning procedure.

input : Data $\{(\mathbf{x}_t, \mathbf{y}_t), t = 1, 2, ..., n\}$

1 Initialize: $\mathbf{w} \leftarrow (0, ..., 0)$
2 **for** $I = 1, 2, ...$ **do**
3 **for** $t = 1, ..., n$ **do**
4 Predict: $\mathbf{y}_t^* = \arg\max_{\mathbf{y} \in \text{GEN}(\mathbf{x}_t)} \mathbf{w}^\top \Phi(\mathbf{x}_t, \mathbf{y})$
5 Suffer loss: $l_t = \rho(\mathbf{y}_t, \mathbf{y}_t^*) + \mathbf{w}^\top \Phi(\mathbf{x}_t, \mathbf{y}_t^*) - \mathbf{w}^\top \Phi(\mathbf{x}_t, \mathbf{y}_t)$
6 Set: $\tau_t = \frac{l_t}{||\Phi(\mathbf{x}_t, \mathbf{y}_t^*) - \Phi(\mathbf{x}_t, \mathbf{y}_t)||^2 + 0.5C}$
7 Update: $\mathbf{w} \leftarrow \mathbf{w} + \tau_t(\Phi(\mathbf{x}_t, \mathbf{y}_t) - \Phi(\mathbf{x}_t, \mathbf{y}_t^*))$
8 **end**
9 **end**

3.1 Models

For both word-based and character-based segmenters, we use linear models introduced in the section above. We use a first order Markov models for training and testing. In particular, for word-based segmenter, the local feature map $\phi(\mathbf{c}, w_{[1:i]})$ is defined only on $\mathbf{c}, w_{i-1}$ and w_i, and thereby Eq. 2 is defined as $\hat{\mathbf{w}} = \arg\max_{\mathbf{w} \in \text{GEN}(\mathbf{c})} \theta^\top \sum_{i=1}^{|\mathbf{w}|} \phi(\mathbf{c}, w_{i-1}, w_i)$. This model has a first-order Semi-Markov structure. For decoding, Zhang and Clark (2007) used a beam search algorithm to get approximate solutions, and Sarawagi and Cohen (2004) introduced a Viterbi style algorithm for exact inference. Since the exact inference algorithm is efficient enough, we use this algorithm in our segmenter at both training and testing time.

For our character-based segmenter, the local feature map $\psi(\mathbf{c}, y_{[1:i]})$ is defined on $\mathbf{c}, y_{i-1}$ and y_i, and Eq. 4 is defined as $\hat{\mathbf{y}} = \arg\max_{\mathbf{y} \in \mathcal{Y}^{|\mathbf{c}|}} \theta^\top \sum_{i=1}^{|\mathbf{c}|} \psi(\theta, y_{i-1}, y_i)$. In our character-based segmenter, we also use a Viterbi algorithm for decoding.

3.2 Learning

We adopt *Passive-Aggressive* (PA) framework (Crammer et al., 2006), a family of margin based online learning algorithms, for the parameter estimation. It is fast and easy to implement. Alg. 1 illustrates the learning procedure. The parameter vector $\mathbf{w}$ is initialized to $(0, ..., 0)$. A *PA* learner processes all the instances (t is from 1 to n) in each iteration (I). If current hypothesis ($\mathbf{w}$) fails to predict $\mathbf{x}_t$, the learner update $\mathbf{w}$ through calculating the loss l_t and the difference between $\Phi(\mathbf{x}_t, \mathbf{y}_t^*)$ and $\Phi(\mathbf{x}_t, \mathbf{y}_t)$ (line 5-7). There are three variants in the update step. We here only present the PA-II rule[1], which performs best in our experiments.

The PA algorithm utilizes a paradigm of cost-sensitive learning to resolve structured prediction. A cost function ρ is necessary to calculate the loss l_t (line 5). For every pair of labels $(\mathbf{y}^*, \mathbf{y})$, users should define a cost $\rho(\mathbf{y}^*, \mathbf{y})$ associated with predicting $\mathbf{y}^*$ when the correct label is $\mathbf{y}$. ρ should be defined differently for different purposes. There are two natural costs for segmentation: (1) sum of the number of wrong and missed word predictions and (2) sum of the number of wrongly classified characters. We tried both cost functions for both models. We find that the first one is suitable for word-based segmenter and the second one is suitable for character-based segmenter. We do not report segmentation performance with "weaker" cost in later sections. C (in line 6) is the slack variable. In our experiments, the segmentation performance is not sensitive to C. In the following experiments, we set $C = 1$.

3.3 Features

3.3.1 Word-based Segmenter

For the convenience of illustration, we denote a candidate word token w_i with a context $c_{j-1}[w_{i-1}c_j...c_k][w_i c_{k+1}...c_l]c_{l+1}$.

The character features includes,

Boundary character unigram: c_j, c_k, c_{k+1}, c_l and c_{l+1}; *Boundary character bigram*: $c_k c_{k+1}$ and $c_l c_{l+1}$.

Inside character unigram: c_s $(k+1 < s < l)$; *Inside character bigram*: $c_s c_{s+1}$ $(k+1 < s < l)$.

Length of current word.

Whether c_{k+1} and c_{k+1} are *identical*.

Combination Features: c_{k+1} and c_l,

The word token features includes,

Word Unigram: previous word w_{i-1} and current word w_i; *Word Bigram*: $w_{i-1}w_i$.

[1] See the original paper for more details.

The *identity* of w_i, if it is a *Single character word*.

Combination Features: w_{i-1} and length of w_i, w_i and length of w_{i-1}. c_{k+1} and length of w_i, c_l and length of w_i.

3.3.2 Character-based Segmenter

We use the exact same feature templates discribed in (Sun et al., 2009b). The features are divided into two types: character features and word type features. Note that the word type features are indicator functions that fire when the local character sequence matches a word unigram or bigram. Dictionaries containing word unigrams and bigrams was collected from the training data. Limited to the document length, we do not give the discription for the features. We suggest readers to refer to the original paper for details.

4 Empirical Analysis

We present a series of experiments that relate segmentation performance to a set of properties of input words. We argue that the results can be correlated to specific theoretical aspects of each model.

4.1 Experimental Setting

We used the data provided by the second SIGHAN Bakeoff (Emerson, 2005) to test the two segmentation models. The data contains four corpora from different sources: Academia Sinica Corpus (AS), City University of Hong Kong (CU), Microsoft Research Asia (MSR), and Peking University (PKU). There is no fixed standard for Chinese word segmentation. The four data sets above are annotated with different standards. To catch general properties, we do experiments on all the four data sets. Three metrics were used for evaluation: precision (P), recall (R) and balanced F-score (F) defined by 2PR/(P+R).

4.2 Baseline Performance

Tab. 1 shows the performance of our two segmenters. Numbers of iterations are respectively set to 15 and 20 for our word-based segmenter and character-based segmenter. The word-based segmenter performs slightly worse than the character-based segmenter. This is different from the experiments reported in (Zhang and Clark, 2007). We think the main reason is that we use a different learning architecture.

	Model	P(%)	R(%)	F
AS	Character	94.8	94.7	94.7
	Word	93.5	94.8	94.2
CU	Character	95.5	94.6	95.0
	Word	94.4	94.7	94.6
MSR	Character	96.1	96.5	96.3
	Word	96.0	96.3	96.1
PKU	Character	94.6	94.9	94.8
	Word	94.7	94.3	94.5

Table 1: Baseline performance.

4.3 Word Frequency Factors

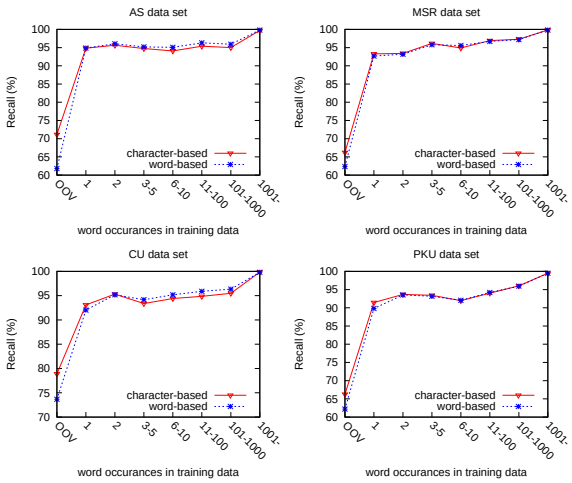

Figure 1: Segmentation recall relative to gold word frequency.

Our theoretical analysis also suggests that character-based has stronger word induction ability because it focuses more on word internal structures and thereby expresses more nonlinearity. To test the word induction ability, we present the recall relative to word frequency. If a word appears in a training data many times, the learner usually works in a "memorizing" way. On the contrary, infrequent words should be correctly recognized in a somehow "inductive" way. Fig. 1 shows the recall change relative to word frequency in each training data. Note that, the words with frequency 0 are out-of-vocabulary (OOV) words. We can clearly see that character-based model outperforms word-based model for infrequent word, especially OOV words, recognition. The "memoriz-

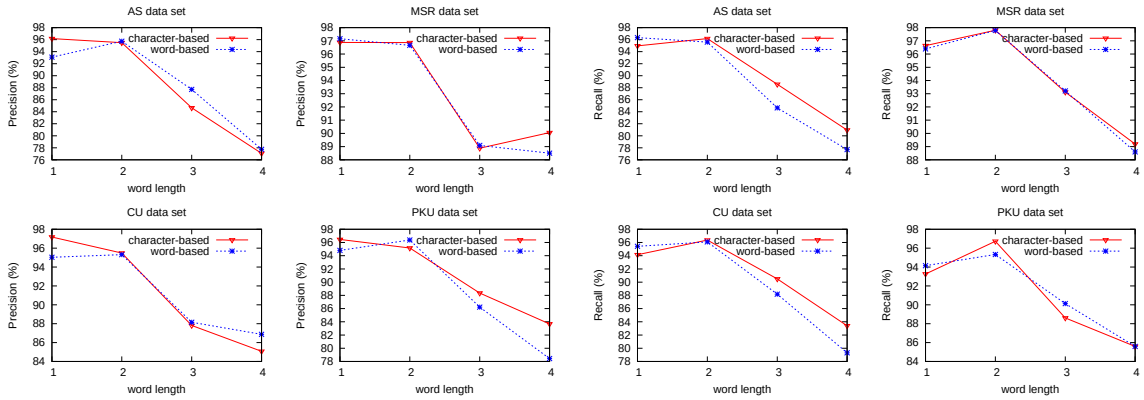

Figure 2: Segmentation precision/recall relative to gold word length in training data.

ing" ability of the two models is similar; on the AS and CU data sets, the word-based model performs slightly better. Neither model is robust enough to reliably segment unfamiliar words. The recall of OOV words is much lower than in-vocabulary words.

4.4 Length Factors

Length	AS	CU	MSR	PKU
1	61254	19116	48092	45911
2	52268	18186	49472	49861
3	6990	2682	4652	5132
4	1417	759	2711	2059
5(+)	690	193	1946	656

Table 2: Word length statistics on test sets.

Tab. 2 shows the statistics of word counts relative to word length on each test data sets. There are much less words with length more than 4. Analysis on long words may not be statistical significant, so we only present length factors on small words (length is less than 5). Fig. 2 shows the precision/recall of both segmentation models relative sentence length. We can see that word-based model tends to predict more single character words, but making more mistakes. Since about 50% word tokens are single-character words, this is one main source of error for word-segmenter. This can be explained by theoretical properties of dynamic token prediction discussed in Sec. 2.3.3. The score of a word boundary assignment in a word-based segmenter is defined like $\theta^\top \sum_{i=1}^{|\mathbf{w}|} \phi(\mathbf{c}, w_{[1:i]})$. The upper bound of this score varies with the length $|\mathbf{w}|$. If a segmentation result is with more fragments, i.e. $|\mathbf{w}|$ is larger, the upper bound of its score is higher. As a result, in many cases, a word-based segmenter prefers shorter words, which may cause errors.

4.5 Feature Factors

We would like to measure the effect of features empirically. In particular, we do not use dynamic *word token features* in our word-based segmenter, and *word type features* in our character-based segmenter as comparison with "standard" segmenters. The difference in performance can be seen as the contribution of *word features*. There are obvious drops in both cases. Though it is not a fair comparison, word token features seem more important, since the numerical decrease in the word-based experiment is larger.

	word-based		character-based	
	$-$	$+$	$-$	$+$
AS	93.1	94.2	94.1	94.7
CU	92.6	94.6	94.2	95.0
MSR	95.7	96.1	95.8	96.3
PKU	93.3	94.5	94.4	94.8

Table 3: F-score of two segmenters, with $(-)$ and without $(+)$ *word token/type features*.

4.6 Discussion

The experiments highlight the fundamental difference between word-based and character-based models, which enlighten us to design new models. The above analysis indicates that the theoretical differences cause different error distribution.

The two approaches are either based on a particular view of segmentation. Our analysis points out several drawbacks of each one. It may be helpful for both models to overcome their shortcomings. For example, one weakness of word-based model is its word induction ability which is partially caused by its neglect of internal structure of words. A word-based model may be improved by solving this problem.

5 System Combination

The error analysis also suggests that there is still space for improvement, just by combining the two existing models. Here, we introduce a classifier ensemble method for system combination.

5.1 Upper Bound of System Combination

To get an upper bound of the improvement that can be obtained by combining the strengths of each model, we have performed an oracle experiment. We think the optimal combination system should choose the right prediction when the two segmenters do not agree with each other. There is a *gold segmenter* that generates gold-standard segmentation results. In the oracle experiment, we let the three segmenters, i.e. baseline segmenters and the gold segmenter, vote. The three segmenters output three segmentation results, which are further transformed into IOB2 representation (Ramshaw and Marcus, 1995). Namely, each character has three *B* or *I* labels. We assign each character an oracle label which is chosn by at least two segmenters. When the baseline segmenters are agree with each other, the gold segmenter cannot change the segmentation whether it is right or wrong. In the situation that the two baseline segmenters disagree, the vote given by the gold segmenter will decide the right prediction. This kind of optimal performance is presented in Tab. 4. Compared these results with Tab. 1, we see a significant increase in accuracy for the four data sets. The upper bound of error reduction with system combination is over 30%.

5.2 Our Model

Bootstrap aggregating (Bagging) is a machine learning ensemble meta-algorithm to improve classification and regression models in terms of stability and classification accuracy (Breiman, 1996). It also reduces variance and helps to avoid overfitting. Given a training set D of size n, Bagging generates m new training sets D_i of size $n' \leq n$, by sampling examples from D uniformly. The m models are fitted using the above m bootstrap samples and combined by voting (for classification) or averaging the output (for regression).

We propose a Bagging model to combine multiple segmentation systems. In the training phase, given a training set D of size n, our model generates m new training sets D_i of size $63.2\% \times n$ by sampling examples from D without replacement. Namely no example will be repeated in each D_i. Each D_i is separately used to train a word-based segmenter and a character-based segmenter. Using this strategy, we can get $2m$ *weak* segmenters. Note that the sampling strategy is different from the standard one. Our experiment shows that there is no significant difference between the two sampling strategies in terms of accuracy. However, the *non-placement* strategy is more efficient. In the segmentation phase, the $2m$ models outputs $2m$ segmentation results, which are further transformed into IOB2 representation. In other words, each character has $2m$ *B* or *I* labels. The final segmentation is the voting result of these $2m$ labels. Note that since $2m$ is an even number, there may be equal number of *B* and *I* labels. In this case, our system prefer *B* to reduce error propagation.

	P(%)	R(%)	F	ER (%)
AS	96.6	96.9	96.7	37.7
CU	97.4	97.1	97.3	46.0
MSR	97.5	97.7	97.6	35.1
PKU	96.8	96.2	96.5	32.7

Table 4: Upper bound for combination. The error reduction (ER) rate is a comparison between the F-score produced by the oracle combination system and the character-based system (see Tab. 1).

5.3 Results

Fig. 4 shows the influence of m in the bagging algorithm. Because each new data set D_i in bagging algorithm is generated by a random procedure, the performance of all bagging experiments are not the same. To give a more stable evaluation, we repeat 5 experiments for each m and show the

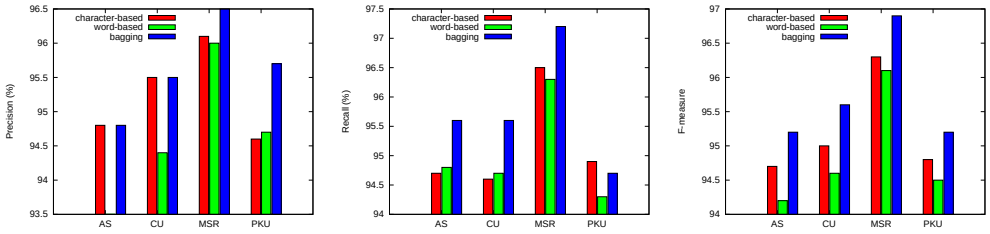

Figure 3: Precision/Recall/F-score of different models.

averaged F-score. We can see that the bagging model taking two segmentation models as basic systems consistently outperform the baseline systems and the bagging model taking either model in isolation as basic systems. An interesting phenomenon is that the bagging method can also improve word-based models. In contrast, there is no significant change in character-based models.

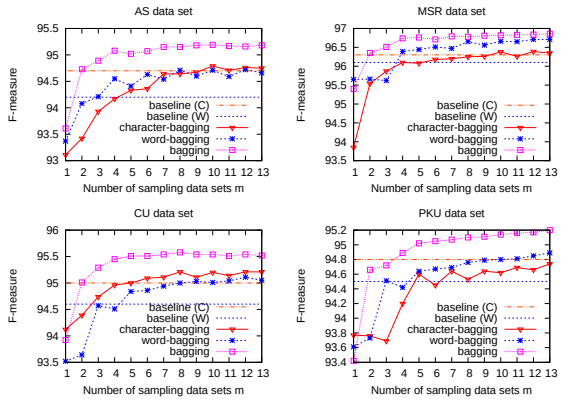

Figure 4: F-score of bagging models with different numbers of sampling data sets. *Character-bagging* means that the bagging system built on the single character-based segmenter. *Word-bagging* is named in the same way.

Fig. 3 shows the precision, recall, F-score of the two baseline systems and our final system for which we generate $m = 15$ new data sets for bagging. We can see significant improvements on the four datasets in terms of the balanced F-score. The improvement of precision and recall are not consistent. The improvement of AS and CU datasets is from the recall improvement; the improvement of PKU datasets is from the precision improvement. We think the different performance is mainly because the four datasets are annotated by using different standards.

Table 5: Segmentation performance presented in previous work and of our combination model.

Tab. 5 summarizes the performance of our final system and other systems reported in a majority of previous work. The left most column indicates the reference of previous systems that represent state-of-the-art results. The comparison of the accuracy between our integrating system and the state-of-the-art segmentation systems in the literature indicates that our combination system is competitive with the best systems, obtaining the highest reported F-scores on three data sets.

6 Conclusion

We have presented a thorough study of the difference between word-based and character-based segmentation approaches for Chinese. The theoretical and empirical analysis provides insights leading to better models. The strengths and weaknesses of the two methods are not exactly the same. To exploit their complementary strengths, we propose a Bagging model for system combination. Experiments show that the combination strategy is helpful.

Confidence Measures for Error Discrimination in an Interactive Predictive Parsing Framework[1]

Ricardo Sánchez-Sáez, Joan Andreu Sánchez and José Miguel Bened
Instituto Tecnológico de Informática
Universidad Politécnica de Valencia
{rsanchez,jandreu,jbenedi}@dsic.upv.es

Abstract

We study the use of Confidence Measures (CM) for erroneous constituent discrimination in an Interactive Predictive Parsing (IPP) framework. The IPP framework allows to build interactive tree annotation systems that can help human correctors in constructing error-free parse trees with little effort (compared to manually post-editing the trees obtained from an automatic parser). We show that CMs can help in detecting erroneous constituents more quickly through all the IPP process. We present two methods for precalculating the confidence threshold (globally and per-interaction), and observe that CMs remain highly discriminant as the IPP process advances.

1 Introduction

Within the Natural Language Processing (NLP) field, we can tell apart two different usage scenarios for automatic systems that output or work with natural language. On one hand, we have the cases in which the output of such systems is expected to be used in a vanilla fashion, that is, without validating or correcting the results produced by the system. Within this usage scheme, the most important factor of a given automatic system is the quality of the results. Although memory and computational requirements of such systems are usually taken into account, the ultimate aim of most research that relates to this scenario is to minimize the amount of error (measured with metrics like Word Error Rate, BLEU, F-Measure, etc.) present within the results that are being produced.

The second usage scenario arises when there exists the need for perfect and completely error-free results, for example, flawlessly translated sentences or correctly annotated syntactic trees. In such cases, the intervention of a human validator/corrector is unavoidable. The corrector will review and validate the results, making the suitable modifications before the system output can be employed. In these kind of tasks, the most important factor to be minimized is the human effort that has to be applied to transform the system's potentially incorrect output into validated and error-free output. Measuring user effort has an intrinsic subjectivity that makes it hard to be quantitatized. Given that the user effort is usually inversely proportional to the quality of the system output, most research about problems associated to this scenario t to minimize just the system's error rate as well.

Interactive Predictive NLP Systems

Only recently, more comparable and reproducible evaluation methods for Interactive Natural Language Systems have started to be developed, within the context of Interactive Predictive Systems (IPS). These systems formally integrate the correcting user into the loop, making him part of the system right at its theoretical framework. IPSs allow for human correctors to spare effort because the system updates its output after each individual user correction, potentially fixing several errors at each step. Interactive Predictive methods have been studied and successfully used in fields

like Handwritten Text Recognition (HTR) (Toselli et al., 2008) and Statistical Machine Translation (SMT) (Vidal et al., 2006; Barrachina et al., 2009) to ease the work of transcriptors and translators.

In IPS related research the importance of the system base error rate *per se* is diminished. Instead, the intention is to measure how well the user and the system work together. For this, formal user simulation protocols together with new objective effort evaluation metrics such as the Word Stroke Ratio (WSR) (Toselli et al., 2008) or the Key-Stroke and Mouse-Ratio (KSMR) (Barrachina et al., 2009) started to be used as a benchmark. These ratios reflect the amount of user effort (whole-word corrections in the case of WSR; keystrokes plus mouse actions in the case of KSMR) given a certain output. To get the amount of user effort into context they should be measured against the corresponding error ratios of comparable non-interactive systems: Word Error Rate for WSR and Character Error Rate for KSMR.

This dichotomy in evaluating either system performance or user effort applies to Syntactic Parsing as well. The objective of parsing is to precisely determine the syntactic structure of sentences written in one of the several languages that humans use. Very bright research has been carried out in this field, resulting in several top performing completely automatic parsers (Collins, 2003; Klein and Manning, 2003; McClosky et al., 2006; Huang, 2008; Petrov, 2010). However, these produce results that are erroneous to some extent, and as such unsuitable for some applications without a previous manual correction. There are many problems where error-free results consisting in perfectly annotated trees are needed, such as handwritten mathematical expression recognition (Yamamoto et al., 2006) or construction of large new gold treebanks (de la Clergerie et al., 2008).

When using automatic parsers as a baseline for building perfect syntactic trees, the role of the human annotator is usually to post-edit the trees and correct the errors. This manner of operating results in the typical two-step process for error correcting, in which the system first generates the whole output and then the user verifies or amends it. This paradigm is rather inefficient and uncomfortable for the human annotator. For example, a basic two-stage setup was employed in the creation of the Penn Treebank annotated corpus: a rudimentary parsing system provided a skeletal syntactic representation, which then was manually corrected by human annotators (Marcus et al., 1994). Additional works within this field have presented systems that act as a computerized aid to the user in obtaining the perfect annotation (Carter, 1997; Oepen et al., 2004; Hiroshi et al., 2005). Subjective measuring of the effort needed to obtain perfect annotations was reported in some of these works, but we feel that a more comparable metric is needed.

With the objective of reducing the user effort and making the laborious task of tree annotation easier, the authors of (Sánchez-Sáez et al., 2009a) devised an Interactive Predictive Parsing (IPP) framework. That work embeds the human corrector into the automatic parser, and allows him to interact in real time within the system. In this manner, the system can use the readily available user feedback to make predictions about the parts of the trees that have not been validated by the corrector. The authors simulated user interaction and calculated effort evaluation metrics, establishing that an IPP system results in amounts slightly above 40% of effort reduction for a manual annotator compared to a two-step system.

Confidence Measures in NLP

Annotating trees syntactically, even with the aid of automatic systems, generally requires human intervention with a high degree of specialization. This fact partially justifies the shortage in large manually annotated treebanks. Endeavors directed at easing the burden for the experts performing this task could be of great help.

One approach that can be followed in reducing user effort within an IPS is adding information that helps the user to locate the individual errors in a sentence, so he can correct them in a hastier fashion. The use of the Confidence Measure (CM) formalism goes in this direction, allowing us to assign a *probability of correctness* for individual erroneous constituents of a more complex output block of a NLP system.

In fields such as HTR, SMT or Automatic Speech Recognition (ASR), the output sentences

have a global probability (or score) that reflects the likeness of the output sentence being correct. CMs allow precision beyond the sentence level in predicting errors: they can be used to label the individual words as either correct or incorrect. Automatic systems can use CMs to help the user in identifying the erroneous parts of the output in a faster way or to aid with the amendments by suggesting replacement words that are likely to be correct.

Previous research shows that CMs have been successfully applied within the ASR (Wessel et al., 2001), HTR (Tarazón et al., 2009; Serrano et al., 2010) and SMT (Ueffing and Ney, 2007) fields. In these works, the ability of CMs in detecting erroneous constituents is assessed by the classical confidence metrics: the Confidence Error Rate (CER) and the Receiver Operating Characteristic (ROC) (Ueffing and Ney, 2007).

However, until recent advances, the use of CMs remained largely unexplored in Parsing. Assessing the correctness of the different parts of a parsing tree can be useful in improving the efficiency and usability of an IPP system, not only by *tagging* parts with low confidence for the user to review, but also by automating part of the correction process itself by presenting constituents that yield a higher confidence when an error is confirmed by the user.

CMs for parsing in the form of combinations of features calculated from n-best lists were proposed in (Benedí et al., 2007). Later on, the authors of (Sánchez-Sáez et al., 2009b) introduced a statistical method for calculating a CM for each of the constituents in a parse tree. In that work, CMs are calculated using the posterior probability of each tree constituent, approach which is similar to the word-graph based methods in the ASR and SMT fields.

In this paper, we apply Confidence Measures to the Interactive Predictive Parsing framework to asses how CMs are increasingly more accurate as the user validates subtrees within the interactive process. We prove that after each correction performed by the user, the CMs of the remaining unvalidated constituents are more helpful to detect errors.

2 Interactive Predictive Parsing

In this section we review the IPP framework (Sánchez-Sáez et al., 2009a) and its underlying operation protocol. In parsing, a syntactic tree t, attached to a string $\boldsymbol{x} = x_1 \dots x_{|x|}$ is composed by substructures called constituents. A constituent c_{ij}^A is defined by the nonterminal symbol (either a *syntactic label* or a *POS tag*) A and its span ij (the starting and ending indexes which delimit the part of the input sentence encompassed by the constituent).

Here follows a general formulation for the non-interactive syntactic parsing scenario, which will allow us to better introduce the IPP formulation. Assume that using a given parsing model G, the parser analyzes the input sentence $\boldsymbol{x}$ and produces the most probable parse tree

$$\hat{t} = \arg\max_{t \in \mathcal{T}} p_G(t|\boldsymbol{x}), \tag{1}$$

where $p_G(t|\boldsymbol{x})$ is the probability of the parse tree t given the input string $\boldsymbol{x}$ using model G, and $\mathcal{T}$ is the set of all possible parse trees for $\boldsymbol{x}$.

In the IPP framework, the manual corrector provides feedback to the system by correcting any of the constituents c_{ij}^A from $\hat{t}$. The system reacts to each of the corrections performed by the human annotator by proposing a new $\hat{t}'$ that takes into account the correction.

Within the IPP framework, the user reviews the constituents contained in the tree to assess their correctness. When the user finds an incorrect constituent he modifies it, setting the correct span and label. This action implicitly validates what it is called the *validated prefix tree* t_p.

We define the validated prefix tree to be composed by the partially corrected constituent, all of its ancestor constituents, and all constituents whose end span is lower than the start span of the corrected constituent. When the user replaces the constituent c_{ij}^A with the correct one $c_{ij}'^A$, the validated prefix tree is

$$\begin{aligned} t_p(c_{ij}'^A) = \{ & c_{mn}^B \ : m \leq i,\ n \geq j\,, \\ & \qquad d(c_{mn}^B) \leq d(c_{ij}'^A)\} \cup \\ & \{c_{pq}^D \ : q < i\ \} \end{aligned} \tag{2}$$

with $d(c^Z_{ab})$ being the depth (distance from root) of constituent c^Z_{ab}.

The validated prefix tree is parallel to the validated sentence prefix commonly used in Interactive Machine Translation or Interactive Handwritten Recognition, and is established after each user action.

This particular definition of the prefix tree determines the fact that the user is expected to review the parse tree in a preorder fashion (left-to-right depth-first). Note that this specific exploration order allows us to simulate the user interaction for the experimentation, as we will explain below. Also note that other types of prefixes could be defined, allowing for different tree review orders.

Within the IPP formulation, when a constituent correction is performed, the prefix tree $t_p(c'^A_{ij})$ is validated and a new tree $\hat{t}'$ that takes into account the prefix is proposed. Incorporating this new evidence into expression (1) yields the following equation

$$\hat{t}' = \arg\max_{t \in \mathcal{T}} p_G(t|\boldsymbol{x}, t_p(c'^A_{ij})). \quad (3)$$

Given the properties of Probabilistic Context-Free Grammars (PCFG) the only subtree that effectively needs to be recalculated is the one starting from the parent of the corrected constituent. This way, just the descendants of the newly introduced constituent, as well as its right hand siblings (along with their descendants) are calculated.

2.1 User Interaction Operation

The IPP formulation allows for a very straightforward operation protocol that is performed by the manual corrector, in which he validates or corrects the successive output parse trees:

1. The IPP system proposes a full parse tree t for the input sentence.

2. Then, the user finds the first incorrect constituent exploring the tree in a certain ordered manner (preorder in our case, given by the tree prefix definition) and amends it, by modifying its span and/or label (implicitly validating the prefix tree t_p).

3. The IPP system produces the most probable tree that is compatible with the validated prefix tree t_p as shown in expression (3).

4. These steps are iterated until a final, perfect parse tree is produced by the system and validated by the user.

It is worth noting that within this protocol, constituents can be automatically deleted or inserted at the end of any subtree in the syntactic structure by adequately modifying the span of the left-neighbouring constituent.

The IPP interaction process is similar to the ones already established in HTR and SMT. In these fields, the user reads the output sentence from left to right. When the user finds and corrects an erroneous word, he is implicitly validating the prefix sentence up to that word. The remaining suffix sentence is recalculated by the system taking into account the validated prefix sentence.

Fig. 1 shows an example that intends to clarify the Interactive Predictive process. First, the system provides a tentative parse tree (Fig. 1.b). Then the user, which has the correct reference tree (Fig. 1.a) in mind, notices that it has two wrong constituents (c^X_{23} and c^Z_{44}) (Fig. 1.c), and chooses to replace c^X_{23} by c^B_{22} (Fig. 1.d). Here, c^B_{22} corresponds to c'^A_{ij} of expression (3). As the user does this correction, the system automatically validates the prefix (dashed line in Fig. 1.d, $t_p(c'^A_{ij})$ of expression (2)). The system also invalidates the subtrees outside the prefix (dotted line line in Fig. 1.d). Finally, the system automatically predicts a new subtree (Fig. 1.e). Notice how c^Z_{34} changes its span and c^D_{44} is introduced which provides the correct reference parse.

For further exemplification, Sánchez-Sáez et al. (2010) demonstrate an IPP based annotation tool that can be accessed at `http://cat.iti.upv.es/ipp/`.

Within the IPP scenario, the user has to manually review all the system output and correct or validate it, which is still a considerable amount of effort. CMs can ease this work by helping to spot the erroneous constituents.

Figure 1: Synthetic example of user interaction with the IPP system.

3 Confidence Measures

Probabilistic calculation of Confidence Measures (Sánchez-Sáez et al., 2009b) for all tree constituents can be introduced within the IPP process.

The CM of each constituent is its posterior probability, which can be considered as a measure of the degree to which the constituent is believed to be correct for a given input sentence $\boldsymbol{x}$. This is formulated as follows

$$p_G(c_{ij}^A|\boldsymbol{x}) = \frac{p_G(c_{ij}^A, \boldsymbol{x})}{p_G(\boldsymbol{x})} = \frac{\sum_{t' \in \mathcal{T};\, c_{ij}'^A \in t'} \delta(c_{ij}^A, c_{ij}'^A)\; p_G(t'|\boldsymbol{x})}{p_G(\boldsymbol{x})} \tag{4}$$

with $\delta()$ being the Kronecker delta function. Numerator in expression (4) stands for the probability of all parse trees for $\boldsymbol{x}$ that contain the constituent c_{ij}^A (see Fig. 2).

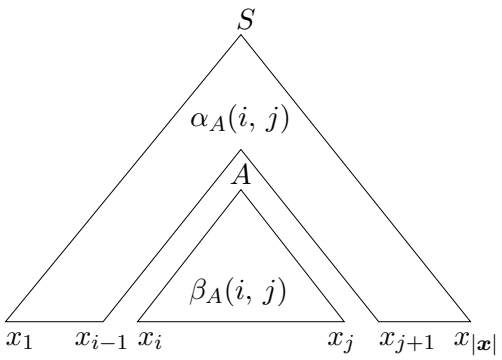

Figure 2: The product of the inside and outside probabilities for each constituent comprises the upper part of expression (5)

The posterior probability is computed with the inside β and outside α probabilities (Baker, 1979)

$$\mathcal{C}(t_{ij}^A) = p_G(c_{ij}^A|\boldsymbol{x}) = \frac{p_G(c_{ij}^A, \boldsymbol{x})}{p_G(\boldsymbol{x})} = \frac{\beta_A(i,\, j)\; \alpha_A(i,\, j)}{\beta_S(1,\, |\boldsymbol{x}|)}\ . \tag{5}$$

It should be clear that the calculation of confidence measures reviewed here is generalizable for any problem that employs PCFGs, and not just NLP tasks. In the experiments presented in the following section we show that CMs are increasingly discriminant when used within the IPP framework to detect erroneous constituents.

4 Experiments

Evaluation of the quality of CMs within the IPP framework is done in a completely automatic fashion by simulating user interaction. Section 4.1 introduces the evaluation protocol and metrics measuring CM quality (i.e., their ability to detect incorrect constituents). The experimentation framework and the results are discussed in section 4.2.

4.1 Evaluation Methods

4.1.1 IPP Evaluation

A good measure of the performance of an Interactive Predictive System is the amount of effort saved by the users of such a system. It is subjective and expensive to test an IPS with real users, so these systems are usually evaluated using automatically calculated metrics that assess the amount of effort saved by the user.

As already mentioned, the objective of an IPP based system is to be employed by annotators to construct correct syntactic trees with less effort. Evaluation of an IPP system was previously done by comparing the IPP usage effort (the number of corrections using the IPP system) against the estimated effort required to manually post-edit the trees after obtaining them with a traditional automatic parsing system (the amount of incorrect constituents) (Sánchez-Sáez et al., 2009a).

In the case of IPP, the gold reference trees are used to simulate system interaction by a human corrector and provide a comparable benchmark. This automatic evaluation protocol is similar to the one presented in section 2.1:

1. The IPP system proposes a full parse tree t for the input sentence.

2. The user simulation subsystem finds the first incorrect constituent by exploring the tree in the order defined by the prefix tree definition (preorder) and comparing it with the *reference*. When the first erroneous constituent is found, it is amended by being replaced in the output tree by the correct one, operation which implicitly validates the prefix tree t_p.

3. The IPP system produces the most probable tree that is compatible with the validated prefix tree t_p.

4. These steps are iterated until a final, perfect parse tree is produced by the IPP system and validated against the *reference* by the user simulation subsystem.

In this work, metrics assessing the quality of CM are introduced within this automatic protocol. We calculate and report them after each of the iterations in the IPP process.

4.1.2 Confidence Measure Evaluation Metrics

The CM of each tree constituent, computed as shown in expression (4) can be seen as its probability of being correct. Once all CM are calculated, a confidence threshold $\tau \in [0, 1]$ can be chosen. Constituents are then marked using τ: the ones with a confidence above this threshold are marked as correct, and the rest as incorrect. Comparing the confidence marks in the output tree with the reference, we obtain the *false rejection* $N_f(\tau) \in [0, N_c]$ (number of correct constituents in the output tree wrongly marked as incorrect by their CM) and the *true rejection* $N_t(\tau) \in [0, N_i]$ (number of incorrect constituents in the output tree that are indeed detected as incorrect by their confidence).

The amount of correct and incorrect constituents in each tree is N_c and N_i respectively. In the ideal case of perfectly error discriminant CM, using the best threshold would yield $N_f(\tau) = 0$ and $N_t(\tau) = N_i$.

A evaluation metric that assess the ability of CMs in telling apart correct constituents from incorrect ones is the *Confidence Error Rate (CER)*:

$$CER(\tau) = \frac{N_f(\tau) + (N_i - N_t(\tau))}{N_c + N_i}. \quad (6)$$

The CER is the number of errors incurred by the CMs divided by the total number of constituents.

The CER can be compared with the Absolute Constituent Error Rate (ACER), which is the CER obtained assuming that all constituents are marked as correct (the only possible assumption when CM are not available):

$$ACER = CER(0) = \frac{N_i}{N_c + N_i}. \quad (7)$$

4.2 Experimental Framework

Our experiments were carried out over the Wall Street Journal Penn Treebank (PTB) manually annotated corpus. Three sets were defined over the PTB: train (sections 2 to 21), test (section 23), and development (the first 346 sentences of section 24). Before carrying out experimentation, the *NoEmpties* transformation was applied to all sets (Klein and Manning, 2001).

We implemented the CYK-Viterbi parsing algorithm as the parse engine within the IPP framework. This algorithm uses grammars in the Chomsky Normal Form (CNF) so we employed the open source Natural Language Toolkit[2] (NLTK) to obtain several right-factored binary

Figure 4: CER results over IPP system interaction. Threshold optimized for each step of the interactive process.

grammars with different markovization parameters from the training set (Klein and Manning, 2003).

The purpose of our experimentation is to determine if CMs can successfully discriminate erroneous constituents from correct ones within an IPP process, that is, if they help the user to find errors in a hastier manner. For this we need to assess if there exists discriminant information in the CMs corresponding to the constituents of the unvalidated part of the successive IPP-proposed trees.

With this objective in mind, we introduced a CM calculation step after each user interaction within the IPP process. CMs for all constituents in each tree were obtained as described in section 3. After each simulated interaction, we also calculated the ACER and CER over all the syntactic constituents of the whole test set.

Each IPP user interaction yields a parse tree which can be seen as the concatenation of two parts: the validated prefix tree (which is known to be correct because the user, or the user simulation subsystem in this case, has already reviewed it) and a new suffix tree which is calculated by the IPP system based on the validated prefix, as shown in section 2.

The fact that the validated prefix is already known to be correct is taken into account by the CM calculation process, and the confidence of the constituents in the prefix tree is automatically set to their maximum score, equal to 1. This fact causes that the CMs become more discriminant after each interaction, because a larger part of the

tree (the prefix) has a completely correct confidence. The key point here is to measure if this increasingly reduced CER (CM error rate) maintains its advantage over the also increasingly reduced ACER (absolute constituent error rate without taking CMs into account) which would mean that the CMs retain their discriminant power and can be useful as an aid for a human annotator using an IPP system.

Two batches of experiments were performed and, in each of them, two different markovizations of the vanilla PCFG were tested as the parsing model.

In the first battery of experiments, the confidence threshold τ was optimized over the development set before starting the IPP process, remaining the same during the user interaction. The results can be seen in Fig. 3, which shows the obtained baseline ACER and the CER (the confidence assessing metric) for the test set after each user interaction. We see how CMs retain all of their error detection capabilities during the IPP process: in the h0v1 PCFG they are able to discern about 25% of incorrect constituents at most stages of the IPP process, with a slight bump up to 27% after about 7 user interactions; for the h0v2 PCFG they are able to detect about 18% of incorrect constituents at the first interactions, but go up to detect 27% of errors after about 7 or more interactions.

In the second experimental setup, a different threshold for each interaction step was calculated by performing the IPP user simulation process over the development set and optimizing the threshold value. The results can be seen in Fig. 4. We observe improvements in the discriminant ability of confidence values after 8 user interactions, with them being capable to detect more errors towards the end of each IPP session: about 34% of errors for h0v1, and 49% of them for h0v2.

The calculated thresholds have also been plotted in the aforementioned figures. For the per-interaction threshold experimentation, we can see how the threshold gets fine-tuned as the IPP process advances. The lower threshold values for the last interactions were expected due to the fact that more constituents have been validated and have the maximum confidence. This method for precalculating one specific threshold for each of the iterations could be useful when incorporating CM to a real IPP based annotator.

5 Conclusions and Future Work

We have proved that using Confidence Measures can be used to discriminate incorrect constituents from correct ones over an Interactive Predictive Parsing process. We have show two methods for calculating the threshold used to mark constituents as correct/incorrect, showing the advantage of precalculating a specific threshold for each of the interaction steps.

Immediate future work involves implementing CMs as a visual aid in a real IPP system like the one presented in (Sánchez-Sáez et al., 2010). Through he use of CMs, all constituents in the successive trees could be color-coded according to their correctness confidence, so the user could focus and make corrections faster.

Future research paths can deal with applying CMs to improve the output of completely automatic parsers, for example, using them as a component of an n-best re-ranking system.

Additionally, the IPP framework is also suitable for studying and applying training algorithms within the Active Learning and Adaptative/Online Parsing paradigms. This kind of systems could improve their models at operating time, by incorporating new ground truth data as it is provided by the user.

Abstract

This paper presents a novel method for acquiring a set of query patterns to retrieve documents containing important information about an entity. Given an existing Wikipedia category that contains the target entity, we extract and select a small set of query patterns by presuming that formulating search queries with these patterns optimizes the overall precision and coverage of the returned Web information. We model this optimization problem as a weighted maximum satisfiability (weighted Max-SAT) problem. The experimental results demonstrate that the proposed method outperforms other methods based on statistical measures such as frequency and point-wise mutual information (PMI), which are widely used in relation extraction.

1 Introduction

Wikipedia[1] is useful for obtaining comprehensive information of entities and concepts. However, even with 3.3 million English articles, Wikipedia does not necessarily include articles about an entity and concept of interest to a user. The ultimate goal of this study is to generate articles about an entity of a specified category from the Web by using Wikipedia articles in the same entity category as *exemplars*.

This study follows previous work of the other authors on query-biased/focused summarization (Tombros and Sanderson, 1998; Berger and Mittal, 2000) for modeling the target article generation process. In that model, when a user inputs an entity of interest, Web pages are retrieved that describe the entity by issuing queries to an information retrieval system. Using the retrieved pages as an information source, an article (summary) can be produced specialized for the target entity. From the application point of view, the article should include the concepts that best describe the target entity. In addition, articles concerning the entities of a category should cover concepts that are typical of the category. For example, an article about an actor is expected to mention his nationality, date of birth, movie credits, awards, etc.

A great number of researchers have addressed the problem of query-focused summarization (Carbonell and Goldstein, 1998; White et al., 2003; Dang, 2005; Daumé and Marcu, 2006; Varadarajan and Hristidis, 2006; Fuentes et al., 2007; Gupta et al., 2007; Wang et al., 2007; Kanungo et al., 2009). However, these studies assume that a document collection is provided for the summarization systems. In other words, collecting source documents that include important concepts for the target entity is not in the scope of these studies. For example, queries such as "(actor) was born in," "(actor) born on," "(actor) plays," and "(actor) won" may be more suitable than the simple query "(actor)" for obtaining concepts concerning the actor.

Source documents can be collected by a similar idea in relation extraction, which extracts entities having specific relations with the target entity (Hearst, 1992; Brin, 1999; Agichtein and Gravano, 2000; Turney, 2001; Pantel and Pennac-

[1] http://en.wikipedia.org/

Coling 2008: Poster Volume, pages 1229–1237,
Beijing, August 2010

chiotti, 2006; Blohm et al., 2007). These studies typically use statistical measures, such as frequency and point-wise mutual information (PMI), to assess the scores of the query patterns. However, these studies cannot eliminate the redundancy of concepts retrieved by a query set because they are designed to extract entities for each relation independently. For example, the query "(actor) born on" would not be necessary if the query "(actor) was born in" could gather documents referring to both the actor's nationality and date of birth.

In this paper, we propose a novel method for acquiring a set of high-quality query patterns that can gather source documents referring to important concepts about a specified entity. Given a category in which the entity is expected to be included, we use existing Wikipedia articles in this category to extract query patterns so that, when used together with the entity, they can retrieve important concepts related to the entity. We then select a small subset of query patterns that maximize the coverage and precision of the query result by modeling the query selection task as a weighted maximum satisfiability (weighted Max-SAT) problem.

2 Proposed method

First, let us define the terminology used in this paper. An *entity* is a topic for which we need to obtain an article (summary). Note that this definition is different from that used in other studies (e.g., named entity recognition). A *concept* is a noun phrase that has a specific relation to an entity. A *query pattern* is a lexical pattern that contains a slot filled by an entity. Used with an entity, a query pattern instantiates a query that collects related concepts. For example, "X was born in" is a query pattern in which X is a slot. When replacing X with an entity (e.g., "Dustin Hoffman"), the query pattern instantiates a query that may return the birthplace.

The goal of this study is, for a given entity category (e.g., *American actor*), to acquire a set of query patterns (*template*) for collecting related concepts from the Web. We learn the template by using Wikipedia articles of the category as supervision data. The method consists of three steps.

1. **Triplet extraction** identifies, for each Wikipedia article, entity mentions, concepts, and phrases that form a bridge between the entity mentions and concepts. In the context of learning query patterns from Wikipedia, we assume that a Wikipedia article is written for an entity. By identifying entity mentions and concepts in the article, we obtain bridging phrases between entity mentions and concepts as candidates for query patterns.

2. **Pattern assessment** verifies whether each candidate query pattern can actually retrieve concepts from the Web. This step issues queries of the form "(entity) (pattern)" to an information retrieval system, analyzes the retrieved Web pages, and examines whether each concept is found in the same sentence as the query expressions.

3. **Pattern selection** obtains a template by choosing a small subset of patterns such that the retrieved Web pages contain as many kinds of concepts as possible. We also eliminate query patterns that can retrieve descriptions other than concepts. We formalize this step as a weighted Max-SAT problem.

2.1 Triplet extraction

We first analyze Wikipedia articles to extract triplets of entities, query patterns, and concepts. Because a Wikipedia article usually describes a single entity, we identify the entity from the title of the article. We then search for occurrences of the entity in the body of the article. However, we might need to resolve coreference expressions because the entity might be described by a number of surface variations. For example, the Wikipedia article titled "Dustin Hoffman" might refer to the entity using "he" and "Hoffman" as well as "Dustin Hoffman"; the entity "Microsoft Corporation" might be described by "Microsoft" and "the company" in the article.

In general, coreference resolution is a non-trivial NLP task. Fortunately, Wikipedia articles are written for target entities. Therefore, we replace the occurrences of the following expressions in the body with the entity name:

Hoffman *was born in* [Los Angeles], [California], the second and youngest son of Lillian and Harry Hoffman, a [Russian]-born father who worked as a prop supervisor/set decorator at [Columbia Pictures] before becoming a furniture salesman. Hoffman *is from a* [Jewish] family, although he did not have a religious upbringing. He *graduated from* [Los Angeles High School] in 1955. He *enrolled at* [Santa Monica College] with the intention of studying medicine but left after a year to join the [Pasadena Playhouse].

Figure 1: A snippet of a Wikipedia article about "Dustin Hoffman."

1. Any token (split by spaces) that appears in the title of the article.

2. The phrase that appears the most frequently with the four anaphoric expressions "he," "she," "they," and "the *noun*."

The first rule deals with anaphoric expression caused by an ellipsis, e.g., "Dustin Hoffman" is referred to by "Dustin" and "Hoffman." The second rule resolves the coreference expressions caused by pronouns and definite noun phrases.

After detecting the entity mentions, we identify the concepts concerning the entity in the article. In this study, we employ WikiLink texts (anchor texts linked with other Wikipedia articles) that co-occur with the entity mentions in the same sentences. Finally, we identify a candidate of a query pattern as a phrase that satisfies the following conditions:

1. It consists of alphanumeric letters and hyphens only.

2. Its length is no longer than 6 tokens.

3. It appears between an entity mention and a concept in a sentence.

Figure 1 shows a snippet of the Wikipedia article about "Dustin Hoffman." The underlined expressions are identified as entity mentions; the text in square brackets represents a WikiLink text. Because all WikiLink texts appear in sentences with the entity mentions, we identify all expressions with square brackets as concepts. Italic texts are candidates of the query patterns.

Finally, we extract triplets of the form $\langle E_k, P_i, C_j \rangle$ from the Wikipedia article, where E_k ($k \in \{1,...,L\}$) denotes the entity, P_i ($i \in \{1,...,M\}$) denotes a query pattern, and C_j ($j \in \{1,...,N\}$) denotes a concept. For each concept C_j found in the Wikipedia article, we build a triplet by setting E_k as the entity of the article and P_j as the query pattern that precedes the concept C_j. Repeating this process for L Wikipedia articles in the same category, we obtain triplets with M query patterns and N concepts.

Table 1: Triplets extracted from Figure 1.

Entity	Query pattern	concept
Dustin Hoffman	was born in	Los Angeles
Dustin Hoffman	was born in	California
Dustin Hoffman	was born in	Russian
Dustin Hoffman	was born in	Columbia Pictures
Dustin Hoffman	is from a	Jewish
Dustin Hoffman	graduated from	Los Angeles High School
Dustin Hoffman	enrolled at	Santa Monica College
Dustin Hoffman	enrolled at	Pasadena Playhouse

Table 1 shows the eight triplets obtained from Figure 1. Here, it might not be clear whether the indefinite article *a* is necessary in the pattern *is from a*. Although we do not address this issue directly in this paper, we determine the popularity and usefulness of the pattern by analyzing Wikipedia articles in the same category. Similarly, some concepts (e.g., *Russian*) are not so important for the entity. It may be better to filter out the concept, but we expect that errors in concept identification are negligible when selecting the query patterns.

2.2 Pattern assessment

In this step, we verify whether each pattern P_i can actually retrieve concepts of the entities from the Web. More specifically, for every combination of an entity mention E_k and a pattern P_i, we issue a query "E_k P_i" (e.g., *"Dustin Hoffman graduated from"*) to Yahoo! Search BOSS[2]. We download the top 10 Web pages retrieved by each query and examine whether any of the concepts, C_j, appear in the same sentence as the query phrase. To describe the capability of the patterns for retrieving concepts, we introduce an $m \times n$ matrix called R,

$$R_{ij} = \begin{cases} 1 & \text{(pattern } P_i \text{ can retrieve concept } C_j\text{)} \\ 0 & \text{(otherwise)} \end{cases}.$$

[2]http://developer.yahoo.com/search/boss/

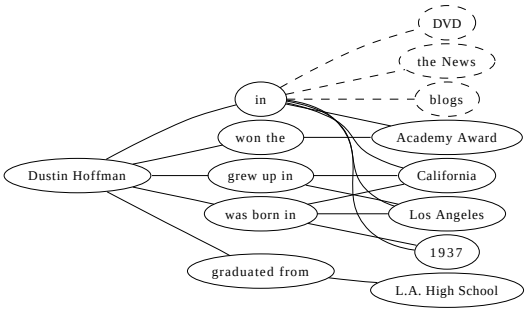

Figure 2: Patterns – collected concepts graph.

Figure 2 illustrates a bipartite graph between the patterns and concepts with R as the biadjacency matrix. Here, nodes with dotted lines are expressions other than concepts but are retrieved by the patterns. For example, the pattern "in" can retrieve four concepts *Academy Award*, *California*, *Los Angeles*, and *1937*, but it also retrieves non-concepts such as *DVD*, *the News*, and *blogs*. In other words, this pattern can retrieve sentences with a number of concepts, but it also gathers unnecessary sentences. Thus, we define the error rate of pattern P_i

$$\varepsilon_i = 1 - \frac{(\text{\# sentences with concepts})}{(\text{\# total sentences retrieved by } P_i)}.$$

2.3 Pattern selection

Based on the pattern assessment in Section 2.2, this step chooses a small set of query patterns as the template. Let $w_1, ..., w_m$ denote m Boolean (0–1 integer) variables, each of which (w_i) indicates whether the corresponding query pattern P_i is selected (1) or unselected (0). Choosing a subset of query patterns is equivalent to assigning Boolean values to the variables $w_1, ..., w_m$. The number of selected patterns is $\sum_{i=1}^{m} w_i$.

Given an assignment of variables $w_1, ..., w_m$ for the query patterns, we can examine whether the concept C_j is retrieved from the patterns by using the logical sum,

$$c_j = w_1 R_{1j} \vee w_2 R_{2j} \vee ... \vee w_m R_{mj} = \bigvee_{i=1}^{m} w_i R_{ij}.$$

Here, c_j is a Boolean (0–1) variable indicating that concept C_j is retrieved (1) or not retrieved (0) by the template. In Figure 2, if either the "in" or "was born in" pattern is selected, we can retrieve the concept "*1937*" from the Web search.

To choose a set of query patterns, we maximize the number of concept coverages $\sum_{j=1}^{n} c_j$ as well as minimize the number of patterns selected $\sum_{i=1}^{m} w_i$ and the total of the error rates of the selected patterns $\sum_{i=1}^{m} \varepsilon_i w_i$. This is achieved by solving the following problem.

Problem 1.

$$\begin{aligned} &\textit{Maximize} \sum_{j=1}^{n} c_j - \alpha \sum_{i=1}^{m} w_i - \beta \sum_{i=1}^{m} \varepsilon_i w_i, \\ &\textit{subject to: } c_1 = \bigvee_{i=1}^{m} w_i R_{i1} \\ &\qquad \cdots \\ &\qquad c_n = \bigvee_{i=1}^{m} w_i R_{in}, \\ &\qquad w_i \in \{0,1\}. \end{aligned}$$

Here, α and β are the parameters for controlling the preference of a smaller number of patterns (α) and the preference of accurate patterns (β).

To solve this problem, we rewrite it as a weighted maximize satisfiability (weighted Max-SAT) problem.

Problem 2.

$$\begin{aligned} &\textit{Maximize} \sum_{k=1}^{n+m} \lambda_k x_k \\ &\textit{Subject to: } x_1 = \bigvee_{i=1}^{m} w_i R_{i1} \quad (\lambda_1 = 1) \\ &\qquad \cdots \quad (\ldots) \\ &\qquad x_n = \bigvee_{i=1}^{m} w_i R_{in} \quad (\lambda_n = 1) \\ &\qquad x_{n+1} = \neg w_1 \quad (\lambda_{n+1} = \alpha + \beta\varepsilon_1) \\ &\qquad \cdots \quad (\ldots) \\ &\qquad x_{n+m} = \neg w_m \quad (\lambda_{n+m} = \alpha + \beta\varepsilon_m) \\ &\qquad w_i \in \{0,1\} \end{aligned}$$

Instead of subtracting the penalty terms from the objective value, we give bonus weights ($\alpha + \beta\varepsilon_i$) if the pattern P_i is not selected. This is achieved by introducing additional clauses x_{n+1}, ..., x_{n+m} that are satisfied by $\neg w_1$, ..., $\neg w_m$, respectively. Therefore, the optimization process tries to find a compromise between selecting patterns (clauses x_1, ..., x_n) and rejecting patterns (clauses x_{n+1}, ..., x_{n+m}). Although the complexity of the weighted Max-SAT problem is NP-hard, we use MiniMaxSAT (Heras et al., 2008) to solve the problem.

3 Evaluation

To verify the performance of the proposed method, we compare the precision, coverage, and F'-score of the information retrieval process by using the template obtained by the proposed method with that by three other baseline methods.

3.1 Experimental Settings

3.1.1 Data

We use articles of five categories in Wikipedia as the data for evaluation: *American actors*, *Genetic disorders*, *American tennis players*, *Software companies*, and *Operas*. Among these categories, the first two (*American actors*, *Genetic disorders*) have been commonly used as evaluation data in previous research on text summarization (Sauper and Barzilay, 2009). The other three (*American tennis players*, *Software companies*, *Operas*) are categories about three distinct topics (*sport*, *business*, *entertainment*).Table 2 shows information about these categories.

We divide the article set of a given category into six subsets. We use one subset as the *development set* for tuning the parameters α and β in the proposed method. The remaining five subsets are the *training set* and the *test set*, which are used for the 5-fold cross-validation. We create the template by using the training set and evaluate it with the test set. For evaluation of the baseline methods, we use only the *training set* and the *test set*.

3.1.2 Baselines

Random Selection

The baseline "*Random Selection*" randomly selects 10 query patterns from the candidate query patterns as the template for the category.

Frequency

In this baseline method, we sort the query patterns for each category in the order of frequency of occurrences in the category. We then select the top 10 frequent query patterns as the template for the category.

PMI-Web

The baseline *PMI-Web* chooses the query patterns that are the most "reliable." Following *KnowItNow* (Cafarella et al., 2005) and *Espresso* (Pantel and Pennacchiotti, 2006), the "reliability" of a pattern is defined by using the strength of the association of the pattern with the entities and concepts co-occurring with the pattern. In *KnowItNow* and *Espresso*, PMI (point-wise mutual information) is used to measure the strength of this association. PMI is estimated with the Web search hit counts as follows:

$$pmi(E_k, P_i, C_j) \approx \frac{\mathrm{hit}(E_k, P_i, C_j)}{\mathrm{hit}(E_k, P_i) \cdot \mathrm{hit}(C_j)},$$

where $\mathrm{hit}(E_k P_i)$, $\mathrm{hit}(C_j)$ are the Web search hit counts for the query "E_k, P_i," "C_j"(E_k, P_i, C_j is *entity, pattern, concept*), and $\mathrm{hit}(E_k, P_i, C_j)$ is the hit count for the query "E_k P_i" and "C_j." The reliability score of the query pattern is defined as the following formula:

$$Score(P_i) = \frac{1}{|S|} \sum_{(E_k, C_j) \in S} pmi(E_k, P_i, C_j),$$

where S is the set of pairs of *entity* E_k and *concept* C_j co-occurring with the *pattern* P_i in a sentence. The method *PMI-Web* chooses the top 10 patterns that have the highest reliability scores.

3.1.3 Experiments

We use each method to generate a template and retrieve information of the entities by using the

Table 2: The five categories used for evaluation.

Category	#Articles	#Patterns	#Concepts
American actors	1864	2951	10495
American tennis players	444	1039	2826
Software companies	1890	1992	5087
Genetic disorders	657	1087	2400
Operas	1425	2125	6365

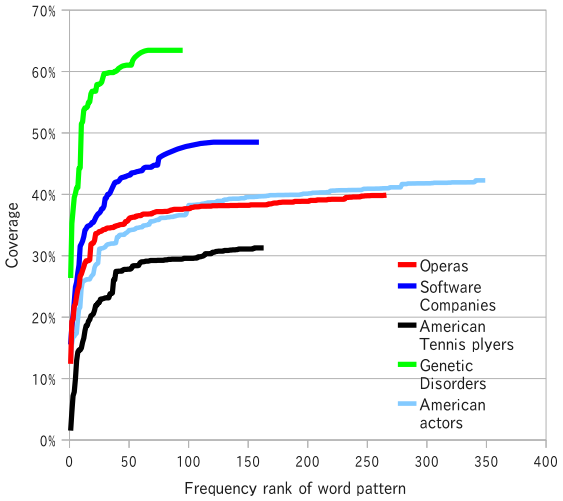

Figure 3: Relation between coverage and query pattern frequency.

query patterns in the template. We remove the query patterns occurring only once in each category from the candidate patterns because these patterns may be too entity-specific or noisy.

Figure 3 shows the coverage of the concept retrieval process when we use the top N frequently appearing patterns in the candidate pattern set. We observe that the coverage does not reach 100% even if we use all the query patterns. This is because some concepts cannot be retrieved by any query pattern. Moreover, we consider a Wikilink as a concept, even though some Wikilink texts do not actually represent a concept.

We use query patterns that occur no less than 3 times (for American actors, American tennis players, Software companies, and Operas) or twice (for Genetic disorders) in the corresponding Wikipedia articles so that the query patterns reach 95% of the upper bound of the coverage. This small subset comprises the final candidate patterns. For the candidate patterns, we use the proposed method (solving the weighted Max-SAT problem) and the three baselines described above to choose N query patterns.

The precision, coverage and quasi F-score (F'-score) of the information retrieval process by each template are defined as follows:

$$\text{precision} = \frac{\text{freq}(\text{E}_\text{k}, \text{P}_\text{i}, \text{C}_\text{j})}{\text{freq}(\text{E}_\text{k}, \text{P}_\text{i})}, \text{coverage} = \frac{\text{C}_\text{collected}}{\text{C}_\text{total}},$$

$$F' = \frac{2 \cdot \text{precision} \cdot \text{coverage}}{\text{precision} + \text{coverage}},$$

where $\text{freq}(E_k, P_i)$ is the frequency of the phrase "E_k P_i" in the retrieved documents, $\text{freq}(E_k, P_i, C_j)$ is the frequency of co-occurrence of the phrase "E_k P_i" and "C_j" in the sentences. C_total is the total number of distinct concepts in the data set, and $\text{C}_\text{collected}$ is the number of distinct concepts which can be collected by the template.

3.2 Result

Table 5 shows the average of the precision, coverage and F' scores of the five categories when we choose 10 query patterns (N=10). The proposed method obtains the highest score of all methods. Moreover, the proposed method outperforms the baselines not only for the average of all categories, but also for each category. This result indicates that the proposed method is able to choose query patterns that precisely and comprehensively collect the target concepts.

Table 5: Performance of the templates produced by the proposed method and the three baselines (N=10).

Method	Precision	Coverage	F' score
Random	16.56	11.40	13.19
Frequency	21.43	29.29	24.40
PMI-Web	22.55	22.08	21.42
Proposed	**27.34**	**30.77**	**27.95**

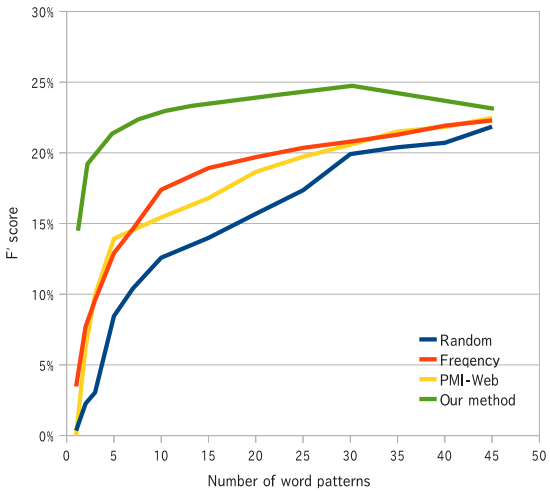

Figure 4: Number of query patterns (N) in template and F' score in *American tennis players*.

Table 3 shows some example templates produced by the proposed method. In this table, the number in the parentheses next to a pattern is the frequency rank of the pattern. We observe that the proposed method generates templates with two types of query patterns: *generic patterns* and *specific patterns*. Generic patterns such as "is a" and "is an" are patterns that can appear in every category. These patterns cover various kinds of concepts (high coverage), but may retrieve sentences that do not describe any concept (low precision). Specific patterns, such as "has a star on the" and "was nominated for a," can retrieve concepts that have specific relations with the entity. Therefore, queries with specific patterns retrieve a small number of concepts with high precision. The proposed method chooses query patterns in both of these types to achieve both high precision and high coverage. Therefore, it is able to retrieve

Table 3: Templates generated by the proposed method (N=10): (n) is the frequency rank.

Category	Template
American actors	"is an"(1), "was an"(2), "was a"(7), "graduated from"(9), "died of"(18), "has a star on the"(24), "was nominated for a"(28), "was married to"(47), "was born on"(56), "has appeared in"(92)
American tennis players	"defeated"(3), "beat"(5), "is a former"(12), "is an"(16), "graduated from"(17), "reached the"(18), "played"(24), "of"(30), "was"(38), "won"
Software companies	"is a"(1), "acquired"(3), "is"(9), "is headquartered in"(11), "was founded by"(15), "has offices in"(22), "was"(29), "include"(36), "introduced"(41), "is an international"(41)
Genetic disorders	"is a"(1), "is an"(2), "has an autosomal recessive pattern of"(3), "has an autosomal dominant pattern of"(9), "is named after"(11), "is a form of"(13), "is caused by"(16), "include"(18), "appears to be inherited in an"(41), "is considered an"(41)
Operas	"is an"(1), "is a"(2), "is an opera by"(17), "was"(18), "is a comic"(20), "premiered at the"(25), "was first performed at"(31), "is the second"(38), "opera"(46), "libretto by"(62)

Table 4: Templates generated by different methods for the *Opera* category (N= 10).

Method	Template	Pre.	Cov.	F'
Random	"was an," "of the complete operas of the," "was on," "was commissioned by," "by," "is," "popular," "for the," "New York," "the same name by"	15.79	8.12	10.73
Frequency	"is an," "is a," "the," "by," "of the," "in," "and," "of," "was a," "a"	16.83	27.12	20.77
PMI-Web	"was created by," "is a three act," "premiered at the," "was an," "is an," "is an opera composed by," "is a Hindi language," "premiered on" "was commissioned by," "was first performed at the,"	30.25	18.29	22.80
Proposed	"is an," "is a," "is an opera by," "was," "is a comic," "premiered at the," "was first performed at," "is the second," "opera," "libretto by"	31.18	27.28	29.10

various types of concepts. This implies that the method achieves high coverage even for concepts that cannot be retrieved by generic patterns.

The baseline *Frequency* obtains the second highest F'-score. It achieves high coverage but low precision. This is because this method chooses high-frequency patterns that can appear with every concept. Therefore, it is able to retrieve concepts with high coverage. However, these patterns do not retrieve specific information concerning a concept. Moreover, some high-frequency patterns, such as "the " and "by," lead to sentences that do not describe any concept.

Table 4 shows the patterns generated for the category *Opera* by each method. We can observe that the method *Frequency* chooses very generic patterns, such as "is a," "and," and "the," which are not specific to *Opera*.

In contrast, the method *PMI-Web* achieves high precision but low coverage. This is because this method chooses highly reliable patterns (e.g., "was commissioned by"), which are strongly associated with a specific kind of concept. However, these patterns cannot retrieve a broad range of concepts related to the target entity. This explains why the method cannot achieve high coverage.

Figure 4 shows the F' scores when we vary the number of selected query patterns (N) for the category *American tennis players*. We observe that the templates generated by the proposed method achieve the highest F'-score at every value of N. The maximum F'-score is 24.7, which is achieved when N is 30. Moreover, the proposed method requires only five query patterns to achieve the F'-score of 21.4. Therefore, the proposed method achieves a high F'-score by using only a small number of patterns. This implies that the method achieves high performance in a short query processing time.

4 Related Work

Many studies have addressed the problem of pattern extraction from Wikipedia (or other large corpora). Filatova et al. (2006) presented an approach for automatically extracting important word patterns from a large corpus. They analyzed the BBC corpus to extract word patterns containing verbs that are supposed to be important for a specific domain. Biadsy et al. (2008) described a system for producing biographies for a given target name. They used Wikipedia to learn the document structures of a biography. Ye et al. (2009)

explored a method for generating a series of summaries of various lengths by using information from Wikipedia.

Sauper and Barzilay (2009) proposed an approach for creating a summary of many chunks of text that are related to an entity and retrieved from the Web. They used Wikipedia not only for producing the template, but also for improving the summaries. Although the target of their work is very close to that of our study, the focus of each study is different. They address the method for selecting appropriate sentences for summarization, whereas we consider the method for selecting query patterns that can generate a comprehensive summary of an entity.

Various studies have addressed Web page summarization and query-focused summarization, from search result summarization (Kanungo et al., 2009) to query biased summarization (Wang et al., 2007). Furthermore, Fujii and Ishikawa (2004) presented a method to automatically compile encyclopedic knowledge from the Web.

Similar to relation extraction, the proposed method retrieves information concerning an entity by using query patterns. This is because query patterns for relation extraction are also appropriate in sentence extraction for multi-document summarization (Hachey, 2009). However, the relation extraction task primarily obtains query patterns that retrieve instances of a specific relation. This is different from the goal of this study, which is obtaining a set of patterns that are able to retrieve a large range of topics related to an entity.

5 Conclusion

We present a novel method to acquire a set of query patterns for retrieving documents that contain important information regarding an entity. Especially, we concentrate on the method for selecting query patterns that are able to comprehensively and precisely retrieve important concepts concerning an entity. The experimental results demonstrate that the proposed method outperforms methods based on statistical measures such as frequency and point-wise mutual information (PMI), which are widely used in relation extraction.

Currently, we use the text between an entity and a WikiLink as a candidate for a query pattern. In the future, we plan to use the text between two noun phrases as query patterns to increase the number of candidates for the pattern selection process. Moreover, we intend to build a text summarization application based on the proposed method to confirm that the selected pattern set is able to generate a comprehensive summary for an entity.

Abstract

This paper proposes a semi-supervised approach for WSD in Word-Class based selectional preferences. The approach exploits syntagmatic and paradigmatic semantic redundancy in the semantic system and uses association computation and minimum description length for the task of WSD. Experiments on Predicate-Object collocations and Subject-Predicate collocations with polysemous predicates in Chinese show that the proposed approach achieves a precision which is 8% higher than the semantic-association based baseline. The semi-supervised nature of the approach makes it promising for constructing large scale selectional preference knowledge base.

1 Introduction

This paper addresses word sense disambiguation (WSD) which is required in the construction of selectional preference (SP) knowledge database. In previous literature of SP, four different types of formalization models are explicitly or implicitly employed. Two types are distinguished in Li and Abe(1998):

Word Model: $P(n \mid v,r) = \sigma$ (1)

Class Model: $P(C \mid v,r) = \sigma$ (2)

where *v* stands for verb, *n* for noun, *C* for the semantic class of *n*, *r* for the grammatical relation between *v* and *n,* and P for the preference strength. Most of the researches(Resnik 1996; Li and Abe 1998; Ciaramita and Johnson 2000; Brockmann and Lapata 2003; Light and Greiff 2002) uses the class model, and a few(Erk 2007) uses the word model. The other two types of model are given as below:

Class-Only Model: $P(C_n \mid C_v,r) = \sigma$ (3)

Word-Class Model: $P(n,C_n \mid v,C_v,r) = \sigma$ (4)

where C_n , C_v are semantic classes for the noun and verb respectively. Class-Only model considers solely the semantic classes, while Word-Class model considers both words and semantic classes. Agirre and Martinez(2001) and Zheng et al(2007) adopted the Class-only Model in research, while in McCarthy and Carroll(2003) and Merlo and Stevenson(2001) the Word-Class Model is employed.

Among the four models, the Word-Class Model is the type which possesses the most granulated knowledge and is the most potential in applications. McCarthy and Carroll(2003) reports that the Word-Class Model performs well in unsupervised WSD. In other NLP tasks such as metaphor recognition, this model may be indispensable. For instance, to distinguish the predicate verb "浮动(float)" in Ex(1a) as

Ex. 1

a. 树 叶 浮 动 (leaf floats)　　b. 价 格 浮 动 (price floats)

Coling 2008: Poster Volume, pages 1238–1246,
Beijing, August 2010

literal and Ex(1b) as metaphorical requires different interpretations of the verb.

The present research is concerned with WSD as in the Word-Class model. Particularly, it aims at disambiguating predicates in subject-predicate (Subj-Pred) and predicate-object (Pred-Obj) constructions. The motivations behind the research are two folds. Firstly, semi-supervised and unsupervised WSD in SP are not fully explored. Merlo and Stevenson(Merlo and Stevenson 2001) employs supervised learning from large annotated corpus, which is difficult to obtain. One known unsupervised learning approach for WSD in SP is McCarthy and Carroll(2003) which addresses the issue via conditional probability. The other motivation derives from the fact few research is done on selectional preferences in languages other than English, as is stated in Brockmann and Lapata(2003). For instance, studies on construction of SP knowledge database in Chinese can only be found in Wu et al(2005), Zhen et al(2007), Jia and Yu(2008) and some others.

The basic idea of the approach proposed for WSD in the paper is that the most acceptable interpretation of senses for a given construction is the pair of senses which encodes the most redundant information in the semantic system of the language. Two principles, namely Syntagmatic Redundancy Principle and Paradigmatic Redundancy Principle, are proposed in the paper to capture the intuition. Two corresponding devices are employed to model the two principles: Association for Syntagmatic Redundancy Principle and Minimum Description Length for Paradigmatic Redundancy Principle. Two experiments are conducted in the paper. The first is based on semantic association, achieving a 61.98% precision for predicates in Subj-Preds and 62.54% in Pred-Objs. This experiment is used as baseline as the approach is also used in McCarthy and Carroll(2003) for verb and adjective disambiguation. In the second experiment, both semantic association and MDL are employed, the precision of WSD amounts to 69.88% and 69.09% for predicates in Subj-Preds and Pred-Objs respectively, indicating that a combination of the two devices are fairly effective in disambiguating word senses for SP.

The rest of the paper is organized as below. The second part gives further illustration of the rationale for the approach. The third part describes the procedure and the fourth part discusses the experiment result. The thesis concludes with some speculations in further researches.

2 Rationale

2.1 Task Formalization

Consider a Subj-Pred or Pred-Obj collocation C=$<W_{pred}, W_{\arg}>$, where W_{pred} is the word of predicate and $W_{\arg}$ is the word of argument. W_{pred} has M senses, denoted by set S_{pred}. $W_{\arg}$ has N senses, denoted by $S_{\arg}$. The possible interpretation of C has M*N possibilities, denoted by $S_C = S_{pred} \times S_{\arg} = \{ \varsigma^i_j \mid \varsigma^i_j = < s^i_{pred}, s^j_{\arg} > \}$, where ς^i_j is called a sense collocation. The task of WSD is to search for a particular sense collocation in S_C and assign it to C as its interpretation. At the initial stage, each sense collocation in S_C is considered to have an even number of frequency, namely $f(\varsigma^i_j) = 1/(N \times M)$. Accordingly, for each $s^i_{pred} \in S_{pred}$, $f(s^i_{pred}) = 1/M$, For each $s^i_{\arg} \in S_{\arg}$, $f(s^i_{\arg}) = 1/N$.

2.2 Syntagmatic Redundancy Principle

Syntagmatic Redundancy Principle (SRP) can be stated as following: among all possible sense collocations for a word collocation, the most appropriate is the one in which senses exhibit the most redundant information between each other.

The syntagmatic redundancy between words has been noticed very early by linguists and has been applied in WSD. Firth(1957) argues that there exists “mutual expectancy” between words in collocations, and the meaning of word is partially encoded in its juxtaposition. Lyons(1977:261) comments that Porzig has noticed in 1934 the “essential meaning relation” between words of collocations like “dog barks” and “tree fells”

and emphasizes that the meanings of collocationally restricted lexemes such as "bark" and "fell" can only be explained by taking into account the collocates they occur with. This notion is also employed in Yarowsky(1995) for WSD, in which the key is the "one-sense-per-collocation" statement. McCarthy and Carroll(2003) also uses this type of redundancy for disambiguation in SP.

SRP can be explained as a statistic correlation between s_{pred} and $s_{\arg}$. The more co-relevant these two senses are, the more likely the pair is to be accepted as the appropriate interpretation. This can be described as below:

$$\overline{\varsigma_j^i} = \arg\max Assoc(s_{pred}^i, s_{\arg}^j) \qquad (5)$$

where $Assoc(s_{pred}^i, s_{\arg}^j)$ is the function for sense association. Four methods can be considered for association computation: conditional probability (Formula 6 and 7), Lift(Han and Kamber 2006:261) (Formula 8), All-Confidence(Han and Kamber 2006:263) (Formula 9) and cosine (Formula 10). Note that two versions of conditional probability are considered, as are denoted in Formula 6 and 7. The first version, Cond-Prob 1, takes argument sense as condition, while the second version Cond-Prob 2 takes predicate sense as condition.

$$p(s_{pred}^i \mid s_{\arg}^j) = \frac{p(s_{pred}^j, s_{\arg}^i)}{p(s_{\arg}^j)} \qquad (6)$$

$$p(s_{\arg}^i \mid s_{pred}^j) = \frac{p(s_{pred}^j, s_{\arg}^i)}{p(s_{pred}^i)} \qquad (7)$$

$$lift(s_{pred}^i, s_{\arg}^j) = \frac{p(s_{pred}^i, s_{\arg}^j)}{p(s_{pred}^i) * p(s_{\arg}^j)} \qquad (8)$$

$$all\_conf(s_{pred}^i, s_{\arg}^j) = \frac{f(s_{pred}^i, s_{\arg}^j)}{\max(f(s_{\arg}^i), f(c_{pred}^j))} \qquad (9)$$

$$\cos ine(s_{pred}^i, s_{\arg}^j) = \frac{p(s_{pred}^i, s_{\arg}^j)}{\sqrt{p(s_{pred}^i) * p(s_{\arg}^j)}} \qquad (10)$$

2.3 Paradigmatic Redundancy Principle

Paradigmatic Redundancy Principle (PRP) can be stated as following: among all possible sense collocations for a word collocation, the most appropriate is the one which is also implicitly or explicitly expressed by other synonymous, metonymic or metaphorical word collocations.

Ex(2) illustrates the explicit redundancy in synonymous and metaphorical ways, in which the sense collocation "[Price|价格] [QuantityChange|量变]" is expressed by five word collocations, each with a different predicate：变化(change), 浮动(float), 调整(adjust), 起伏(go up and down), 变动(alter).

Ex 2.

a. 价格变化 price changes
b. 价格浮动 price floats
c. 价格调整 price adjusts
d. 价格起落 price goes up and down
e. 价格变动 price alters

Ex(3) reveals the implicit redundancy in metonymic way, in which the meaning "人(human) 安心(is eased)" is implicitly expressed in all the six collocations, established by semantic relatedness among the arguments "马拉多纳(Maradona)", "学生(student)", "工作(work)", "劳动(labour)", "行车(driving)", and "生活(life)".

Ex 3.

a. 马拉多纳 安心 了 Maradona is eased
b. 学生 安心 了 Student is eased
c. 工作 安心 了 work is eased
d. 劳动 安心 了 labour is eased
e. 行车 安心 了 driving is eased
f. 生活 安心 了 Life is eased

To apply PRP, WSD in SP is casted as an issue of model selection. Given a set of word collocations Θ, the process of WSD is to assign to each word collocation one sense collocation from a number of possibilities. Those assigned sense collocations form a set, or a model for Θ. The goal of WSD in SP is to select from all those models the one which best interprets Θ. For this purpose, Miminum Description Length(Barron et al. 1998; Michell 2003; MacKay 2003) can be used. MDL selects models by relying on induction bias based on Occam's Razor, which stipulates that the simplest solution is usually the correct one. One way to interpret MDL in Bays' analysis is as below(Michell 2003:124):

$$m' = \arg\min L_M(m) + L_D(D \mid m) \qquad (11)$$

In (11), $L_M(m)$ is the model description length when model m is considered, $L_D(D \mid m)$ is the data description length when model m is used for description. The model with minimum length is the best model.

For model description length, we have adopted the method used in (Li and Abe 1998) which considers only the size of the model:

$$L_M(m) = \frac{size(m)-1}{2}\log(N) \qquad (12)$$

where size(m) is the number of sense collocation contained in model m, and N is the number of word collocation in consideration. In this study, the set of word collocation with the same predicate word, denoted by Θ, is used as the unit for model description length calculation instead of the whole corpus, so as to reduce computation complexity. Accordingly, each word collocation in Θ can be assigned one and only one sense collocation in the model m, out of all the potential sense collocations as is explained in section 2.1.

Data description length is calculated on model m and Θ, as is denoted in formulas (13), (14) and (15) below. The calculation is

$$L(\Theta \mid m) = -\sum \log(p(\varsigma_j^i)) = -\sum \log(\frac{\overline{f}(\varsigma_j^i)}{Num_\Theta{}^2}) \qquad (13)$$

$$\overline{f}(\varsigma_j^i) = f(\varsigma_j^i) + f(\varsigma_j^i) * \sum_{\varsigma_j^i, \varsigma_l^k \in m} w(\varsigma_j^i, \varsigma_l^k) \qquad (14)$$

$$w(\varsigma_j^i, \varsigma_l^k) = rel(< s_{pred}^i, s_{\arg}^j >, < s_{pred}^k, s_{\arg}^l >) = \begin{cases} rel(s_{\arg}^j, s_{\arg}^l) & \text{if } s_{\text{pred}}^i = s_{pred}^k \\ 0 & \text{if } s_{\text{pred}}^i \neq s_{pred}^k \end{cases} \qquad (15)$$

based on the probability of sense collocation $\varsigma_j^i =< s_{pred}^i, s_{\arg}^j >$, which in turn is calculated on a modified frequency of the collocation $\overline{f}(\varsigma_j^i)$. The frequency is modified by counting the explicit occurrence of the sense collocation itself and the implicit occurrence expressed by other sense collocations in Θ. This idea is equivalent to enlarge the corpus by 1 fold, thus the overall collocation number is the two times of the original number.

The modified frequency is a sum of two parts, denoted in formula (14). The first part is $f(\varsigma_j^i)$, the frequency of ς_j^i. The second part is the weighted frequency of ς_j^i. The weight is determined by the relatedness of the sense collocation ς_j^i and all the other sense collocation ς_l^k in the model ***m***. According to this formula, if the sense collocation is found to be more similar to other sense collocations, it should obtain a higher modified frequency, and thus more likely to be the correct one for the word collocation.

The way to calculate the weight is given in formula (15). If two sense collocations have identical predicate sense, namely $s_{\text{pred}}^i = s_{pred}^k$, then the weight between the two sense collocations is measured by $rel(s_{\arg}^j, s_{\arg}^l)$, the semantic relatedness between the argument sense $s_{\arg}^j$ and $s_{\arg}^l$. Otherwise, 0 is returned. There are different ways to measure sense relatedness. The present study has used semantic similarity based on HowNet(Liu and Li 2002) to calculate the semantic relatedness.

3 Procedure

Figure 1 maps out the procedure for WSD in SP in the present study. The procedure is divided into two phases: data collection and disambiguation. The collocation data are collected from three sources: Sketch Engine, Collocation Dictionary and HowNet Examples. Two types of collocation data are collected: subject-predicate collocations (Subj-Pred) and predicate-object collocations (Pred-Obj) from Sketch Engine and Collocation Dictionary. Collocation Retriever reduces HowNet examples into Subj-Preds and Pred-Objs using simple heuristic methods. As a result, about 70,000 subject-predicate collocations and 106,000 predicate-object collocations are obtained.

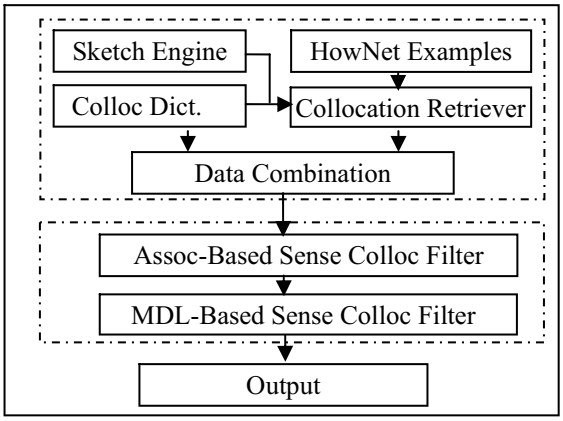

Figure 1. WSD Procedure

In disambiguation phase, two devices are employed to filter out unlikely sense collocations: Association-Based Sense Collocation Filter, following SRP, and MDL-Based Sense Collocation Filter, following PRP.

In this phase, Subj-Preds and Pred-Objs are processed independently but following the same route.

Each phase alone can perform WSD independently. Accordingly, two experiments are conducted to evaluate the method proposed in this paper. The first experiment uses association-based filter for word sense disambiguation, which is also used as the baseline. The approach is also used in (McCarthy and Carroll 2003) to disambiguate verbs and adjectives in collocations. To be particular, the method used by McCarthy and Carroll(2003) is formula (6). The second experiment is based on the result of the first one so as to observe the improvement obtained by MDL-Based approach. In the second experiment, unsupervised and semi-supervised WSD are also investigated by including some annotated collocations in the evaluation data.

Two corpora are constructed for evaluation. One corpus is a set of 1034 subject-predicate constructions. The other is a set of 1841 predicate-object constructions. Both are manually annotated by the authors with sense definitions defined in HowNet(Dong 2006). All together there are 52 highly ambiguous predicates involved in the study.

4 Experiments and Discussion

4.1 Collocation Retriever

The major task in data collocation is in Collocation Retriever, which retrieves collocations from HowNet examples. Ex(4) gives a partial entry structure in HowNet,

```
Ex 4.
W_C=浮动
E_C=人心~，开始~，工作指标不停地~
DEF=[change|变]
```

in which W_C stands for Chinese Word, DEF for definition, E_C for Examples of Chinese, and the wave "~" for the word in question. From E_C, possible Subj-Preds such as "人心(public opinion) 浮动(floats)", "指标(index) 浮动(floats)" can be retrieved, in which the sense of "浮动(float)" is annotated with DEF. But there are also noises. A simple heuristic method is applied to automatically filter out unwanted collocations. The heuristic method checks whether the collocation retrieved from HowNet share possible sense collocations with collocations in Collocation Dictionary. If yes, it is accepted as a collocation of the type, otherwise, it is rejected. Procedures are given below:

(a) Use Subj-Pred collocations and Pred-Obj collocations in Collocation Dictionary to build sense collocation set $\Gamma_{Subj-Pred}$ and $\Gamma_{Pred-Obj}$;

(b) For each example sentence in E_C, segment it using ICTCLAS[1] to obtain an array of words. Words before "~" forms potential Subj-Pred collocations $A_{Subj-Pred}$ and Words after form potential Pred-Obj collocations $B_{Pred-Obj}$.

(c) For each $a \in A_{Subj-Pred}$ or $b \in B_{Subj-Pred}$, construct possible sense collocation set Γ_a or Γ_b, if $\Gamma_a \cap \Gamma_{Subj-Pred} \neq \phi$ or $\Gamma_b \cap \Gamma_{Pred-Obj} \neq \phi$, add it as a Subj-Pred collocation or Pred-Obj collocation.

Evaluation on partial retrieved collocations shows that about 70% of obtained collocations are valid collocations, while about 30% are errors. Thus manual edition has been applied to rid those invalid collocations.

4.2 Association-Based Filter

Association-Based Sense Collocation Filter filters out those sense collocations that are very unlikely to be the right interpretation for a word collocation. Table 1 gives association computation result for the six senses related to the predicate "粗(rough)" in Subj-Pred collocation "性格(personality) 粗(rough)". The 2nd, 3rd, 4th, and 6th are very unlikely interpretations and should be filtered, while the 5th seems to be the most appropriate.

Table 1. Association-Based Filter Example

No.	Pred Sense	Arg Sense	Assoc. Dgr
1	[Behavior|举止]	[careless|粗心]	0.0019
2	[Behavior|举止]	[coarse|糙]	0.0002
3	[Behavior|举止]	[hoarse|沙哑]	0.0004
4	[Behavior|举止]	[roughly|大概]	0.0002
5	[Behavior|举止]	[vulgar|俗]	0.0071
6	[Behavior|举止]	[widediameter|粗]	0.0002

Following the procedure in Figure 1, to filter out those unlikely sense collocations, average

[1] A Chinese segmentation system, please refer to http://www.ictclas.org for further information.

association value is used as the filter and those below the average are dropped and those above are chosen for MDL-Based Filter. In Table 1, the average is 0.0017, and the 1rd and 5th are chosen.

However, in order to obtain a baseline and to decide which association computation model to use, we have followed the definition in Formula 5 and perform WSD test by choosing the sense collocation with highest association as the correct sense tags. for used this step solely for WSD, as is defined in Formula 4. Table 2 gives the experiment results for Subj-Pred and Pred-Obj collocations with all the association computation models denoted in Formula 6-10.

Table 2. WSD Result by Association

	Subj-Pred(%)	Pred-Obj(%)
Cond-Prob 1	61.98	62.54
Cond-Prob 2	55.15	42.4
Lift	63.09	40.84
All_Conf	56.16	48.54
Cosine	58.83	55.72

One interesting phenomenon about all the five models is null-invariance. In selecting models for association computation, null-invariance is an important feature to be considered(Han and Kamber 2006). A model with null-invariance is not influenced by additional irrelevant data and thus is more stable. In the experiment, the model Lift is the only one not featured with null-invariance. The experiments show that Lift is not stable in different collocation types, achieving high precision in Subj-Pred but low precision in Pred_Obj.

A second interesting phenomenon is collocation directionality exposed by the experiments, which can be observed in the two models of conditional probability: Cond-Prob 1, with argument as condition, and Cond-Prob 2, with predicate as condition. Directionality in collocation has been noticed earlier in some researches, for example Qu(2008). Our experiment shows that when using Cond-Prob 1, we are able to get a precision of 61.98% and 62.54% for Subj-Pred and Pred-Obj respectively, while Cond-Prob 2 gets a much lower precision. This fact can be interpreted that arguments tend to have a stronger selectional preference strength, and the possible selection range is comparatively narrower, while predicates have weaker selectional preference strength and a wider selectional range.

4.3 MDL-Based Filter

MDL-Based Filter takes as input result from Association-Based Filter using Cond-Prob 1 for association computation and average association as filter. Table 3 and 4 give the final experiment outcome for Pred-Obj and Subj-Pred constructions and individual predicates.

It can be seen in Table 3 that MDL-Based Filter Several inferences can be made from the experiments. Firstly, comparison between Association-Based WSD (Table 2) and MDL WSD (Table 3) shows that MDL can improve overall performance up to 8%. As is mentioned earlier, Association-Based WSD is used as baseline in the present study. Given the fact that the average number of senses for word in question is fairly high, the improvement is considered as significant.

Table 3. General WSD Results[2]

	Ave. N.O.S.	Assoc. WSD (%)	MDL WSD (%)
Subj-Pred	4.16	61.98	69.09
Pred-Obj	5.03	62.54	69.88

Analysis on the individual predicates in Table 4 gives a clearer picture of WDL-based WSD. Firstly, it can be seen that MDL is especially effective when the demarcation of word senses is clear-cut. Predicate words such as “安静(quiet)”, “肮脏(dirty)”, “困难(difficult)” in Subj-Preds and “锤炼(beat)”, “触动(touch)” and “打断(break)” in Pred-Objs are successfully disambiguated in Table 4. These words generally have 2 or 3 senses, and the senses generally differ in terms of abstractness and concreteness, as is indicated in table 5. This is due to the fact that the arguments in these collocations are clearly delimitated in HowNet and this delimitation is well captured by the modified frequency calculation defined in formula (14). Via the formula, the concrete sense collocations can

[2] In Table 3 and 4, Ave. N.O.S stands for average number of senses of predicates, N.O.S stands for number of senses of the predicate, Assoc. WSD stands for Association-based WSD, and MDL WSD stands for MDL-based WSD.

Table 4. Detailed WSD Experiment Results

Table 5. Word Sense Distinction

Pred	Concrete Sense	Abstract Sense(s)
安静	[quiet|静]	[calm|镇静], [peaceful|宁]
肮脏	[dirty|龌]	[despicable|卑劣], [immoral|不道德]
困难	[difficult|难]	[poor|穷]
锤炼	[beat|打]	[MakeBetter|优化], [cultivate|培养]
触动	[touch|触]	[excite|感动]
打断	[break|折断]	[obstruct|阻止]

increase the modified frequency of concrete sense collocations, and the abstract sense collocation can increase the modified frequency of abstract sense collocations, thus leading to the clear demarcation of abstract senses and concrete senses.

The role of semantic relevance can also be clearly noticed in the predicates which have a decreased precision in MDL in Table 4. Via Paradigmatic Redundancy Principle, the information encoded in one collocation are diffused to other collocations. Consequently, errors can be diffused. This explains why the precisions of some predicates such as "沉(sink)", "麻木(dumb)", "黑暗(dark)" in Subj-Pred and "开(open)", "套(harness)" in Pred-Objs decrease after MDL. Further analysis shows that this is because MDL has diffused the errors produced by Association Filter. For instance, at Association Filter phase, the collocation "箱子(box) 沉(sink)" is assigned with the only sense collocation "[tool|用具] [very|很]" and all other potential sense collocations are filtered. When MDL is applied, other collocations such as "机器(machine) 沉(heavy)", "镐头(pick) 沉(heavy)", "镢头(chaw) 沉(heavy)", "篮子(basket) 沉(heavy)", "盒子(box) 沉(heavy)", "家具(furniture) 沉(heavy)", in which the arguments are tightly correlated with that of "箱子(box) 沉(sink)", all takes the sense "[very|很]", thus leading to the decrease of precision.

The diffusion of senses can also best seen in the comparison between those predicates whose WSD are semi-supervised and those whose WSD are not supervised. Some predicates have collocations successfully retrieved from HowNet examples in which the word sense is already identified. These collocations are diffused in MDL filtering and play important roles in improving precision, while some other predicates do not have such resource. In Table 4, those unsupervised predicates are "陷落(fall)", "垮(collapse)", "细腻(exquisite)", "麻木(dumb)", "开阔(wide)", "开发(develop)" in Subj-Preds and "展开(spread)", "洗刷(brush)", "陷入(get into)", "带(bring)", and "糟蹋(mar)" in Pred-Objs. The other predicates are semi-supervised. As can be seen in Table 4, most of these unsupervised predicates generally have a precision of 40%-60%, while those semi-supervised predicates enjoy are much higher precision between 50%-100%. The explanation

for the result is straight forward. When one sense collocation of one word collocation is correctly identified, by way of Paradigmatic Redundancy Principle, the sense collocation which is similar to the correctly identified will have a higher modified frequency and is thus singled out as the best choice. This feature of MDL has great significance in the process of annotating large scale collocation data. With only a small number of annotated collocations for each predicate, a fairly high precision can be achieved for all the rest of the data through MDL.

5 Conclusion

The present paper believes that the Word-Class Model gives the fullest description for selectional preference and thus makes efforts to disambiguate predicates in selectional preferences. From the perspective of semantic system, two principles of semantic redundancy, namely the Syntagmatic Redundancy Principle and Paradigmatic Redundancy Principle, are proposed in the paper and are applied in WSD in SP via Association Computation and Minimum Description Length. The experiments show that the approach proposed is fairly encouraging in disambiguation of polysemous predicates, especially under semi-supervised conditions when a small portion of data is annotated. With such a tool, we are able to build large scale selectional preference knowledge database based on Word-Class Models, which can be applied in various tasks, of which metaphor recognition is the particular one we bear in mind.

A Comparison of Models for Cost-Sensitive Active Learning

Katrin Tomanek and **Udo Hahn**
Jena University Language & Information Engineering (JULIE) Lab
Friedrich-Schiller-Universität Jena
http://www.julielab.de

Abstract

Active Learning (AL) is a selective sampling strategy which has been shown to be particularly cost-efficient by drastically reducing the amount of training data to be manually annotated. For the annotation of natural language data, cost efficiency is usually measured in terms of the number of tokens to be considered. This measure, assuming uniform costs for all tokens involved, is, from a linguistic perspective at least, intrinsically inadequate and should be replaced by a more adequate cost indicator, *viz.* the time it takes to manually label selected annotation examples. We here propose three different approaches to incorporate costs into the AL selection mechanism and evaluate them on the MUC7$_\mathcal{T}$ corpus, an extension of the MUC7 newspaper corpus that contains such annotation time information. Our experiments reveal that using a cost-sensitive version of semi-supervised AL, up to 54% of true annotation time can be saved compared to random selection.

1 Introduction

Active Learning (AL) is a selective sampling strategy for determining those annotation examples which are particularly informative for classifier training, while discarding those that are already easily predictable for the classifier given previous training experience. While the efficiency of AL has already been shown for many NLP tasks based on measuring the number of tokens or sentences that are saved in comparison to random sampling (e.g., Engelson and Dagan (1996), Tomanek et al. (2007) or Settles and Craven (2008)), it is obvious that just counting tokens under the assumption of *uniform* annotation costs for each token is empirically questionable, from a linguistic perspective, at least.

As an alternative, we here explore annotation costs that incur for AL based on an empirically more plausible cost metric, *viz.* the time it takes to annotate selected linguistic examples. We investigate three approaches to incorporate costs into the AL selection mechanism by modifying the standard (fully supervised) mode of AL and a non-standard semi-supervised one according to cost considerations. The empirical backbone of this comparison is constituted by MUC7$_\mathcal{T}$, a re-annotation of a part of the MUC7 newspaper corpus that contains annotation time information (Tomanek and Hahn, 2010).

2 Active Learning

Unlike random sampling, AL is a selective sampling technique where the learner is in control of the data to be chosen for training. By design, the intention behind AL is to reduce annotation costs, usually considered as the amount of labeled training material required to achieve a particular target performance of the model. The latter is yielded by querying labels only for those examples which are assumed to have a high training utility. In this section, we introduce different AL frameworks – the default, fully supervised AL approach (Section 2.1), as well as a semi-supervised variant of it (Section 2.2). In Section 2.3 we then propose three methods how these approaches to AL can be made cost-sensitive without further modifications.

Coling 2008: Poster Volume, pages 1247–1255,
Beijing, August 2010

2.1 Fully Supervised AL (FuSAL)

As we consider AL for the NLP task of Named Entity Recognition (NER), some design decisions have to be made. Firstly, the selection granularity is set to complete sentences – a reasonable linguistic annotation unit which still allows for fairly precise selection. Second, a batch of examples instead of a single example is selected per AL iteration to reduce the computational overhead of the sampling process.

We base our approach to AL on Conditional Random Fields (CRFs), which we employ as base learners (Lafferty et al., 2001). For observation sequences $\vec{x} = (x_1, \ldots, x_n)$ and label sequences $\vec{y} = (y_1, \ldots, y_n)$, a linear-chain CRF is defined as

$$P_\theta(\vec{y}|\vec{x}) = \frac{1}{Z_\theta(\vec{x})} \cdot \prod_{i=1}^{n} \exp \sum_{j=1}^{k} \lambda_j f_j\Big(y_{i-1}, y_i, \vec{x}, i\Big)$$

where $Z_\theta(\vec{x})$ is the normalization factor, and k feature functions $f_j(\cdot)$ with feature weights $\theta = (\lambda_1, \ldots, \lambda_k)$ appear.

The core of any AL approach is a utility function $u(p, \theta)$ which estimates the informativeness of each example p, a complete sentence $p = (\vec{x})$, drawn from the pool P of all unlabeled examples, for model induction. For our experiments, we employ two alternative utility functions which have produced the best results in previous experiments (Tomanek, 2010, Chapter 4). The first utility function is based on the confidence of a CRF model θ in the predicted label sequence $\vec{y}^*$ which is given by the probability distribution $P_\theta(\vec{y}^*|\vec{x})$. The utility function based on this probability boils down to

$$u_{\mathrm{LC}}(p, \theta) = 1 - P_\theta(\vec{y}^*|\vec{x})$$

so that sentences for which the predicted label sequence $\vec{y}^*$ has a low probability is granted a high utility. Instead of calculating the model's confidence on the complete sequence, we might alternatively calculate the model's confidence in its predictions on single tokens. To obtain an overall confidence for the complete sequence, the average over the single token-confidence values can be computed by the marginal probability $P_\theta(y_i|\vec{x})$. Now that we are calculating the confidence on the token level, we might also obtain the performance of the second best label and calculate the margin between the first and second best label as a confidence score so that the final utility function is obtained by

$$u_{\mathrm{MA}}(p, \theta) = -\frac{1}{n} \sum_{i=1}^{n} \Big(\max_{y' in \mathcal{Y}} P_\theta(y_i = y'|\vec{x}) - \max_{\substack{y'' in \mathcal{Y} \\ y' \neq y''}} P_\theta(y_i = y''|\vec{x}) \Big)$$

Algorithm 1 formalizes our AL framework. Depending on the utility function, the best b examples are selected per round, manually labeled, and then added to the set of labeled data $\mathcal{L}$ which feeds the classifier for the next training round.

Algorithm 1 NER-specific AL Framework

Given:
b: number of examples to be selected in each iteration
$\mathcal{L}$: set of labeled examples $l = (\vec{x}, \vec{y}) \in \mathcal{X}^n \times \mathcal{Y}^n$
$\mathcal{P}$: set of unlabeled examples $p = (\vec{x}) \in \mathcal{X}^n$
$T(\mathcal{L})$: a learning algorithm
$u(p, \theta)$: utility function

Algorithm:
loop until stopping criterion is met

1. learn model: $\theta \leftarrow T(\mathcal{L})$
2. sort $p \in \mathcal{P}$: let $S \leftarrow (p_1, \ldots, p_m) : u(p_i, \theta) \geq u(p_{i+1}, \theta), i \in [1, m], p \in \mathcal{P}$
3. select b examples p_i with highest utility from S: $\mathcal{B} \leftarrow \{p_1, \ldots, p_b\}, b \leq m, p_i \in \mathcal{S}$
4. query labels for all $p \in \mathcal{B}$: $\mathcal{B}' \leftarrow \{l_1, \ldots, l_b\}$
5. $\mathcal{L} \leftarrow \mathcal{L} \cup \mathcal{B}', \mathcal{P} \leftarrow \mathcal{P} \setminus \mathcal{B}$

return $\mathcal{L}^* \leftarrow \mathcal{L}$ and $\theta^* \leftarrow T(\mathcal{L}^*)$

The specification is still not cost-sensitive as the selection of examples depends only on the utility function. Using u_{LC} will result in a reduction of the number of examples (i.e., sentences) selected irrespective of the sentence length so that a model learns the most from it. As a result, we observed that the selected sentences are quite long which might even cause higher annotation costs per sentence (Tomanek, 2010, Chapter 4). As for u_{MA} there is at least a slight normalization sensitive to costs since the sum over all token-level utility scores is normalized by the length of the selected sentence.

2.2 Semi-supervised AL (SeSAL)

Tomanek and Hahn (2009) extendeded this standard fully supervised AL framework by a semi-supervised variant (SeSAL). The selection of sentences is performed in a standard manner, i.e., similarly to the procedure in Algorithm 1. However, once selected, rather than manually annotating the complete sentence, only (uncertain) subsequences of each selected sentence are manually labeled, while the remaining (certain) ones are automatically annotated using the current version of the classifier.

After the selection of an informative example $p = (\vec{x})$ with $\vec{x} = (x_1, \ldots, x_n)$, the subsequences $\vec{x}' = (x_a, \ldots, x_b)$, $1 \leq a \leq b \leq n$, with low local uncertainty have to be identified. For reasons of simplicity, only sequences of length 1, i.e., single tokens, are considered. For a token x_i from a selected sequence $\vec{x}$ the model's confidence $C_\theta(y_i^*)$ in label y_i^* is estimated. Token-level confidence for a CRF is calculated as the marginal probability so that

$$C_\theta(y_i^*) = P_\theta(y_i = y_i^* | \vec{x})$$

where y_i^* specifies the label at the respective position of the predicted label sequence $\vec{y}^*$ (the one which is obtained by the Viterbi algorithm). If $C_\theta(y_i^*)$ exceeds a confidence threshold t, y_i^* is assigned as the putatively correct label. Otherwise, manual annotation of this token is required.

Employing SeSAL, savings of over 80 % of the tokens compared to random sampling are reported by Tomanek and Hahn (2009). Even when compared to FuSAL, still 60 % of the number of tokens are eliminated. A crucial question, however, not answered in these experiments, is whether this method actually reduces the overall annotation expenses in time rather than just in the number of tokens. Also SeSAL does not incorporate labeling costs in the selection process.

2.3 Cost-Sensitive AL (CoSAL)

In this section, we turn to an extension of FuSAL and SeSAL which incorporates cost sensitivity into the AL selection process (CoSAL). Three different approaches of CoSAL will be explored. The challenge we now face is that two contradictory criteria – utility and costs – have to be balanced.

2.3.1 Cost-Constrained Sampling

CoSAL can be realized in the most straightforward way by simply constraining the sampling to a particular maximum cost c_{max} per example. Therefore, in a pre-processing step all examples $p \in \mathcal{P}$ for which $\text{cost}(p) > c_{\text{max}}$ are removed from $\mathcal{P}$. The unmodified NER-specific AL framework can then be applied.

An obvious shortcoming of Cost-Constrained Sampling (CCS) is that it precludes any form of compensation between utility and costs. Thus, an exceptionally useful example with a cost factor slightly above c_{max} will be rejected. Another critical issue is how to fix c_{max}. If chosen too low, the pre-filtering of $\mathcal{P}$ results in a much too strong restriction of selection options when only few examples remain inside $\mathcal{P}$. If chosen too high, the cost constraint becomes ineffective.

2.3.2 Linear Rank Combination

A general solution to fit different criteria into a single one is by way of linear combination. If, however, different units of measurement are used, a transformation function for the alignment of benefit, or utility, and costs must be found. This can be difficult to determine. In our scenario, benefits measured by utility scores and costs measured in seconds are clearly incommensurable. As it is not immediately evident how to express utility in monetary terms (or vice versa), we transform utility and cost information into ranks $R\big(u(p,\theta)\big)$ and $R'\big(\text{cost}(p)\big)$ instead. As for utility, higher utility leads to higher ranks. As for costs, lower costs lead to higher ranks. The linear rank combination (LRK) is defined as

$$\phi_{\text{LRK}}(\vec{v}(p)) = \alpha R\big(u(p,\theta)\big) + (1-\alpha) R'\big(\text{cost}(p)\big)$$

where α is a weighting term. In a CoSAL scenario, where utility is the primary criterion, $\alpha > 0.5$ seems a reasonable choice. Alternatively, as costs and utility are contradictory, allowing equal influence for both criteria, as with $\alpha = 0.5$, it may be difficult to find appropriate examples in a medium-sized corpus. Thus, the choice of α depends on size and diversity with respect to combinations of utility and costs within $\mathcal{P}$.

2.3.3 Benefit-Cost Ratio

Our third approach to CoSAL is based on the Benefit-Cost Ratio (BCR). Given equal units of measurement for benefits and costs, the benefit-cost ratio indicates whether a scenario is profitable (ratio > 1). BCR can also be applied when units are incommensurable and a transformation function is available, as is the case for the combination of utility and cost. This holds as long as benefit and costs can be expressed in the same units by a linear transformation function, i.e., $u(p, \theta) = \beta \cdot \text{cost}(p) + b$. If such a transformation function exists, one can refrain from finding proper values for the above variables b and β and instead calculate BCR as

$$\phi_{\text{BCR}}(p) = \frac{u(p, \theta)}{\text{cost}(p)}$$

Since annotation costs are usually expressed on a linear scale, this is also required for utility, if we want to use BCR. But when utility is based on model confidence as we do it here, this property gets lost.[1] Hence a non-linear transformation function is needed to fit the scales of utility and costs. Assuming a linear relationship between utility and costs, BCR has already been applied by Haertel et al. (2008) and Settles et al. (2008). Our approach provides a crucial extension as we explicitly consider scenarios where such a linear relationship is not given and a non-linear transformation function is required instead.

In a direct comparison of LRK with BCR, LRK may be used when such a transformation function would be needed but is unknown and hard to find. Choosing LRK over BCR is also motivated by findings in the context of data fusion in information retrieval where Hsu and Taksa (2005) remark that, given incommensurable units and scales, one would do better when ranks rather than the actual scores or values were combined.

3 Experiments

In the following, we study possible benefits of CoSAL, relative to FuSAL and SeSAL, in the light of real annotation times as a cost measure (instead of the standard, yet inadequate one, *viz.* the number of tokens being selected). Such timing data is available in the MUC7$_\mathcal{T}$ corpus (Tomanek and Hahn, 2010), a re-annotation of the MUC7 corpus containing the ENAMEX types (persons, locations, and organizations) and a time stamp reflecting the time it took annotators to decide on each entity type. The MUC7$_\mathcal{T}$ corpus contains 3,113 sentences (76,900 tokens).

The results we report on are averaged over 20 independent runs. For each run, we split the MUC7$_\mathcal{T}$ corpus randomly into a pool to select from (90%) and an evaluation set (10%). AL was started from a random seed set of 20 sentences. As utility scores to estimate benefits we applied u_{MA} and u_{LC} as defined in Section 2.1.

The plots in the following sections depict costs in terms of annotation time (in seconds) relative to annotation quality (expressed via F1-scores). Learning curves are only shown for early AL iterations. Later on, in the convergence phase, due to the two conflicting criteria now considered simultaneously, selection options become more and more scarce so that CoSAL necessarily performs sub-optimally.

3.1 Parametrization of CoSAL Approaches

Preparatory experiments were run to analyze how different parameters affected different CoSAL settings. For the CCS and LRK experiments, we used the u_{LC} utility function.

For CCS, we tested three c_{max} values, *viz.* 7.5, 10, and 15, to determine the maximum performance attainable on MUC7$_\mathcal{T}$ when only examples below the chosen threshold were included. Our choices of the maximum were based on the distributions of annotation times over the sentences (see Figure 1) where 7.5s marks the 75% quantile and 15s is just above the 90% quantile. For 7.5s, we peaked at $F_{max} = 0.84$, for 10s at $F_{max} = 0.86$, and for 15s at $F_{max} = 0.88$. Figure 2 (top) shows the learning curves of CoSAL with CCS and different c_{max} values. With $c_{max} = 15$, as could be expected from the boxplot in Figure 1, no difference can be observed compared to cost-*in*sensitive FuSAL. CCS with lower values for c_{max} stagnates at the maximum perfor-

[1] Though normalized to $[0, 1]$, confidence estimates, especially for sequence classification, are often not on a linear scale so that confidence values that are twice as high do not necessarily mean that the benefit in training a model on such an example is doubled.

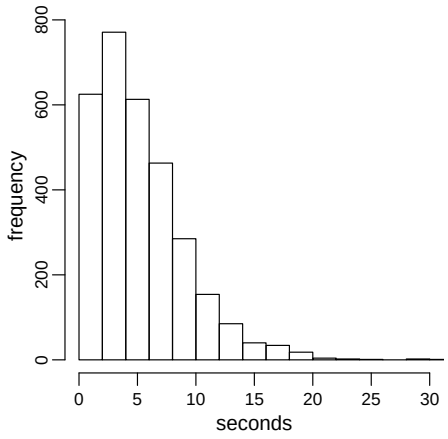

Figure 1: Distribution of annotation times per sentence in MUC7$_\mathcal{T}$.

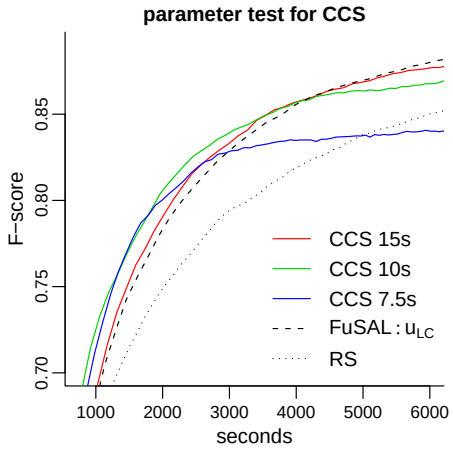
mance reported above, but still improves upon cost-*in*sensitive FuSAL in early AL iterations.

At some point in time all economical examples, with costs below c_{max} but high utility, have been consumed from the corpus. Even in a corpus much larger than MUC7$_\mathcal{T}$ this effect will only occur with some delay. Indeed, any choice of a restrictive value for c_{max} will cause similar exhaustion effects. Unfortunately, it is unclear how to tune c_{max} suitably in a real-life annotation scenario where pretests for maximum performance for a particular c_{max} are not possible. For further experiments, we chose $c_{max} = 10$.

For LRK, we tested three different weights α, *viz.* 0.5, 0.75, and 0.9. Figure 2 (bottom) shows their effects on the learning curves. Similar tendencies as for c_{max} for CCS can be observed. With $\alpha = 0.9$, CoSAL does not fall below default FuSAL, at least in the observed range. A lower weight of $\alpha = 0.75$ results in larger improvements in earlier AL iterations but then falls back to FuSAL and in later AL iterations (not shown here) even below FuSAL. If the time parameter is granted too much influence, as with $\alpha = 0.5$, performance even drops to random selection level. This might also be due to corpus exhaustion. For further experiments, we chose $\alpha = 0.75$ because of its potential to improve upon FuSAL in early iterations.

For BCR with u_{MA}, we change this utility function to $n \cdot u_{\mathrm{MA}}$ to compensate for the normalization by token length which is otherwise already contained in u_{MA}(n is the length of the respective sentence). For u_{LC}, the preparatory experiments already showed that this utility function does not behave on a linear scale. This is so because u_{LC} is based on $P_\theta(\vec{y}|\vec{x})$ for confidence estimation of the complete label sequence $\vec{y}$. Hence, a u_{LC} score twice as high does not indicate doubled benefit for classifier training. Thus, we need a non-linear calibration function to transform u_{LC} into a proper utility estimator on a linear scale so that BCR can be applied.

To determine such a non-linear calibration function, the *true* benefit of an example p would



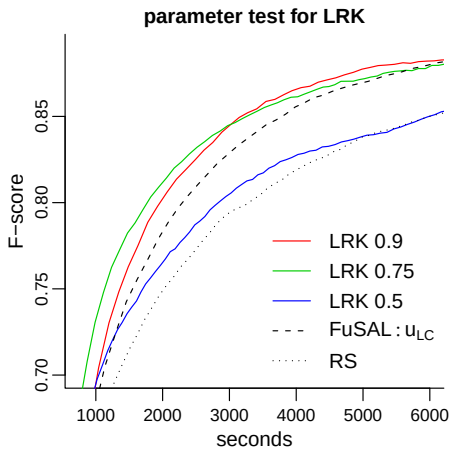


Figure 2: Different parameter settings for CCS and LRK based on FuSAL with u_{LC} as utility function. FuSAL: u_{LC} refers to cost-*in*sensitive FuSAL, CCS and LRK to the cost-sensitive versions of FuSAL with the respective parameters.

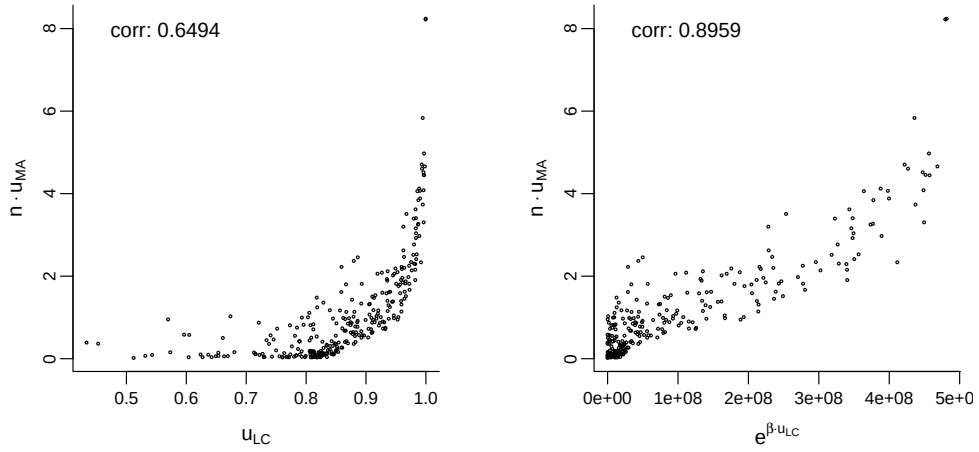

Figure 3: Scatter plots for (a) u_{LC} versus $n \cdot u_{\mathrm{MA}}$ and (b) $e^{\beta \cdot u_{\mathrm{LC}}}$ versus $n \cdot u_{\mathrm{MA}}$

be needed. In the absence of such information, we consider $n \cdot u_{\mathrm{MA}}$ as a good approximation. To identify the relationship between u_{LC} and $n \cdot u_{\mathrm{MA}}$, we trained a model on a random subsample from $P' \subset \mathcal{P}$ and used this model to obtain the scores for u_{LC} and $n \cdot u_{\mathrm{MA}}$ for each example from the test set $\mathcal{T}$.[2] Figure 3 (left) shows a scatter plot of these scores which provides ample evidence that the relationship between u_{LC} and benefit is indeed non-linear. As calibration function for u_{LC} we propose $f(p) = e^{\beta \cdot u_{\mathrm{LC}}(p)}$. Experimentally, we determined $\beta = 20$ as a good value. Figure 3 (right) reveals that $e^{\beta \cdot u_{\mathrm{LC}}(p)}$ is a better utility estimator; the correlation with $n \cdot u_{\mathrm{MA}}$ is now $corr = 0.8959$ and the relationship is close to being linear.

In Figure 4, learning curves for BCR with the utility function u_{LC} and the calibrated function $e^{\beta \cdot u_{\mathrm{LC}}(p)}$ are compared. BCR with the uncalibrated utility function u_{LC} fails miserably (the performance falls even below random selection). This adds credibility to our claim that while u_{LC} may be appropriate for *ranking* examples (as for standard, cost-*in*sensitive AL), it is inappropriate for *estimating* true benefit/utility which is needed when costs are to be incorporated with the BCR method. BCR with the calibrated utility $e^{\beta \cdot u_{\mathrm{LC}}(p)}$, in contrast, outperforms cost-*in*sensitive FuSAL. For further experiments with BCR, we either apply $n \cdot u_{\mathrm{MA}}$ or $e^{\beta \cdot u_{\mathrm{LC}}(p)}$ as utility functions.

[2] We experimented with different sizes for P', with almost identical results.

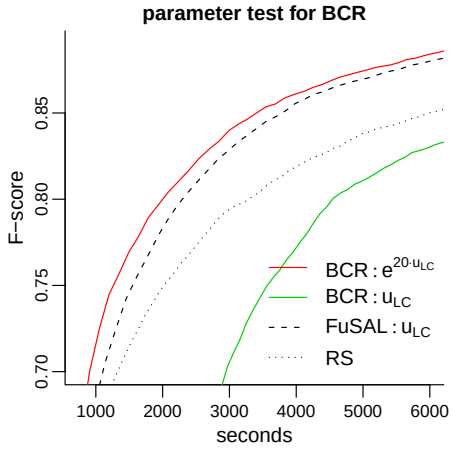

Figure 4: Different parameter settings for BCR

3.2 Comparison of CoSAL Approaches

We compared all three approaches to CoSAL in the parametrization chosen above for the utility functions u_{MA} and u_{LC}. Learning curves are shown in Figure 5. Improvements over cost-*in*sensitive AL are only achieved in early AL iterations up to 2,500s (for CoSAL based on u_{MA}) or 4,000s (for CoSAL based on u_{LC}) of annotation time. This exclusiveness of early improvements can be explained by the size of the corpus and, by this, the limited number of good selection options. Since AL selects with respect to two conflicting criteria, the pool $\mathcal{P}$ should be much larger to increase the chance for examples that are favorable with respect to both criteria.

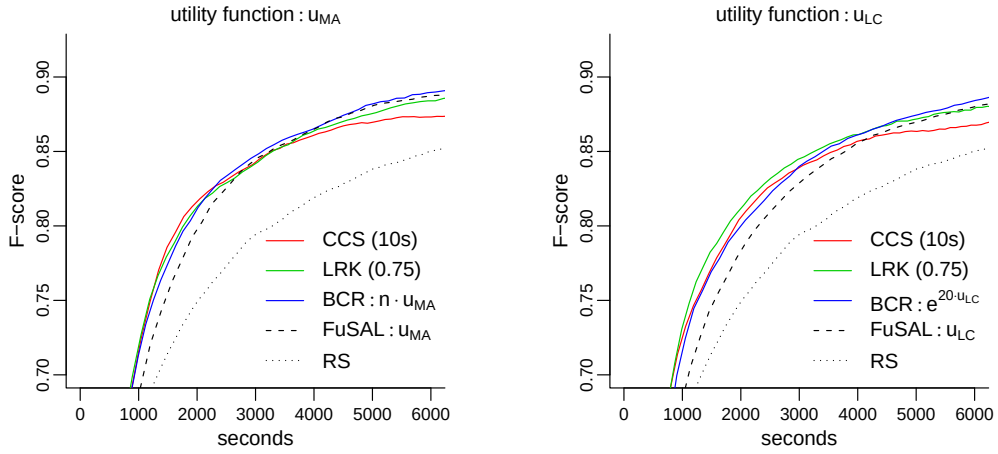

Figure 5: Comparison of CoSAL approaches for the utility functions u_{MA} and u_{LC}. Baseline given by random selection (RS) and standard FuSAL with either u_{MA} or u_{LC}.

Improvements for CoSAL based on u_{LC} are generally higher than for u_{MA}. Moreover, cost-*in*sensitive AL based on u_{LC} does not exhibit any normalization where, in contrast, u_{MA} is normalized at least to the number of tokens per example. In CoSAL, both u_{LC} and u_{MA} are normalized by costs, which is methodologically a more substantial enhancement for u_{LC} than for u_{MA}.

For CoSAL based on u_{MA} we cannot proclaim a clear winner among the different approaches. All three CoSAL approaches improve upon cost-*in*sensitive AL. For CoSAL based on u_{LC}, LRK performs best, while CCS and BCR perform similarly well. Given this result, we might prefer LRK or CCS over BCR. A disadvantage of the first two approaches is that they require corpus-specific parameters which may be difficult to find for a new learning problem for which no data for experimentation is at hand. Though not the best performer, BCR does not require further parametrization and appears more appropriate for real-life annotation projects – as long as utility is an appropriate estimator for benefit. CoSAL with BCR has already been studied by Settles et al. (2008). They also applied a utility function based on sequence-confidence estimation which presumably, as with our u_{LC} utility function, is not a good benefit estimator. The fact that Settles et al. did not explicitly treat this issue might explain why cost-sensitive AL based on BCR often performed worse than cost-*in*sensitive AL in their experiments.

3.3 CoSAL Applied to SeSAL

We looked at a cost-sensitive version of SeSAL by applying the cost-sensitive FuSAL approach together with BCR and the transformation function for the utility as discussed above. On top of this selection, we ran the standard SeSAL approach – only tokens below a confidence threshold were selected for annotation. The following experiments are all based on the u_{LC} utility function (and the transformation function of it).

Figure 6 depicts learning curves for cost-*in*sensitive and cost-sensitive SeSAL and FuSAL which reveal that cost-sensitive SeSAL consid-

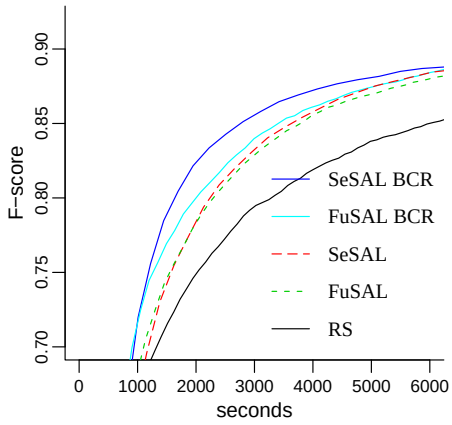

Figure 6: Cost-sensitive (BCR variants) *vs.* cost-*in*sensitive FuSAL and SeSAL with u_{LC} as utility function.

erably outperforms cost-sensitive FuSAL. Cost-sensitive SeSAL attains a target performance of F=0.85 with only 2806s, while cost-sensitive FuSAL needs 3410s, and random selection consumes over 6060s. Thus, cost-sensitive SeSAL here reduces true annotation time by about 54 % compared to random selection, whereas cost-sensitive FuSAL reduces annotation time by only 44 %.

4 Related Work

Although the reduction of data acquisition costs that result from human labeling efforts have always been the main driver for AL studies, *cost-sensitive AL* is a new branch of AL. In an early study on cost metrics for AL, Becker and Osborne (2005) examined whether AL, while decreasing the sample size on the one hand, on the other hand increased annotation efforts. For a real-world AL annotation project, they demonstrated that the actual sampling efficiency measure for an AL approach depends on the cost metric being applied. In a companion paper, Hachey et al. (2005) studied how sentences selected by AL affected the annotators' performance both in terms of the time needed and the annotation accuracy achieved. They found that selectively sampled examples are, on the average, more difficult to annotate than randomly sampled ones. This observation, for the first time, questioned the widespread assumption that all annotation examples can be assigned a uniform cost factor.

Making a standard AL approach cost-sensitive by normalizing utility in terms of annotation time has been proposed before by Haertel et al. (2008), Settles et al. (2008), and Donmez and Carbonell (2008). CoSAL based on the net-benefit (costs subtracted from utility) was proposed by Vijayanarasimhan and Grauman (2009) for object recognition in images and Kapoor et al. (2007) for voice message classification.

5 Conclusions

We investigated three approaches to incorporate the notion of cost into the AL selection mechanism, including a fixed maximal cost budget per example, a linear rank combination to express net-benefit, and a benefit-cost ratio. The cost metric we applied was the *time* needed by human coders for annotating particular annotation examples.

Among the three approaches to cost-sensitive AL, we see a slight advantage for benefit cost ratios in real-world settings because they do not require additional corpus-specific parametrization, once a proper calibration function is found.

Another observation is that advantages of the three cost-sensitive AL models over cost-*in*sensitive ones consistently occur only in early iteration rounds – a result we attribute to corpus exhaustion effects since cost-sensitive AL selects for two criteria (utility and cost) and thus requires a extremely large pool to be able to pick up really advantageous examples. Consequently, applied to real-world annotation settings where the pools may be extremely large, we expect cost-sensitive approaches to be even more effective in terms of the reduction of annotation time.

To be applicable in real-world scenarios, annotation costs which, in our experiments, were directly traceable in the MUC7$_\mathcal{T}$ corpus have to be estimated since they are not known prior to annotation. In Tomanek et al. (2010), we investigated the reading behavior during named entity annotation using eye-tracking technology. With the insights gained from this study on crucial factors influencing annotation time we were able to induce such a much needed *predictive* model of annotation costs. In future work, we plan to incorporate this empirically founded cost model into our approaches to cost-sensitive AL and to investigate whether our positive findings can be reproduced with estimated costs as well.

Abstract

We present a general methodology for extracting multi-word expressions (of various types), along with their translations, from small parallel corpora. We automatically align the parallel corpus and focus on *mis*alignments; these typically indicate expressions in the source language that are translated to the target in a non-compositional way. We then use a large monolingual corpus to rank and filter the results. Evaluation of the quality of the extraction algorithm reveals significant improvements over naïve alignment-based methods. External evaluation shows an improvement in the performance of machine translation that uses the extracted dictionary.

1 Introduction

Multi-word Expressions (MWEs) are lexical items that consist of multiple orthographic words (e.g., *ad hoc*, *by and large*, *New York*, *kick the bucket*). MWEs are numerous and constitute a significant portion of the lexicon of any natural language. They are a heterogeneous class of constructions with diverse sets of characteristics, distinguished by their idiosyncratic behavior. Morphologically, some MWEs allow some of their constituents to freely inflect while restricting (or preventing) the inflection of other constituents. In some cases MWEs may allow constituents to undergo non-standard morphological inflections that they would not undergo in isolation. Syntactically, some MWEs behave like words while other are phrases; some occur in one rigid pattern (and a fixed order), while others permit various syntactic transformations. Semantically, the compositionality of MWEs is gradual, ranging from fully compositional to idiomatic (Bannard et al., 2003).

Because of their prevalence and irregularity, MWEs must be stored in lexicons of natural language processing applications. Handling MWEs correctly is beneficial for a variety of applications, including information retrieval, building ontologies, text alignment, and machine translation.

Identifying MWEs and extracting them from corpora is therefore both important and difficult. In Hebrew (which is the subject of our research), this is even more challenging due to two reasons: the rich and complex morphology of the language; and the dearth of existing language resources, in particular parallel corpora, semantic dictionaries and syntactic parsers.

We propose a novel algorithm for identifying MWEs in bilingual corpora, using automatic word alignment as our main source of information. In contrast to existing approaches, we do not limit the search to one-to-many alignments, and propose an error-mining strategy to detect misalignments in the parallel corpus. We also consult a large monolingual corpus to rank and filter out the expressions. The result is fully automatic extraction of MWEs of various types, lengths and syntactic patterns, along with their translations. We demonstrate the utility of the methodology on Hebrew-English MWEs by incorporating the extracted dictionary into an existing machine translation system.

The main contribution of the paper is thus a new alignment-based algorithm for MWE extraction that focuses on misalignments, augmented by validating statistics computed from a monolingual corpus. After discussing related work, we detail in Section 3 the methodology we propose. Section 4 provides a thorough evaluation of the results. We then extract translations of the identified MWEs and evaluate the contribution of the extracted dictionary in Section 5. We conclude with suggestions for future research.

Beijing, August 2010

2 Related Work

Early approaches to identifying MWEs concentrated on their collocational behavior (Church and Hanks, 1989). Pecina (2008) compares 55 different association measures in ranking German Adj-N and PP-Verb collocation candidates. This work shows that combining different collocation measures using standard statistical classification methods improves over using a single collocation measure. Other results (Chang et al., 2002; Villavicencio et al., 2007) suggest that some collocation measures (especially PMI and Log-likelihood) are superior to others for identifying MWEs. Soon, however, it became clear that mere co-occurrence measurements are not enough to identify MWEs, and their linguistic properties should be exploited as well (Piao et al., 2005). Hybrid methods that combine word statistics with linguistic information exploit morphological, syntactic and semantic idiosyncrasies to extract idiomatic MWEs.

Semantic properties of MWEs can be used to distinguish between compositional and non-compositional (idiomatic) expressions. Katz and Giesbrecht (2006) and Baldwin et al. (2003) use Latent Semantic Analysis for this purpose. They show that compositional MWEs appear in contexts more similar to their constituents than non-compositional MWEs. Van de Cruys and Villada Moirón (2007) use unsupervised learning methods to identify non-compositional MWEs by measuring to what extent their constituents can be substituted by semantically related terms. Such techniques typically require lexical semantic resources that are unavailable for Hebrew.

An alternative approach to using semantics capitalizes on the observation that an expression whose meaning is non-compositional tends to be translated into a foreign language in a way that does not result from a combination of the literal translations of its component words. Alignment-based techniques explore to what extent word alignment in parallel corpora can be used to distinguish between idiomatic expressions and more transparent ones. A significant added value of such works is that MWEs can thus be both identified in the source language and associated with their translations in the target language.

Villada Moirón and Tiedemann (2006) focus on Dutch expressions and their English, Spanish and German translations in the Europarl corpus (Koehn, 2005). To extract the candidates, they use syntactic properties (based on full parsing of the Dutch text) and statistical association measures. This approach requires syntactic resources that are unavailable for Hebrew.

Some recent works concentrate on exploiting translational correspondences of MWEs from (small) parallel corpora. MWE candidates and their translations are extracted as a by-product of automatic word alignment of parallel texts. Unlike Villada Moirón and Tiedemann (2006), who use aligned parallel texts to *rank* MWE candidates, Caseli et al. (2009) actually use them to extract the candidates. After the texts are word-aligned, Caseli et al. (2009) extract sequences of length 2 or more in the source language that are aligned with sequences of length 1 or more in the target. Candidates are then filtered out of this set if they comply with pre-defined part-of-speech patterns, or if they are not sufficiently frequent in the parallel corpus. Even with the most aggressive filtering, precision is below 40% and recall is extremely low (F-score is below 10 for all experiments). Our setup is similar, but we extract MWE candidates from the aligned corpus in a very different way; and we use statistics collected from a *monolingual* corpus to filter and rank the results.

Zarrieß and Kuhn (2009) also use aligned parallel corpora but only focus on one-to-many word alignments. To restrict the set of candidates, they focus on specific syntactic patterns as determined by parsing both sides of the corpus (again, using resources unavailable to us). The results show high precision but very low recall.

3 Methodology

We propose an alternative approach to existing alignment-based techniques for MWE extraction. Using a small bilingual corpus, we extract MWE candidates from noisy word alignments in a novel way. We then use statistics from a large monolingual corpus to rank and filter the list of candidates. Finally, we extract the translation of candidate MWEs from the parallel corpus and use them in a machine translation (MT) system.

3.1 Motivation

Parallel texts are an obvious resource from which to extract MWEs. By definition, idiomatic expressions have a non-compositional meaning, and hence may be translated to a single word (or to an expression with a different meaning) in a foreign language. The underlying assumption of alignment-based approaches to MWE extraction is that MWEs are aligned across languages in a way that differs from compositional expressions; we share this assumption. However, existing approaches focus on the results of word alignment in their quest for MWEs, and in particular consider 1:n and n:m alignments as potential areas in which to look for MWEs. This is problematic for two reasons: first, word alignment algorithms have difficulties aligning MWEs, and hence 1:n and n:m alignments are often noisy; while these environments provide cues for identifying MWEs, they also include much noise. Second, our experimental scenario is such that our parallel corpus is particularly small, and we cannot fully rely on the quality of word alignments, but we have a bilingual dictionary that compensates for this limitation. In contrast to existing approaches, then, we focus on *misalignments*: we trust the quality of 1:1 alignments, which we verify with the dictionary; and we search for MWEs exactly in the areas that word alignment *failed* to properly align, not relying on the alignment in these cases.

Moreover, in contrast to existing alignment-based approaches, we also make use of a large monolingual corpus from which statistics on the distribution of word sequences in Hebrew are drawn. This has several benefits: of course, monolingual corpora are easier to obtain than parallel ones, and hence tend to be larger and provide more accurate statistics. Furthermore, this provides validation of the MWE candidates that are extracted from the parallel corpus: rare expressions that are erroneously produced by the alignment-based technique can thus be eliminated on account of their low frequency in the monolingual corpus.

Specifically, we use pointwise mutual information (PMI) as our association measure. While PMI has been proposed as a good measure for identifying MWEs, it is also known not to discriminate accurately between MWEs and other frequent collocations. This is because it promotes collocations whose constituents rarely occur in isolation (e.g., typos and grammar errors), and expressions consisting of some word that is very frequently followed by another (e.g., *say that*). However, such cases do not have idiomatic meanings, and hence at least one of their constituents is likely to have a 1:1 alignment in the parallel corpus; we only use PMI *after* such alignments have been removed.

An added value of our methodology is the automatic production of an MWE translation dictionary. Since we start with a parallel corpus, we can go back to that corpus after MWEs have been identified, and extract their translations from the parallel sentences in which they occur.

Finally, alignment-based approaches can be symmetric, and ours indeed is. While our main motivation is to extract MWEs in Hebrew, a by-product of our system is the extraction of *English* MWEs, along with their translations to Hebrew. This, again, contributes to the task of enriching our existing bilingual dictionary.

3.2 Resources

Our methodology is in principle language-independent and appropriate for medium-density languages (Varga et al., 2005). We assume the following resources: a small bilingual, sentence-aligned parallel corpus; large monolingual corpora in both languages; morphological processors (analyzers and disambiguation modules) for the two languages; and a bilingual dictionary. Our experimental setup is Hebrew-English. We use a small parallel corpus (Tsvetkov and Wintner, 2010) consisting of 19,626 sentences, mostly from newspapers. The corpus consists of 271,787 English tokens (14,142 types) and 280,508 Hebrew tokens (12,555 types), and is similar in size to that used by Caseli et al. (2009).

We also use data extracted from two monolingual corpora. For Hebrew, we use the morphologically-analyzed MILA corpus (Itai and Wintner, 2008) with part-of-speech tags produced by Bar-Haim et al. (2005). This corpus is much larger, consisting of 46,239,285 tokens (188,572 types). For English we use Google's Web 1T corpus (Brants and Franz, 2006).

Finally, we use a bilingual dictionary consist-

ing of 78,313 translation pairs. Some of the entries were collected manually, while others are produced automatically (Itai and Wintner, 2008; Kirschenbaum and Wintner, 2010).

3.3 Preprocessing the corpora

Automatic word alignment algorithms are noisy, and given a small parallel corpus such as ours, data sparsity is a serious problem. To minimize the parameter space for the alignment algorithm, we attempt to reduce language specific differences by pre-processing the parallel corpus. The importance of this phase should not be underestimated, especially for alignment of two radically different languages such as English and Hebrew (Dejean et al., 2003).

Hebrew,[1] like other Semitic languages, has a rich, complex and highly productive morphology. Information pertaining to gender, number, definiteness, person, and tense is reflected morphologically on base forms of words. In addition, prepositions, conjunctions, articles, possessives, etc., may be concatenated to word forms as prefixes or suffixes. This results in a very large number of possible forms per lexeme. We therefore tokenize the parallel corpus and then remove punctuation. We analyze the Hebrew corpus morphologically and select the most appropriate analysis in context. Adopting this selection, the surface form of each word is reduced to its base form, and bound morphemes (prefixes and suffixes) are split to generate stand-alone "words". We also tokenize and lemmatize the English side of the corpus, using the Natural Language Toolkit package (Bird et al., 2009).

Then, we remove some language-specific differences automatically. We remove frequent function words: in English, the articles *a*, *an* and *the*, the infinitival *to* and the copulas *am*, *is* and *are*; in Hebrew, the accusative marker *at*. These forms do not have direct counterparts in the other language.

For consistency, we pre-process the monolingual corpora in the same way. We then compute the frequencies of all word bi-grams occurring in each of the monolingual corpora.

[1] To facilitate readability we use a transliteration of Hebrew using Roman characters; the letters used, in Hebrew lexicographic order, are *abgdhwzxTiklmns'pcqršt*.

3.4 Identifying MWE candidates

The motivation for our MWE identification algorithm is the assumption that there may be three sources to misalignments (anything that is not a 1:1 word alignment) in parallel texts: either MWEs (which trigger 1:n or n:m alignments); or language-specific differences (e.g., the source language lexically realizes notions that are realized morphologically, syntactically or in some other way in the target language); or noise (e.g., poor translations, low-quality sentence alignment, and inherent limitations of word alignment algorithms).

This motivation induces the following algorithm. Given a parallel, sentence-aligned corpus, it is first pre-processed as described above, to reduce the effect of language-specific differences. We then use Giza++ (Och and Ney, 2003) to word-align the text, employing *union* to merge the alignments in both directions. We look up all 1:1 alignments in the dictionary. If the pair exists in our bilingual dictionary, we remove it from the sentence and replace it with a special symbol, '*'. Such word pairs are not parts of MWEs. If the pair is not in the dictionary, but its alignment score is very high (above 0.5) and it is sufficiently frequent (more than 5 occurrences), we add the pair to the dictionary but also retain it in the sentence. Such pairs are still candidates for being (parts of) MWEs.

Example 1 *Figure 1-a depicts a Hebrew sentence with its word-by-word gloss, and its English translation in the parallel corpus. Here,* bn adm *"person" is a MWE that cannot be translated literally. After pre-processing (Section 3.3), the English is represented as "and i tell her keep away from person" (note that* to *and* the *were deleted). The Hebrew, which is aggressively segmented, is represented as in Figure 1-b. Note how this reduces the level of (morphological and orthographic) difference between the two languages. Consequently, Giza++ finds the alignment depicted in Figure 1-c. Once 1:1 alignments are replaced by '*', the alignment of Figure 1-d is obtained.*

If our resources were perfect, i.e., if word alignment made no errors, the dictionary had perfect coverage and our corpora induced perfect statis-

a. *wamrti* *lh* *lhzhr* *mbn* *adm* *kzh*
and-I-told to-her to-be-careful from-child man like-this
"and I told her to keep away from the person"

b. *w* *ani* *amr* *lh* *lhzhr* *m* *bn* *adm* *k* *zh*
and I tell to-her to-be-careful from child man like this

c. *w* *ani* *amr* *lh* *lhzhr* *m* *bn adm* *k* *zh*
and I told her keep away from person {} {}

d. * * * * *lhzhr* * *bn adm* *k* *zh*
* * * * keep away * person

Figure 1: Example sentence pair (a); after pre-processing (b); after word alignment (c); and after 1:1 alignments are replaced by '*' (d)

tics, then all remaining text (other than the special symbol) in the parallel text would be part of MWEs. In other words, all sequences of remaining source words, separated by '*', are MWE candidates. As our resources are far from perfect, further processing is required in order to prune these candidates. For this, we use association measures computed from the monolingual corpus.

3.5 Ranking and filtering MWE candidates

The algorithm described above produces sequences of Hebrew word forms (free and bound morphemes produced by the pre-processing stage) that are not 1:1-aligned, separated by '*'s. Each such sequence is a MWE candidate. In order to rank the candidates we use statistics from a large *monolingual* corpus. We do *not* rely on the alignments produced by Giza++ in this stage.

We extract all word bi-grams from the remaining candidates. Each bi-gram is associated with its PMI-based score,[2] computed from the monolingual corpus. Interestingly, about 20,000 candidate MWEs are removed in this stage because they do not occur at all in the monolingual corpus.

We then experimentally determine a threshold (see Section 4). A word sequence *of any length* is considered MWE if all the adjacent bi-grams it contains score above the threshold. Finally, we restore the original forms of the Hebrew words in the candidates, combining together bound morphemes that were split during pre-processing; and we restore the function words. Many of the candidate MWEs produced in the previous stage are eliminated now, since they are not genuinely multi-word in the original form.

Example 2 *Refer back to Figure 1-d. The sequence* bn adm k zh *is a MWE candidate. Two bi-grams in this sequence score above the threshold:* bn adm*, which is indeed a MWE, and* k zh*, which is converted to the original form* kzh *and is hence not considered a candidate. We also consider* adm k*, whose score is low. Note that the same aligned sentence can be used to induce the* English *MWE keep away, which is aligned to a single Hebrew word.*

3.6 Results

As an example of the results obtained with this setup, we list in Table 1 the 15 top-ranking extracted MWEs. For each instance we list an indication of the type of MWE: person name (PN), geographical term (GT), noun-noun compound (NNC) or noun-adjective combination (N-ADJ). Of the top 100 candidates, 99 are clearly MWEs,[3] including *mzg awir* (*temper-of air*) "weather", *kmw kn* (*like thus*) "furthermore", *bit spr* (*house-of book*) "school", *šdh t'wph* (*field-of flying*) "airport", *tšwmt lb* (*input-of heart*) "attention", *ai apšr* (*not possible*) "impossible" and *b'l ph*

[2] PMI^k is a heuristic variant of the PMI measure, proposed and studied by Daille (1994), where k, the exponent, is a frequency-related factor, used to demote collocations with low-frequency constituents. The value of the parameter k can be chosen freely ($k > 0$) in order to tune the properties of the PMI to the needs of specific applications. We conducted experiments with k = 0, 0.1, ... , 3 and found k = 2.7 to give the best results for our application.

[3] This was determined by two annotators.

(*in-on mouth*) "orally". Longer MWEs include *ba lidi biTwi* (*came to-the-hands-of expression*) "was expressed"; *xzr ‘l ‘cmw* (*returned on itself*) "recurred"; *ixd ‘m zat* (*together with it*) "in addition"; and *h‘crt hkllit šl haw”m* (*the general assembly of the UN*) "the UN general assembly".

4 Evaluation

MWEs are notoriously hard to define, and no clear-cut criteria exist to distinguish between MWEs and other frequent collocations. In order to evaluate the utility of our methodology, we conducted three different types of evaluations that we detail below and in Section 5.

First, we use a small annotated corpus of Hebrew noun-noun constructions that was made available to us (Al-Haj and Wintner, 2010). The corpus consists of 463 high-frequency bi-grams of the same syntactic construction; of those, 202 are tagged as MWEs (in this case, noun compounds) and 258 as non-MWEs. This corpus consolidates the annotation of three annotators: only instances on which all three agreed were included. Since it includes both positive and negative instances, this corpus facilitates a robust evaluation of precision and recall. Of the 202 positive examples, only 121 occur in our parallel corpus; of the 258 negative examples, 91 occur in our corpus. We therefore limit the discussion to those 212 examples whose MWE status we can determine, and ignore other results produced by the algorithm we evaluate.

On this corpus, we compare the performance of our algorithm to four baselines: using only PMI to rank the bi-grams in the parallel corpus; using PMI computed from the monolingual corpus to rank the bi-grams in the parallel corpus; and using Giza++ 1:n alignments, ranked by their PMI (with bi-grams statistics computed once from parallel and once from monolingual corpora). ‘MWE’ refers to our algorithm. For each of the above methods, we set the threshold at various points, and count the number of true MWEs above the threshold (true positives) and the number of non-MWEs above the threshold (false positives), as well as the number of MWEs and non-MWEs below the threshold (false positives and true negatives, respectively). From these four figures we compute precision, recall and their harmonic mean, f-score, which we plot against (the number of results above) the threshold in Figure 2. Clearly, the performance of our algorithm is consistently above the baselines.

Second, we evaluate the algorithm on additional datasets. We compiled three small corpora of Hebrew two-word MWEs. The first corpus, **PN**, contains 785 person names (names of Knesset members and journalists), of which 157 occur in the parallel corpus. The second, **Phrases**, consists of 571 entries beginning with the letter *x* from a dictionary of Hebrew phrases (Rosenthal, 2009), and a set of 331 idioms we collected from internet resources. Of those, 154 occur in the corpus. The third set, **NN**, consists of the positive examples in the annotated corpus of noun-noun constructions described above.

Since we do not have negative examples for these sets, we only evaluate recall, using a threshold reflecting 2750 results. For each of these datasets, we report the number of MWEs in the dataset (which also occur in the parallel corpus, of course) our algorithm detected. We compare in Table 2 the recall of our method (MWE) to Giza++ alignments, as above, and list also the upper bound (UB), obtained by taking all above-threshold bi-grams in the corpus.

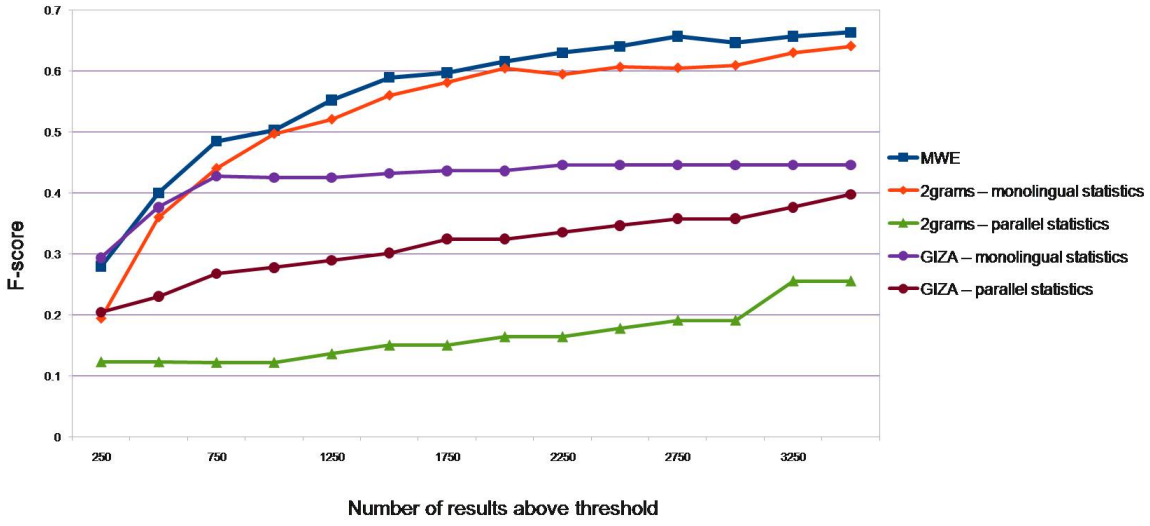

Figure 2: Evaluation results compared with baselines: noun-noun compounds

Method	PN		Phrases		NN	
	#	%	#	%	#	%
UB	74	100	40	100	89	100
MWE	66	89.2	35	87.5	67	75.3
Giza	7	9.5	33	82.5	37	41.6

Table 2: Recall evaluation

5 Extraction of MWE translations

An obvious benefit of using parallel corpora for MWE extraction is that the translations of extracted MWEs are available in the corpus. We use a naïve approach to identify these translations. For each MWE in the source-language sentence, we consider as translation all the words in the target-language sentence (in their original order) that are aligned to the word constituents of the MWE, as long as they form a contiguous string. Since the quality of word alignment, especially in the case of MWEs, is rather low, we remove "translations" that are longer than four words (these are most often wrong). We then associate each extracted MWE in Hebrew with all its possible English translations.

The result is a bilingual dictionary containing 2,955 MWE translation pairs, and also 355 translation pairs produced by taking high-quality 1:1 word alignments (Section 3.4). We used the extracted MWE bilingual dictionary to augment the existing (78,313-entry) dictionary of a transfer-based Hebrew-to-English statistical machine translation system (Lavie et al., 2004b). We report in Table 3 the results of evaluating the performance of the MT system with its original dictionary and with the augmented dictionary. The results show a statistically-significant ($p < 0.1$) improvement in terms of both BLEU (Papineni et al., 2002) and Meteor (Lavie et al., 2004a) scores.

Dictionary	BLEU	Meteor
Original	13.69	33.38
Augmented	13.79	33.99

Table 3: External evaluation

As examples of improved translations, a sentence that was originally translated as "His teachers also hate to the Zionism and besmirch his HRCL and Gurion" (fully capitalized words indicate lexical omissions that are transliterated by the MT system) is translated with the new dictionary as "His teachers also hate to the Zionism and besmirch his Herzl and David Ben-Gurion"; a phrase originally translated as "when so" is now properly translated as "likewise"; and several occurrences of "down spring" and "height of spring" are corrected to "Tel Aviv".

6 Conclusion

We described a methodology for extracting multiword expressions from parallel corpora. The algorithm we propose capitalizes on semantic cues provided by ignoring 1:1 word alignments, and viewing all other material in the parallel sentence as potential MWE. It also emphasizes the importance of properly handling the morphology and orthography of the languages involved, reducing wherever possible the differences between them in order to improve the quality of the alignment. We use statistics computed from a large monolingual corpus to rank and filter the results. We used the algorithm to extract MWEs from a small Hebrew-English corpus, demonstrating the ability of the methodology to accurately extract MWEs of various lengths and syntactic patterns. We also demonstrated that the extracted MWE bilingual dictionary can improve the quality of MT.

This work can be extended in various ways. While several works address the choice of association measure for MWE identification and for distinguishing between MWEs and other frequent collocations, it is not clear which measure would perform best in our unique scenario, where candidates are produced by word (mis)alignment. We intend to explore some of the measures discussed by Pecina (2008) in this context. The algorithm used for extracting the translations of candidate MWEs is obviously naïve, and we intend to explore more sophisticated algorithms for improved performance. Also, as our methodology is completely language-symmetric, it can be used to produce MWE candidates in English. In fact, we already have such a list of candidates, whose quality we will evaluate in the future. Finally, as our main motivation is high-precision, high-recall extraction of Hebrew MWEs, we develop other, non-alignment-based approaches to the task (Al-Haj and Wintner, 2010), and would like to explore the utility of combining different approaches to the same task under a unified framework. We are actively pursuing these research directions.

Acknowledgments

This research was supported by THE ISRAEL SCIENCE FOUNDATION (grants No. 137/06, 1269/07). We are grateful to Hassan Al-Haj for providing the noun compound annotated corpus and to Gennadi Lembersky for his help with the machine translation system.

Citation Author Topic Model in Expert Search

Yuancheng Tu, Nikhil Johri, Dan Roth, Julia Hockenmaier

Abstract

This paper proposes a novel topic model, Citation-Author-Topic (CAT) model that addresses a semantic search task we define as expert search – given a research area as a query, it returns names of experts in this area. For example, *Michael Collins* would be one of the top names retrieved given the query *Syntactic Parsing*.

Our contribution in this paper is two-fold. First, we model the cited author information together with words and paper authors. Such extra contextual information directly models linkage among authors and enhances the author-topic association, thus produces more coherent author-topic distribution. Second, we provide a preliminary solution to the task of expert search when the learning repository contains exclusively research related documents authored by the experts. When compared with a previous proposed model (Johri et al., 2010), the proposed model produces high quality author topic linkage and achieves over 33% error reduction evaluated by the standard MAP measurement.

1 Introduction

This paper addresses the problem of searching for people with similar interests and expertise, given their field of expertise as the query. Many existing people search engines need people's names to do a "keyword" style search, using a person's name as a query. However, in many situations, such information is insufficient or impossible to know beforehand. Imagine a scenario where the statistics department of a university invited a world-wide known expert in Bayesian statistics and machine learning to give a keynote speech; how can the organizer notify all the people on campus who are interested without spamming those who are not? Our paper proposes a solution to the aforementioned scenario by providing a search engine which goes beyond "keyword" search and can retrieve such information semantically. The organizer would only need to input the research domain of the keynote speaker, i.e. *Bayesian statistics, machine learning*, and all professors and students who are interested in this topic will be retrieved and an email agent will send out the information automatically.

Specifically, we propose a **C**itation-**A**uthor-**T**opic (CAT) model which extracts academic research topics and discovers different research communities by clustering experts with similar interests and expertise. CAT assumes three steps of a hierarchical generative process when producing a document: first, an author is generated, then that author generates topics which ultimately generate the words and cited authors. This model links authors to observed words and cited authors via latent topics and captures the intuition that when writing a paper, authors always first have topics in their mind, based on which, they choose words and cite related works.

Corpus linguists or forensic linguists usually

Coling 2008: Poster Volume, pages 1265–1273,
Beijing, August 2010

identify authorship of disputed texts based on stylistic features, such as vocabulary size, sentence length, word usage that characterize a specific author and the general semantic content is usually ignored (Diederich et al., 2003). On the other hand, graph-based and network based models ignore the content information of documents and only focus on network connectivity (Zhang et al., 2007; Jurczyk and Agichtein, 2007). In contrast, the model we propose in this paper fully utilizes the content words of the documents and combines them with the stylistic flavor contextual information to link authors and documents together to not only identify the authorship, but also to be used in many other applications such as paper reviewer recommendation, research community identification as well as academic social network search.

The novelty of the work presented in this paper lies in the proposal of jointly modeling the cited author information and using a discriminative multinomial distribution to model the co-author information instead of an artificial uniform distribution. In addition, we apply and evaluate our model in a semantic search scenario. While current search engines cannot support interactive and exploratory search effectively, our model supports search that can answer a range of exploratory queries. This is done by semantically linking the interests of authors to the topics of the collection, and ultimately to the distribution of the words in the documents.

In the rest of this paper, we first present some related work on author topic modeling and expert search in Sec. 2. Then our model is described in Sec. 3. Sec. 4 introduces our expert search system and Sec. 5 presents our experiments and the evaluation. We conclude this paper in Sec. 6 with some discussion and several further developments.

2 Related Work

Author topic modeling, originally proposed in (Steyvers et al., 2004; Rosen-Zvi et al., 2004), is an extension of Latent Dirichlet Allocation (LDA) (Blei et al., 2003), a probabilistic generative model that can be used to estimate the properties of multinomial observations via unsupervised learning. LDA represents each document as a mixture of probabilistic topics and each topic as a multinomial distribution over words. The Author topic model adds an author layer over LDA and assumes that the topic proportion of a given document is generated by the chosen author.

Author topic analysis has attracted much attention recently due to its broad applications in machine learning, text mining and information retrieval. For example, it has been used to predict authors for new documents (Steyvers et al., 2004), to recommend paper reviewers (Rosen-Zvi et al., 2004), to model message data (Mccallum et al., 2004), to conduct temporal author topic analysis (Mei and Zhai, 2006), to disambiguate proper names (Song et al., 2007), to search academic social networks (Tang et al., 2008) and to generate meeting status analyses for group decision making (Broniatowski, 2009).

In addition, there are many related works on expert search at the TREC enterprise track from 2005 to 2007, which focus on enterprise scale search and discovering relationships between entities. In that setting, the task is to find the experts, given a web domain, a list of candidate experts and a set of topics [1]. The task defined in our paper is different in the sense that our topics are hidden and our document repositories are more homogeneous since our documents are all research papers authored by the experts. Within this setting, we can explore in depth the influence of the hidden topics and contents to the ranking of our experts. Similar to (Johri et al., 2010), in this paper we apply CAT in a semantic retrieval scenario, where searching people is associated with a set of hidden semantically meaningful topics instead of their personal names.

In recent literature, there are three main lines of work that extend author topic analyses. One line of work is to relax the model's "bag-of-words" assumption by automatically discovering multi-word phrases and adding them into the original model (Johri et al., 2010). Similar work has also been proposed for other topic models such as Ngram topic models (Wallach, 2006; Wang and McCallum, 2005; Wang et al., 2007; Griffiths et al., 2007).

[1] http://trec.nist.gov/pubs.html

Another line of work models authors information as a general contextual information (Mei and Zhai, 2006) or associates documents with network structure analysis (Mei et al., 2008; Serdyukov et al., 2008; Sun et al., 2009). This line of work aims to propose a general framework to deal with collections of texts with an associated networks structure. However, it is based on a different topic model than ours; for example, Mei's works (Mei and Zhai, 2006; Mei et al., 2008) extend probabilistic latent semantic analysis (PLSA), and do not have cited author information explicitly.

Our proposal follows the last line of work which extends author topic modeling with specific contextual information and directly captures the association between authors and topics together with this contextual information (Tang et al., 2008; Mccallum et al., 2004). For example, in (Tang et al., 2008), publication venue is added as one extra piece of contextual information and in (Mccallum et al., 2004), email recipients, which are treated as extra contextual information, are paired with email authors to model an email message corpus. In our proposed method, the extra contextual information consists of the cited authors in each documents. Such contextual information directly captures linkage among authors and cited authors, enhances author-topic associations, and therefore produces more coherent author-topic distributions.

3 The Citation-Author-Topic (CAT) Model

CAT extends previously proposed author topic models by explicitly modelling the cited author information during the generative process. Compared with these models (Rosen-Zvi et al., 2004; Johri et al., 2010), whose plate notation is shown in Fig. 1, CAT (shown in Fig. 2) adds cited author information and generates authors according to the observed author distribution.

Four plates in Fig. 1 represent topic ($\mathcal{T}$), author ($\mathcal{A}$), document ($\mathcal{D}$) and words in each document ($\mathcal{N}_d$) respectively. CAT (Fig. 2) has one more plate, cited-author topic plate, in which each topic is represented as a multinomial distribution over all cited authors (λ_c).

Within CAT, each author is associated with a multinomial distribution over all topics, $\vec{\theta_a}$, and each topic is a multinomial distribution over all words, $\vec{\phi_t}$, as well as a multinomial distribution over all cited authors $\vec{\lambda_c}$. Three symmetric Dirichlet conjugate priors, η, β and γ, are defined for each of these three multinomial distributions in CAT as shown in Fig. 2.

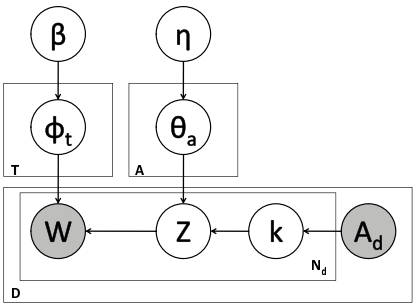

Figure 1: Plate notation of the previously proposed author topic models (Rosen-Zvi et al., 2004; Johri et al., 2010).

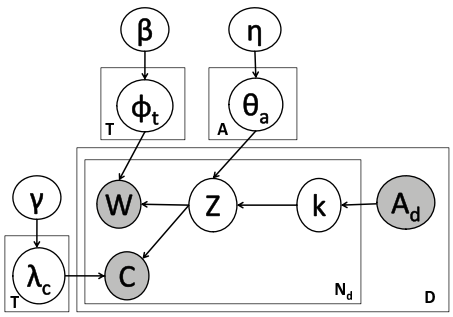

Figure 2: Plate notation of our current model: CAT generates words W and cited authors C independently given the topic.

The generative process of CAT is formally defined in Algorithm 1. The model first samples the word-topic, cited author-topic and the author-topic distributions according to the three Dirichlet hyperparameters. Then for each word in each document, first the author k is drawn from the observed multinomial distribution and that author chooses the topic z_i, based on which word w_i and cited author c_i are generated independently.

CAT differs from previously proposed MAT (Multiword-enhanced Author Topic) model (Johri et al., 2010) in two aspects. First of all, CAT uses

Algorithm 1: CAT: $\mathcal{A}, \mathcal{T}, \mathcal{D}, \mathcal{N}$ are four plates as shown in Fig. 2. The generative process of CAT modeling.

Data: $\mathcal{A}, \mathcal{T}, \mathcal{D}, \mathcal{N}$
for *each topic* $t \in \mathcal{T}$ **do**
  draw a distribution over words:
  $\vec{\phi_t} \sim Dir_{\mathcal{N}}(\beta)$;
  draw a distribution over cited authors:
  $\vec{\lambda_c} \sim Dir_{\mathcal{C}}(\gamma)$;
for *each author* $a \in \mathcal{A}$ **do**
  draw a distribution over topics:
  $\vec{\theta_a} \sim Dir_{\mathcal{T}}(\eta)$;
for *each document* $d \in \mathcal{D}$ *and* k *authors* $\in d$ **do**
  for *each word* $w \in d$ **do**
    choose an author
    $k \sim Multinomial(A_d)$;
    assign a topic i given the author:
    $z_{k,i}|k \sim Multinomial(\theta_a)$;
    draw a word from the chosen topic:
    $w_{d,k,i}|z_{k,i} \sim Multinomial(\phi_{z_{k,i}})$;
    draw a cited author from the topic:
    $c_{d,k,i}|z_{k,i} \sim Multinomial(\lambda_{z_{k,i}})$

cited author information to enhance the model and assumes independence between generating the words and cited authors given the topic. Secondly, instead of an artificial uniform distribution over all authors and co-authors, CAT uses the observed discriminative multinomial distribution to generate authors.

3.1 Parameter Estimation

CAT includes three sets of parameters. The $\mathcal{T}$ topic distribution over words, ϕ_t which is similar to that in LDA. The author-topic distribution θ_a as well as the cited author-topic distribution λ_c. Although CAT is a relatively simple model, finding its posterior distribution over these hidden variables is still intractable due to their high dimensionality. Many efficient approximate inference algorithms have been used to solve this problem including Gibbs sampling (Griffiths and Steyvers, 2004; Steyvers and Griffiths, 2007; Griffiths et al., 2007) and mean-field variational methods (Blei et al., 2003). Gibbs sampling is a special case of Markov-Chain Monte Carlo (MCMC) sampling and often yields relatively simple algorithms for approximate inference in high dimensional models.

In our CAT modeling, we use a collapsed Gibbs sampler for our parameter estimation. In this Gibbs sampler, we integrated out the hidden variables θ, ϕ and λ using the Dirichlet delta function (Heinrich, 2009). The Dirichlet delta function with an M dimensional symmetric Dirichlet prior δ is defined as:

$$\Delta_M(\delta) = \frac{\Gamma(\delta^M)}{\Gamma(M\delta)}$$

Based on the independence assumptions defined in Fig. 2, the joint distribution of topics, words and cited authors given all hyperparameters which originally represented by integrals can be transformed into the delta function format and formally derived in Equation 1.

$$\begin{aligned} & P(\vec{z}, \vec{w}, \vec{c}|\beta, \eta, \lambda) \\ = \; & P(\vec{z}|\beta, \eta, \lambda) P(\vec{w}, \vec{c}|\vec{z}, \beta, \eta, \lambda) \\ = \; & P(\vec{z}) P(\vec{w}|\vec{z}) P(\vec{c}|\vec{z}) \\ = \; & \prod_{a=1}^{A} \frac{\Delta(n_A+\eta)}{\Delta(\eta)} \prod_{z=1}^{T} \frac{\Delta(n_{Z_w}+\beta)}{\Delta(\beta)} \prod_{z=1}^{T} \frac{\Delta(n_{Z_c}+\lambda)}{\Delta(\lambda)} \end{aligned} \tag{1}$$

The updating equation from which the Gibbs sampler draws the hidden variable for the current state j, i.e., the conditional probability of drawing the k^{th} author K_j^k, the i^{th} topic Z_j^i, and the c^{th} cited author C_j^c tuple, given all the hyperparameters and all the observed documents and authors, cited authors except the current assignment (the exception is denoted by the symbol $\forall \neg j$), is defined in Equation 2.

$$\begin{aligned} & P(Z_j^i, K_j^k, C_j^c | W_j^w, \forall \neg j, A_d, \beta, \eta, \gamma) \\ \propto \; & \frac{\Delta(n_Z+\beta)}{\Delta(n_{Z,\neg j}+\beta)} \frac{\Delta(n_K+\eta)}{\Delta(n_{K,\neg j}+\eta)} \frac{\Delta(n_C+\gamma)}{\Delta(n_{C,\neg j}+\gamma)} \\ = \; & \frac{n^w_{i,\neg j}+\beta_w}{\sum_{w=1}^{V} n^w_{i,\neg j}+V\beta_w} \frac{n^i_{k,\neg j}+\eta_i}{\sum_{i=1}^{T} n^i_{k,\neg j}+T\eta_i} \frac{n^c_{i,\neg j}+\lambda_c}{\sum_{c=1}^{C} n^c_{i,\neg j}+C\lambda_c} \end{aligned} \tag{2}$$

The parameter sets ϕ and θ, λ can be interpreted as sufficient statistics on the state variables of the Markov Chain due to the Dirichlet conjugate priors we used for the multinomial distributions.

These three sets of parameters are estimated based on Equations 3 , 4 and 5 respectively, in which n_i^w is defined as the number of times the word w is generated by topic i; n_k^i is defined as the number of times that topic i is generated by author k and n_c^i is defined as the number of times that the cited author c is generated by topic i. The vocabulary size is V, the number of topics is T and the cited-author size is C.

$$\phi_{w,i} = \frac{n_i^w + \beta_w}{\sum_{w=1}^{V} n_i^w + V\beta_w} \quad (3)$$

$$\theta_{k,i} = \frac{n_k^i + \eta_i}{\sum_{i=1}^{T} n_k^i + T\eta_i} \quad (4)$$

$$\lambda_{c,i} = \frac{n_i^c + \lambda_c}{\sum_{c=1}^{C} n_i^c + C\lambda_c} \quad (5)$$

The Gibbs sampler used in our experiments is adapted from the Matlab Topic Modeling Toolbox [2].

4 Expert Search

In this section, we describe a preliminary retrieval system that supports *expert search*, which is intended to identify groups of research experts with similar research interests and expertise by inputting only general domain key words. For example, we can retrieve *Michael Collins* via search for *natural language parsing*.

Our setting is different from the standard TREC expert search in that we do not have a pre-defined list of experts and topics, and our documents are all research papers authored by experts. Within this setting, we do not need to identify the status of our experts, i.e., a real expert or a communicator, as in TREC expert search. All of our authors and cited authors are experts and the task amounts to ranking the experts according to different topics given samples of their research papers.

The ranking function of this retrieval model is derived through the CAT parameters. The search aims to link research topics with authors to bypass the proper names of these authors. Our retrieval function ranks the joint probability of the query words (W) and the target author (a), i.e., $P(W, a)$. This probability is marginalized over all topics, and the probability that an author is cited given the topic is used as an extra weight in our ranking function. The intuition is that an author who is cited frequently should be more prominent and ranked higher. Formally, we define the ranking function of our retrieval system in Equation 6. c_a denotes when the author is one of the cited authors in our corpus. CAT assumes that words and authors, and cited authors are conditionally independent given the topic, i.e., $w_i \perp \text{a} \perp c_a$.

$$\begin{aligned} P(W, a) &= \sum_{w_i} \alpha_i \sum_t P(w_i, a|t, c_a)P(t, c_a) \\ &= \sum_{w_i} \alpha_i \sum_t P(w_i|t)P(a|t)P(c_a|t)P(t) \end{aligned} \quad (6)$$

W is the input query, which may contain one or more words. If a multiword is detected within the query, it is added into the query. The final score is the sum of all words in this query weighted by their inverse document frequency α_i.

In our experiments, we chose ten queries which cover several popular research areas in computational linguistics and natural language processing and run the retrieval system based on three models: the original author topic model (Rosen-Zvi et al., 2004), the MAT model (Johri et al., 2010) and the CAT model. In the original author topic model, query words are treated token by token. Both MAT and CAT expand the query terms with multiwords if they are detected inside the original query. For each query, top 10 authors are returned from the system. We manually label the relevance of these 10 authors based on the papers collected in our corpus.

Two standard evaluation metrics are used to measure the retrieving results. First we evaluate the precision at a given cut-off rank, namely precision at rank k with k ranging from 1 to 10. We then calculate the average precision (AP) for each query and the mean average precision (MAP) for

[2] http://psiexp.ss.uci.edu/research/programs_data/

the queries. Unlike precision at k, MAP is sensitive to the ranking and captures recall information since it assumes the precision of the non-retrieved documents to be zero. It is formally defined as the average of precisions computed at the point of each of the relevant documents in the ranked list as shown in Equation 7.

$$AP = \frac{\sum_{r=1}^{n}(Precision(r) \times rel(r))}{\mid relevant\, documents \mid} \quad (7)$$

To evaluate the recall of our system, we collected a pool of authors for six of our queries returned from an academic search engine, ArnetMiner (Tang et al., 2008)[3] as our reference author pool and evaluate our recall based on the number of authors we retrieved from that pool.

5 Experiments and Analysis

In this section, we describe the empirical evaluation of our model qualitatively and quantitatively by applying our model to the expert search we defined in Sec. 4. We compare the retrieving results with two other models: Multiword- enhanced Author Topic (MAT) model (Johri et al., 2010) and the original author topic model (Rosen-Zvi et al., 2004).

5.1 Data set and Pre-processing

We crawled the ACL anthology website and collected papers from ACL, EMNLP and CONLL over a period of seven years. The ACL anthology website explicitly lists each paper together with its title and author information. Therefore, the author information of each paper can be obtained accurately without extracting it from the original paper. However, many author names are not represented consistently. For example, the same author may have his/her middle name listed in some papers, but not in others. We therefore normalized all author names by eliminating middle names from all authors.

Cited authors of each paper are extracted from the reference section and automatically identified by a named entity recognizer tuned for citation extraction (Ratinov and Roth, 2009). Similar to regular authors, all cited authors are also normalized with their first name initial and their full last name. We extracted about 20,000 cited authors from our corpus. However, for the sake of efficiency, we only keep those cited authors whose occurrence frequency in our corpus is above a certain threshold. We experimented with thresholds of 5, 10 and 20 and retained the total number of 2,996, 1,771 and 956 cited authors respectively.

Conf.	Year	Paper	Author	uni.	Vocab.
ACL	03-09	1,326	2,084	34,012	205,260
EMNLP	93-09	912	1,453	40,785	219,496
CONLL	97-09	495	833	27,312	123,176
Total	93-09	2,733	2,911	62,958	366,565

Table 1: Statistics about our data set. *Uni.* denotes unigram words and *Vocab.* denotes all unigrams and multiword phrases discovered in the data set.

We applied the same strategy to extract multiwords from our corpus and added them into our vocabulary to implement the model described in (Johri et al., 2010). Some basic statistics about our data set are summarized in Table 1 [4].

5.2 Qualitative Coherence Analysis

As shown by other previous works (Wallach, 2006; Griffiths et al., 2007; Johri et al., 2010), our model also demonstrates that embedding multiword tokens into the model can achieve more cohesive and better interpretable topics. We list the top 10 words from two topics of CAT and compare them with those from the unigram model in Table 2. Unigram topics contain more general words which can occur in every topic and are usually less discriminative among topics.

Our experiments also show that CAT achieves better retrieval quality by modeling cited authors jointly with authors and words. The rank of an author is boosted if that author is cited more frequently. We present in Table 3 the ranking of one of our ten query terms to demostrate the high quality of our proposed model. When compared to the model without cited author information, CAT not only retrieves more comprehensive expert list, its ranking is also more reasonable than the model without cited author information.

Another observation in our experiments is that

Table 2: CAT with embedded multiword components achieves more interpretable topics compared with the unigram Author Topic (AT) model.

some experts who published many papers, but on heterogeneous topics, may not be ranked at the very top by models without cited author information. However, with cited author information, those authors are ranked higher. Intuitively this makes sense since many of these authors are also the most cited ones.

5.3 Quantitative retrieval results

One annotator labeled the relevance of the retrieval results from our expert search system. The annotator was also given all the paper titles of each corresponding retrieved author to help make this binary judgment. We experiment with ten queries and retrieve the top ten authors for each query.

Precision@K		
K	CAT Model	Model w/o Cited Authors
1	0.80	0.80
2	0.80	0.70
3	0.73	0.60
4	0.70	0.50
5	0.68	0.48
6	0.70	0.47
7	0.69	0.40
8	0.68	0.45
9	0.73	0.44
10	0.70	0.44

Table 4: Precision at K evaluation of our proposed model and the model without cited author information.

We first used the precision at k for evaluation. We calculate the precision at k for both our proposed CAT model and the MAT model, which does not have the cited author information. The results are listed in Table 4. It can be observed that at every rank position, our CAT model works better. In order to focus more on relevant retrieval results, we also calculated the mean average precision (MAP) for both models. For the given ten queries, the MAP score for the CAT model is 0.78, while the MAT model without cited author information has a MAP score of 0.67. The CAT model with cited author information achieves about 33% error reduction in this experiment.

Query ID	Query Term
1	parsing
2	machine translation
3	dependency parsing
4	transliteration
5	semantic role labeling
6	coreference resolution
7	language model
8	Unsupervised Learning
9	Supervised Learning

Table 5: Queries and their corresponding ids we used in our experiments.

Recall for each query		
Query ID	CAT Model	Model w/o Cite
1	0.53	0.20
2	0.13	0.20
3	0.27	0.13
4	0.13	0.2
5	0.27	0.20
6	0.13	0.26
Average	0.24	0.20

Table 6: Recall comparison between our proposed model and the model without cited author information.

Since we do not have a gold standard experts pool for our queries, to evaluate recall, we collected a pool of authors returned from an academic search engine, ArnetMiner (Tang et al., 2008) as our reference author pool and evaluated our recall based on the number of authors we retrieved from that pool. Specifically, we get the top 15 returned persons from that website for each query and treat them as the whole set of relevant experts for that query and our preliminary recall results are shown in Table 6.

In most cases, the CAT recall is better than that of the compared model, and the average recall is better as well. All the queries we used in our experiments are listed in Table 5. And the average recall value is based on six of the queries which have at least one overlap author with those in our reference recall pool.

6 Conclusion and Further Development

This paper proposed a novel author topic model, CAT, which extends the existing author topic model with additional cited author information.

We applied it to the domain of expert retrieval and demonstrated the effectiveness of our model in improving coherence in topic clustering and author topic association. The proposed model also provides an effective solution to the problem of *community mining* as shown by the promising retrieval results derived in our expert search system.

One immediate improvement would result from extending our corpus. For example, we can apply our model to the ACL ARC corpus (Bird et al., 2008) to check the model's robustness and enhance the ranking by learning from more data. We can also apply our model to data sets with rich linkage structure, such as the TREC benchmark data set or ACL Anthology Network (Radev et al., 2009) and try to enhance our model with the appropriate network analysis.

Abstract

We present a web-based algorithm for the task of POS tagging of *unknown words* (words appearing only a small number of times in the training data of a supervised POS tagger). When a sentence s containing an unknown word u is to be tagged by a trained POS tagger, our algorithm collects from the web contexts that are partially similar to the context of u in s, which are then used to compute new tag assignment probabilities for u. Our algorithm enables fast multi-domain unknown word tagging, since, unlike previous work, it does not require a corpus from the new domain. We integrate our algorithm into the MXPOST POS tagger (Ratnaparkhi, 1996) and experiment with three languages (English, German and Chinese) in seven in-domain and domain adaptation scenarios. Our algorithm provides an error reduction of up to 15.63% (English), 18.09% (German) and 13.57% (Chinese) over the original tagger.

1 Introduction

Part-of-speech (POS) tagging is a fundamental NLP task that has attracted much research in the last decades. While supervised POS taggers have achieved high accuracy (e.g., (Toutanova et al., 2003) report a 97.24% accuracy in the WSJ Penn Treebank), tagger performance on words appearing a small number of times in their training corpus (*unknown words*) is substantially lower. This effect is especially pronounced in the *domain adaptation* scenario, where the training and test corpora are from different domains. For example, when training the MXPOST POS tagger (Ratnaparkhi, 1996) on sections 2-21 of the WSJ Penn Treebank it achieves 97.04% overall accuracy when tested on WSJ section 24, and 88.81% overall accuracy when tested on the BNC corpus, which contains texts from various genres. For unknown words (test corpus words appearing 8 times or less in the training corpus), accuracy drops to 89.45% and 70.25% respectively.

In this paper we propose an unknown word POS tagging algorithm based on web queries. When a new sentence s containing an unknown word u is to be tagged by a trained POS tagger, our algorithm collects from the web contexts that are partially similar to the context of u in s. The collected contexts are used to compute new tag assignment probabilities for u.

Our algorithm is particularly suitable for *multi-domain* tagging, since it requires no information about the domain from which the sentence to be tagged is drawn. It does not need domain specific corpora or external dictionaries, and it requires no preprocessing step. The information required for tagging an unknown word is very quickly collected from the web.

This behavior is unlike previous works for the task (e.g (Blitzer et al., 2006)), which require a time consuming preprocessing step and a corpus collected from the target domain. When the target domain is heterogeneous (as is the web itself), a corpus representing it is very hard to assemble. To the best of our knowledge, ours is the first paper to provide such an *on-the-fly* unknown word tagging algorithm.

To demonstrate the power of our algorithm as a

Coling 2008: Poster Volume, pages 1274–1282,
Beijing, August 2010

fast multi-domain learner, we experiment in three languages (English, German and Chinese) and several domains. We implemented the MXPOST tagger and integrated it with our algorithm. We show error reduction in unknown word tagging of up to 15.63% (English), 18.09% (German) and 13.57% (Chinese) over MXPOST. The run time overhead is less than 0.5 seconds per an unknown word in the English and German experiments, and less than a second per unknown word in the Chinese experiments.

Section 2 reviews previous work on unknown word Tagging. Section 3 describes our web-query based algorithm. Section 4 and Section 5 describe experimental setup and results.

2 Previous Work

Most supervised POS tagging works address the issue of unknown words. While the general methods of POS tagging vary from study to study – Maximum Entropy (Ratnaparkhi, 1996), conditional random fields (Lafferty et al., 2001), perceptron (Collins, 2002), Bidirectional Dependency Network (Toutanova et al., 2003) – the treatment of unknown words is more homogeneous and is generally based on additional features used in the tagging of the unknown word.

Brants (2000) used only suffix features. Ratnaparkhi (1996) used orthographical data such as suffixes, prefixes, capital first letters and hyphens, combined with a local context of the word. In this paper we show that we improve upon this method. Toutanova and Manning (2000), Toutanova et al. (2003), Lafferty et al. (2001) and Vadas and Curran (2005) used additional language-specific morphological or syntactic features. Huihsin et al. (2005) combined orthographical and morphological features with external dictionaries. Nakagawa and Matsumoto (2006) used global and local information by considering interactions between POS tags of unknown words with the same lexical form.

Unknown word tagging has also been explored in the context of domain adaptation of POS taggers. In this context two directions were explored: a supervised method that requires a manually annotated corpus from the target domain (Daume III, 2007), and a semi-supervised method that uses an unlabeled corpus from the target domain (Blitzer et al., 2006).

Both methods require the preparation of a corpus of target domain sentences and re-training the learning algorithm. Blitzer et al. (2006) used 100K unlabeled sentences from the WSJ (source) domain as well as 200K unlabeled sentences from the biological (target) domain. Daume III (2007) used an 11K words labeled corpus from the target domain.

There are two serious problems with these approaches. First, it is not always realistically possible to prepare a corpus representing the target domain, for example when that domain is the web (e.g., when the POS tagger serves an application working on web text). Second, preparing a corpus is time consuming, especially when it needs to be manually annotated. Our algorithm requires no corpus from the target data domain, no preprocessing step, and it doesn't even need to know the identity of the target domain. Consequently, the problem we address here is more difficult (and arguably more useful) than that addressed in previous work[1].

The domain adaptation techniques above have not been applied to languages other than English, while our algorithm is shown to perform well in seven scenarios in three languages.

Qiu et al. (2008) explored Chinese unknown word POS tagging using internal component and contextual features. Their work is not directly comparable to ours since they did not test a domain adaptation scenario, and used substantially different corpora and evaluation measures in their experiments.

Numerous works utilized web resources for NLP tasks. Most of them collected corpora using data mining techniques and used them offline. For example, Keller et al., (2002) and Keller and Lapata (2003) described a method to obtain frequencies for unseen adjective-noun, noun-noun and verb-object bigrams from the web by query-

[1]We did follow their experimental procedure as much as we could. Like (Blitzer et al., 2006), we compare our algorithm to the performance of the MXPOST tagger trained on sections 2-21 of WSJ. Like both papers, we experimented in domain adaptation from WSJ to a biological domain. We used the freely available Genia corpus, while they used data from the Penn BioIE project (PennBioIE, 2005).

ing a Web engine.

On-line usage of web queries is less frequent and was used mainly in semantic acquisition applications: the discovery of semantic verb relations (Chklovski and Pantel, 2004), the acquisition of entailment relations (Szpektor et al., 2004), and the discovery of concept-specific relationships (Davidov et al., 2007). Chen et al. (2007) used web queries to suggest spelling corrections.

Our work is related to self-training (McClosky et al., 2006a; Reichart and Rappoport, 2007) as the algorithm used its own tagging of the sentences collected from the web in order to produce a better final tagging. Unlike most self-training works, our algorithm is not re-trained using the collected data but utilizes it at test time. Moreover, unlike in these works, in this work the data is collected from the web and is used only during unknown words tagging. Interestingly, previous works did not succeed in improving POS tagging performance using self-training (Clark et al., 2003).

3 The Algorithm

Our algorithm utilizes the correlation between the POS of a word and the contexts in which the word appears. When tackling an unknown word, the algorithm searches the web to find contexts similar to the one in which the word appears in the sentence. A new tag assignment is then computed for the unknown word based on the extracted contexts as well as the original ones.

We start with a description of the web-based context searching algorithm. We then describe how we combine the context information collected by our algorithm with the statistics of the MXPOST tagger. While in this paper we implemented this tagger and used it in our experiments, the context information collected by our web-query based algorithm can be integrated into any POS tagger.

3.1 Web-Query Based Context Collection

An unknown word usually appears in a given sentence with other words on its left and on its right. We use three types of contexts. The first includes all of these neighboring words, the second includes the words on the left, and the third includes the words on the right.

For each context type we define a web query using two common features supported by the major search engines: wild-card search, expressed using the '*' character, and exact sentence search, expressed by quoted characters. The retrieved sentences contain the parts enclosed in quotes in the exact same place they appear in the query, while an asterisk can be replaced by any single word.

For a word u we execute the following three queries for each of its test contexts:

1. **Replacement**: "$u_{-2}u_{-1} * u_{+1}u_{+2}$". This retrieves words that appear in the same context as u.

2. **Left-side**: "$*\ *\ u\ u_{+1}\ u_{+2}$". This retrieves alternative left-side contexts for the word u and its original right-side context.

3. **Right-side**: query "$u_{-2}\ u_{-1}\ u\ *\ *$". This retrieves alternative right-side contexts for u and its original left-side context.

Query Type	Query	Matches (Counts)
Replacement	"irradiation and * treatment of"	heat (15) chemical (7) the (6) radiation (1) pressure (1)
Left-side	"* * H2O2 treatment of"	by an (9) indicated that (5) enhanced by (4) familiar with (3) observed after (3)
Right-side	"irradiation and H2O2 * *"	in comparison (3) on Fe (1) treatment by (1) cause an (1) does not (1)

Table 1: Top 5 matches of each query type for the word 'H2O2' in the GENIA sentence: "UV irradiation and H2O2 treatment of T lymphocytes induce protein tyrosine phosphorylation and Ca2+ signals similar to those observed following biological stimulation.". For each query the matched words (matches) are ranked by the number of times they occur in the query results (counts).

An example is given in Table 1, presenting the top 5 matches of every query type for the word 'H2O2', which does not appear in the English WSJ corpus, in a sentence taken from the English Genia corpus. Since matching words can appear

multiple times in the results, the algorithm maintains for each match a counter denoting the number of times it appeared in the results, and sorts the results according to this number.

Seeing the table, readers might think of the following algorithm: take the leading match in the Replacement query, and tag the unknown word using its most frequent tag (assuming it is a known word). We have experimented with this method, and it turned out that its results are worse than those given by MXPOST, which we use as a baseline.

The web queries are executed by Yahoo! BOSS[2], and the resulting XML containing up to a 1000 results (a limit set by BOSS) is processed for matches. A list of matches is extracted from the *abstract* and *title* nodes of the web results along with counts of the number of times they appear. The matches are filtered to include only known words (words that appear in the training data of the POS tagger more than a threshold) and to exclude the original word or context.

Our algorithm uses a positive integer parameter N_{web}: only the N_{web} top-scoring unique results of each query type are used for tagging. If a left-side or right-side query returns less than N_{web} results, the algorithm performs a 'reduced' query: "$* \ * \ u \ u_{+1}$" for left-side and "$u_{-1} \ u \ * \ *$" for the right side. These queries should produce more results than the original ones due to the reduced context. If these reduced queries do not produce N_{web} results, the web query algorithm is not used to assist the tagger for the unknown word u at hand. If a replacement query does not produce at least N_{web} unique results, only the left-side and right-side queries are used.

For Chinese queries, search engines do their own word segmentation so the semantics of the '*' operator is supposedly the same as for English and German. However, the answer returned by the search engine does not provide this segmentation. To obtain the words filling the '*' slots in our queries, we take all possible segmentations in which the two words appears in our training data.

The queries we use in our algorithm are not the only possible ones. For example, a possible query we do not use for the word u is "$**u_{-1}uu_{+1}u_{+2}$". The aforementioned set of queries gave the best results in our English, German and Chinese development data and is therefore the one we used.

[2]http://developer.yahoo.com/search/boss/

3.2 Final Tagging

The MXPOST Tagger. We integrated our algorithm into the maximum entropy tagger of (Ratnaparkhi, 1996). The tagger uses a set h of contexts ('history') for each word w_i (the index i is used to allow an easy notation of the previous and next words, whose lexemes and POS tags are used as features). For each such word, the tagger computes the following conditional probability for the tag t_r:

$$p(t_r|h) = \frac{p(h,t_r)}{\sum_{t'_r \in T} p(h,t'_r)} \quad (1)$$

where T is the tag set, and the denominator is simply $p(h)$. The joint probability of a history h and a tag t is defined by:

$$p(h,t) = Z \prod_{j=1}^{k} \alpha_j^{f_j(h,t)} \quad (2)$$

where $\alpha_1, \ldots, \alpha_k$ are the model parameters, $f_1, \ldots, f_k$ are the model's binary features (indicator functions), and Z is a normalization term for ensuring that $p(h,t)$ is a probability.

In the training phase the algorithm performs maximum likelihood estimation for the α parameters. These parameters are then used when the model tags a new sentence (the test phase). For words that appear 5 times or less in the training data, the tagger extracts special features based on the morphological properties of the word.

Combining Models. In general, we use the same equation as MXPOST to compute joint probabilities, and our training phase is identical to its training phase. What we change are two things. First, we add new contexts to the 'history' of a word when it is considered as unknown (so Equation (2) is computed using different histories). Second, we use a different equation for computing the conditional probability (below).

When the algorithm encounters an unknown word w_i in the context h during tagging, it performs the web queries defined in Section 3.1. For

each of the N_{web} top resulting matches for each query, $\{h'_n | n \in [1, N_{web}]\}$, the algorithm creates its corresponding history representation h_n. Converting h'_n to h_n is required since in MXPOST a history consists of an ordered set of words together with their POS tags, while h'_n is an ordered set of words without POS tags. Consequently, we define h_n to consist of the same ordered set of words as h'_n, and we tag each word using its most frequent POS tag in the training corpus. If w_{i-1} or w_{i-2} are unknown words, we do not tag them, letting MXPOST use its back-off technique for such a case (which is simply to compute the features that it can and ignore those it cannot).

For each possible tag $t \in T$, its final assignment probability to w_i is computed as an average between its probability given the various contexts:

$$\tilde{p}(t_r|h) = \frac{p_{org}(t_r|h) + \sum_{n=1}^{QN_{web}} p_n(t_r|h_n)}{QN_{web} + 1} \quad (3)$$

where Q is the number of query types used (1, 2 or 3, see Section 3.1).

During inference, we use the two search space constraints applied by the original MXPOST. First, we apply a beam search procedure that considers the 10 most probable different tag sequences of the tagged sentence at any point in the tagging process. Second, known words are constrained to be annotated only by tags with which they appear in the training corpus.

4 Experimental Setup

Languages and Datasets. We experimented with three languages, English, German and Chinese, in various combinations of training and testing domains (see Table 2). For English we used the Penn Treebank WSJ corpus (WSJ) (Marcus et al., 1993) from the economics newspapers domain, the GENIA corpus version 3.02p (GENIA) (Kim et al., 2003) from the biological domain and the British National Corpus version 3 (BNC) (Burnard, 2000) consisting of various genres. For German we used two different corpora from the newspapers domain: NEGRA (Brants, 1997) and TIGER (Brants et al., 2002). For Chinese we used the Penn Chinese Treebank corpus version 5.0 (CTB) (Xue et al., 2002).

All corpora except of WSJ were split using random sampling. For the NEGRA and TIGER corpora we used the Stuttgart-Tuebingen Tagset (STTS).

According to the annotation policy of the GENIA corpus, only the names of journals, authors, research institutes, and initials of patients are annotated by the 'NNP' (Proper Name) tag. Other proper names such as general people names, technical terms (e.g. 'Epstein-Barr virus') genes, proteins, etc. are tagged by other noun tags ('NN' or 'NNS'). This is in contrast to the WSJ corpus, in which every proper name is tagged by the 'NNP' tag. We therefore omitted cases where 'NNP' is replaced by another noun tag from the accuracy computation of the GENIA domain adaptation scenario (see analysis in (Lease and Charniak, 2005)).

In all experimental setups except of WSJ-BNC the training and test corpora are tagged with the same POS tag set. In order to evaluate the WSJ-BNC setup, we converted the BNC tagset to the Penn Treebank tagset using the comparison table provided in (Manning and Schuetze, 1999) (pages 141–142).

Baseline. As a baseline we implemented the MXPOST tagger. An executable code for MXPOST written by its author is available on the internet, but we needed to re-implement it in order to integrate our technique. We made sure that our implementation does not degrade results by running it on our WSJ scenario (see Table 2), which is very close to the scenario reported in (Ratnaparkhi, 1996). The accuracy of our implementation is 97.04%, a bit better than the numbers reported in (Ratnaparkhi, 1996) for a WSJ scenario using different sections.

Parameter Tuning. We ran experiments with three values of the unknown word threshold T: 0 (only words that do not appear in the training data are considered unknown), 5 and 8. That is, the algorithm performs the web context queries and utilizes the tag probabilities of equation 3 for words that appear up to 0 ,5 or 8 times in the training data.

Our algorithm has one free parameter N_{web}, the number of query results for each context type used

Language	Expe. name	Training	Development	Test
English	WSJ	sections 2-21 (WSJ)	section 22 (WSJ)	section 23 (WSJ) (2.4%,6.7%,8.4%)

Table 3: Accuracy of unknown word tagging in the English (top table), German (middle table) and Chinese (bottom table) experiments. Results are presented for three values of the unknown word threshold parameter T: 0, 5 and 8. For all setups our models improves over the MXPOST baseline of (Ratnaparkhi, 1996). The bottom line of each table ('best imp.') presents the improvement (top number) and error reduction (bottom number) of the best performing model over the baseline. The best improvement is in domain adaptation scenarios.

in the probability computation of equation 3. For each setup (Table 2) we ran several combinations of query types and values of N_{web}. We report results for the four leading combinations:

- $N_{web} = 5$, left-side and right-side queries (Top 5 (-)).
- $N_{web} = 10$, left-side and right-side queries (Top 10 (-)).
- $N_{web} = 10$, replacement, left-side and right-side queries (Top 10 (+)).
- $N_{web} =$ Unlimited (in practice, this means 1000, the maximum number of results provided by Yahoo! Boss), left-side and right-side queries (Unlimited (-)).

The order of the models with respect to their performance was identical for the development and test data. That is, the best parameter/queries combination for each scenario can be selected using the development data. We experimented with other parameter/queries combinations and additional query types but got worse results.

5 Results

The results of the experiments are shown in Table 3. Our algorithm improves the accuracy of the MXPOST tagger for all three languages and for all values of the unknown word parameter.

Our experimental scenarios consist of three in-domain setups in which the model is trained and tested on the same corpus (the WSJ, NEGRA and CTB experiments), and four domain adaptation setups: WSJ-GENIA, WSJ-BNC, TIGER-NEGRA and NEGRA-TIGER.

Table 3 shows that our model is relatively more effective in the domain adaptation scenarios. While in the in-domain setups the error reduction values are 7.23% – 9.66% (English), 9.95% – 11.8% (German) and 10.35% – 13.57% (Chinese), in the domain adaptation scenarios they are 8.38% – 11.02% (WSJ-BNC), 14.48% – 15.63% (WSJ-GENIA), 8.04% – 9.84% (NEGRA-TIGER) and 16.3% – 18.09% (TIGER-NEGRA).

Run Time. As opposed to previous approaches to unknown word tagging (Blitzer et al., 2006; Daume III, 2007), our algorithm does not contain a step in which the base tagger is re-trained with a corpus collected from the target domain. Instead, when an unknown word is tackled at test time, a set of web queries is run. This is an advantage for flexible multi-domain POS tagging because preprocessing times are minimized, but might cause an issue of overhead per test word.

To show that the run time overhead created by our algorithm is small, we measured its time performance (using an Intel Xeon 3.06GHz, 3GB RAM computer). The average time it took the best configuration of our algorithm to process an unknown word and the resulting total addition to the run time of the base tagger are given in Table 4. The average time added to an unknown word tagging is less than half a second for English, even less for German, and less than a second for Chinese. This is acceptable for interactive applications that need to examine a given sentence without being provided with any knowledge about its domain.

Error Analysis. In what follows we try to analyze the cases in which our algorithm is most effective and the cases where further work is still required. Due to space limitations we focus only on the (Top 10 (+), $T = 5$) parameters setting, and report the patterns for one English setup. The corresponding patterns of the other parameter settings, languages and setups are similar.

We report the errors of the base tagger that our algorithm most usually fixes and the errors that our algorithm fails to fix. We describe the base tagger errors of the type 'POS tag 'a' is replaced with POS tag 'b' (denoted by: a -> b)' using the following data: (1) total number of unknown words whose correct tag is 'a' that were assigned 'b' by the base tagger; (2) the percentage of unknown words whose correct tag is 'a' that were assigned 'b' by the base tagger; (3) the percentage of unknown words whose correct tag is 'a' that were assigned 'b' by our algorithm; (4) the percentage of mistakes of type (1) that were corrected by our algorithm.

In the English WSJ-BNC setup, the base tagger mistakes that our algorithm handles well (according to the percentage of corrected mistakes) are: (1) NNS -> VBZ (23, 3.73%, 0.8%, 65.2%); (2) CD -> JJ (19 ,13.2% ,9.7% ,37.5%); (3) NN ->

	WSJ	WSJ-BNC	WSJ-GENIA	NEGRA	NEGRA-TIGER	TIGER-NEGRA	CTB
Total addition	00:28:26	00:31:53	1:37:32	00:57:03	00:19:10	00:36:54	2:29:13
Avg. time per word	0.42	0.32	0.33	0.36	0.11	0.21	0.95

Table 4: The processing time added by the web based algorithm to the base tagger. For each setup results are presented for the best performing model and for the unknown word threshold of 8. Results for the other models and threshold parameters are very similar. The top line presents the total time added in the tagging of the full test data (hours:minutes:seconds). The bottom line presents the average processing time of an unknown word by the web based algorithm (in seconds).

JJ (97, 6.17%, 5.3%, 27.8%); (4) JJ -> NN (69, 9.73%, 7.76%, 33.3%). The errors that were not handled well by our algorithm are: (1) IN -> JJ (70, 46.36% , 41%, 8.57%); (2) VBP -> NN (25, 19.5%, 21.9% , 0%).

In this setup, 'CD' is a cardinal number, 'IN' is a preposition, 'JJ' is an adjective, 'NN' is a noun (singular or mass), 'NNS' is a plural noun, 'VBP' is a verb in non-third person singular present tense and 'VBZ' is a verb in third person, singular present tense.

We can see that no single factor is responsible for the improvement over the baseline. Rather, it is due to correcting many errors of different types. The same general behavior is exhibited in the other setups for all languages.

Multiple Unknown Words. Our method is capable of handling sentences containing several unknown words. Query results in which '*' is replaced by an unknown word are filtered. For queries in which an unknown word appears as part of the query (when it is one of the two right or left non-'*' words), we let MXPOST invoke its own unknown word heuristics if needed[3].

In fact, the relative improvement of our algorithm over the baseline is *better* for adjacent unknown words than for single words. For example, consider a sequence of consecutive unknown words as correctly tagged if all of its words are assigned their correct tag. In the WSJ-GENIA scenario (Top 10 (+), $T = 5$), the error reduction for sequences of length 1 (unknown words surrounded by known words, 8767 sequences) is 8.26%, while for 2-words (2620 sequences) and 3-words (614 sequences) it is 11.26% and 19.11% respectively. Similarly, for TIGER-NEGRA (same parameters setting) the error reduction is 6.85%, 8.07% and 18.18% for sequences of length 1 (4819) ,2 (1126) and 3 (223) respectively.

[3]They are needed only if the word is on the left of the word to be tagged.

6 Conclusions and Future Work

We presented a web-based algorithm for POS tagging of unknown words. When an unknown word is tackled at test time, our algorithm collects web contexts of this word that are then used to improve the tag probability computations of the POS tagger.

In our experiments we used our algorithm to enhance the unknown word tagging quality of the MXPOST tagger (Ratnaparkhi, 1996), a leading state-of-the-art tagger, which we implemented for this purpose. We showed significant improvement (error reduction of up to 18.09%) for three languages (English, German and Chinese) in seven experimental setups. Our algorithm is especially effective in domain-adaptation scenarios where the training and test data are from different domains.

Our algorithm is fast (requires less than a second for processing an unknown word) and can handle test sentences coming from any desired unknown domain without the costs involved in collecting domain-specific corpora and retraining the tagger. These properties makes it particularly appropriate for applications that work on the web, which is highly heterogeneous.

In future work we intend to integrate our algorithm with additional POS taggers, experiment with additional corpora and domains, and improve our context extraction mechanism so that our algorithm will be able to fix more error types.

Urdu and Hindi: Translation and sharing of linguistic resources

Karthik Visweswariah, Vijil Chenthamarakshan, Nandakishore Kambhatla
IBM Research India
{v-karthik,vijil.e.c,kambhatla}@in.ibm.com

Abstract

Hindi and Urdu share a common phonology, morphology and grammar but are written in different scripts. In addition, the vocabularies have also diverged significantly especially in the written form. In this paper we show that we can get reasonable quality translations (we estimated the Translation Error rate at 18%) between the two languages even in absence of a parallel corpus. Linguistic resources such as treebanks, part of speech tagged data and parallel corpora with English are limited for both these languages. We use the translation system to share linguistic resources between the two languages. We demonstrate improvements on three tasks and show: statistical machine translation from Urdu to English is improved (0.8 in BLEU score) by using a Hindi-English parallel corpus, Hindi part of speech tagging is improved (upto 6% absolute) by using an Urdu part of speech corpus and a Hindi-English word aligner is improved by using a manually word aligned Urdu-English corpus (upto 9% absolute in F-Measure).

1 Introduction

Hindi and Urdu are official languages of India and Urdu is also the national language of Pakistan. Hindi is spoken by around 853 million people and Urdu by around 164 million people (Malik et al., 2008). Although native speakers of Hindi can comprehend most of spoken Urdu and vice versa, these languages have diverged a bit since independence of India and Pakistan – with Hindi deriving a lot of words from Sanskrit and Urdu from Persian. One clear difference between Hindi and Urdu is the script: Hindi is written in a left-to-right Devanagari script while Urdu is written in Nastaliq calligraphy style of the right-to-left Perso-Arabic script. Hence, despite the similarities, it is impossible for an Urdu speaker to read Hindi text and vice versa. The first problem we address is the translation between Hindi and Urdu in the absence of a Hindi-Urdu parallel corpus.

Though these languages together are spoken by around a billion people they are not very rich in linguistic resources. A treebank for Hindi is still under development[1] and part of speech taggers for Hindi and Urdu are trained on very small amounts of data. For translation between Hindi/Urdu and English there are no large corpora, the available corpora are an order of magnitude smaller than those available for European languages or Arabic-English. Given the lack of linguistic resources in each of the languages and the similarities between these languages, we explore whether each language can benefit from resources available in the other language.

1.1 Urdu-Hindi script conversion/translation

Sharing resources between Hindi and Urdu requires us to be able to convert from one written form to the other. Given that the languages share a good fraction of their spoken vocabularies, the obvious approach to convert between the two scripts would be to transliterate between them. While this approach has recently been attempted (Malik et al., 2009), (Malik et al., 2008) there are two main problems with this approach.

Challenges in Hindi-Urdu transliteration: Urdu uses diacritical marks that were taken from the Arabic script which serve various purposes. Urdu has short and long vowels. Short vowels are indicated by placing a diacritic with the con-

Coling 2008: Poster Volume, pages 1283–1291,
Beijing, August 2010

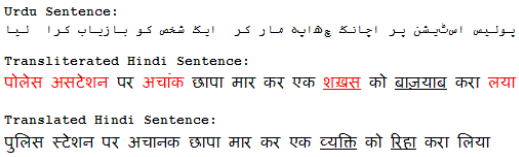

Figure 1: An Urdu sentence transliterated and translated to Hindi

sonant that precedes it in the syllable. The diacritical marks are also used for gemination (doubling of a consonant), which in Hindi is handled using a conjunct form where the consonant is essentially repeated twice. Yet another function of diacritical marks is to mark the absence of a vowel following a base consonant. Though diacritical marks are critical for correct pronunciation and sometimes even for disambiguation of certain words, they are sparingly used in written material intended for native speakers of the language. Missing diacritical marks create substantial difficulties for transliteration systems. Another difficulty is created by the fact that Urdu words cannot have a short vowel at the end of a word, whereas the corresponding Hindi word can sometimes have a short vowel. This cannot be resolved deterministically and results ambiguity in transliteration from Urdu to Hindi. A third issue is the presence of certain sounds (and their corresponding letters) that have no equivalent in Urdu. These letters are approximated in Urdu with phonetic equivalents. Transliteration from Urdu to Hindi suffers in the presence of words with these letters. Recent work on Urdu-Hindi transliteration (Malik et al., 2009) report transliteration word error rates of 16.4% and 23.1% for Urdu sentences with and without diacritical marks respectively. This problem is illustrated in Figure 1. The figure shows an Urdu sentence that is transliterated to Hindi using the Hindi Urdu Machine Transliteration (HUMT) system [2] and translated using our Statistical Machine Translation System. The words which are in red are transliteration errors (mainly because of missing diacritical marks).

Difference in Word Frequency Distributions: Even if we could transliterate perfectly between Urdu and Hindi it might not be desirable to do so from the point of view of human understanding or for machine consumption. This is because word frequencies of shared words would be different in Hindi and Urdu. At the extreme, there are several Urdu words that a fluent Hindi speaker would not understand and vice versa. More commonly, native speakers of Hindi and Urdu would use different words to refer to the same concept, even though both these words are technically correct in either of these languages. In initial experiments to quantify this issue on our corpus, which is mainly from the news domain, we estimated that around 28% of the word tokens in Urdu would not be natural in Hindi. This estimate assumes perfect transliteration, and we estimated the total error rate including transliteration at around 55% for the publicly available HUMT system. In Figure 1, the words that have been underlined have been replaced using a different word by our SMT system, even though the original word might be technically correct. Our preliminary experiments exploring this issue convinced us that to be able to convert from Urdu into natural Hindi (and vice versa) we would need to go beyond transliteration to translation to deal with the divergence of the vocabularies in the written forms of the two languages.

Importance of Context We would like to point out that in addition to word for word fidelity, there are more subtle issues in translating from Urdu-Hindi. One issue is that words in Hindi are drawn from different source languages, and with word to word translations, we might end up with phrases that are unnatural. For example, consider different ways of writing the English phrase *National* and *News* in Hindi. The word *National* in Hindi could possibly be written as *rashtriya*, *kaumi* or *national* which have origins in Sanskrit, Persian/Arabic and English respectively. Similarly the word *News* could be written as *samachar*, *khabaren* or *news* (once again with origins in Sanskrit, Persian/Arabic and English). The natural ways for writing the phrase *national news* are: *rashtriya samachar*, *kaumi khabaren* or *national news*, any of the other six combinations would be quite rare.

Another issue is that corresponding words in Hindi and Urdu might have different genders. An

[2] http://www.puran.info/HUMT/HUMT.aspx

example from (Sinha, 2009) are the words *vajah* (Urdu, feminine) and *karan* (Hindi, masculine), which would mean that the phrase *because of him* would be written as *us ke karan* in Hindi and as *us ki vajah se* in Urdu. We note that the *ke* in Hindi and *ki* in Urdu are different because of the difference in genders of the word following them. This suggests we would need to go beyond word for word translation and would need to use a higher order n-gram language model to translate with fidelity between Hindi and English.

We have established the need for going beyond transliteration, but a key challenge is to achieve good translation accuracy in the absence of a Hindi-Urdu parallel corpus. In Section 3 we describe a multi-pronged approach to translate between Hindi and Urdu in the absence of a parallel corpus that exploits the similarities between the languages.

1.2 Applications: sharing linguistic resources

We next outline the three tasks for which we consider sharing resources between Hindi and Urdu which serve as a test of the efficacy of our systems.

Statistical machine translation

In recent years, there is a lot of interest in Statistical Machine Translation (SMT) Systems (Brown et al., 1993). Modern SMT systems (Koehn et al., 2003; Ittycheriah and Roukos, 2007) learn translation models based on large amounts of parallel data. The quality of an SMT system is dependent on the amount of parallel data on which the system is trained. Unfortunately, for the pairs Urdu-English and Hindi-English, parallel data are not available in large quantities, thereby limiting the quality of these SMT systems. In this paper we show that we can improve the accuracy of an Urdu→English SMT system by using a Hindi-English parallel corpus.

Part of Speech tagging

Part of Speech (POS) tagging involves marking the part of speech of a word based on its definition and surrounding context in a sentence. Sequential modeling techniques like Hidden Markov Models (Rabiner, 1990) and Conditional Random Fields (Lafferty et al., 2001) are commonly used to build Part of Speech taggers. These models are typically trained using a manually tagged part of speech corpus. Manual tagging of data requires lot of human effort and hence large corpora are not readily available for many languages. We improve a Hindi POS tagger by using a manually tagged Urdu POS corpus.

Supervised bitext alignment

Machine generated word alignments between pairs of languages have many applications: building statistical machine translation systems, building dictionaries, projection of syntactic information to resource poor languages (Yarowsky and Ngai, 2001). Most of the early work on generating word alignments has been unsupervised, e.g. IBM Models 1-5 (Brown et al., 1993), recent improvements on the IBM Models (Moore, 2004), and the HMM algorithm described in (Vogel et al., 1996). Recently, significant improvements in performance of aligners have been achieved by the use of human annotated word alignments (Ittycheriah and Roukos, 2007; Lacoste-Julien et al., 2006). We describe a method to transfer manual word alignments from Urdu-English to Hindi-English to improve Hindi-English word alignments.

1.3 Contributions

Our main contributions are summarized below: We present a hybrid technique to translate between Hindi and Urdu in the *absence* of a Hindi-Urdu parallel corpus that significantly improves upon past efforts to convert between Hindi and Urdu via transliteration. We validate the efficacy of the translation systems we present, by using it to share linguistic resources between Hindi and Urdu for three important tasks:

1. We improve a part of speech tagger for Hindi using an Urdu part of speech corpus.

2. We use manual Urdu-English word alignments to improve the task of Hindi-English bitext alignments.

3. We use a Hindi-English parallel corpus to improve translation from Urdu to English.

2 Related work

Converting between the scripts of Hindi and Urdu is non-trivial and has been a recent focus (Malik et al., 2008; Malik et al., 2009). (Malik et al., 2008) uses hand designed rules encoded using finite state transducers to transliterate between Hindi and Urdu. As reported in (Malik et al., 2009) these hand designed rules achieve accuracies of only about 50% in the absence of diacritical marks. (Malik et al., 2009) improves Urdu→Urdu transliteration performance to 79% by post processing the output of the transducer with a statistical language model. In contrast to (Malik et al., 2009) we use a statistical model for character transliteration. As discussed in Section 1.1, due to the divergence of vocabularies in written Hindi and Urdu, transliteration is not sufficient to convert from written Urdu to written Hindi. We also use a more flexible model that allows for more natural translations by allowing Urdu words to translate into Hindi words that do not sound the same.

(Sinha, 2009) builds an English-Urdu machine translation system using an English-Hindi machine translation system and a Hindi-Urdu word mapping table, suitably adjusted for part of speech and gender. Their system is not statistical, and is largely based on manual creation of a large database of Hindi-Urdu correspondences. Additionally, as mentioned in the conclusion, their system cannot be used for direct translation from Hindi to Urdu, since a grammatical analysis of the English provides information necessary for the Hindi to Urdu mapping. In contrast to this work, our techniques are largely statistical, require minimal manual effort and can directly translate between Hindi and Urdu without the associated English.

3 Approach to translating between Hindi and Urdu

As discussed in Section 1, transliteration between Hindi and Urdu is not a straightforward task and current efforts result in fairly high error rates. We would like to combine the approaches of transliteration and translation since our goal is to use the translation for sharing linguistic resources rather than for direct consumption.

We use a fairly standard phrase based translation system to translate between Hindi and Urdu. The key challenge that we overcome is being able to develop such a system with acceptable accuracy in the absence of Hindi-Urdu resources (we have neither a parallel corpus nor a dictionary with sufficient coverage). In spite of the absence of resources, translation between this language pair is made feasible by the fact that word order is largely maintained and translation can be done maintaining a word to word correspondence. There are some exceptions to the monotonicity in the two languages. Consider the English phrase *Government of Sindh* which in Urdu would be *hukumat e sindh* in the same word order as in English, while in Hindi it would be *sindhi sarkar* with the word order flipped (with respect to English and Urdu). This example also shows that sometimes we do not have a word for word translation between Hindi and Urdu, the word *sindhi* in Hindi corresponding to the Urdu words *e sindh*. In spite of these exceptions, Hindi-Urdu translation can largely be done with the monotonicity assumption and with the assumption of word to word correspondences. Thus the central issue in translating between Hindi and Urdu is the creation of a word to word conditional probability table. We explain our technique assuming we are translating from Urdu to Hindi. We take a hybrid approach to creating this table, using three different approaches.

The first approach is the pivot language approach (Wu and Wang, 2007), with English as a pivot language. We get probabilities of a Urdu word u being generated by a Hindi word h, considering intermediate English phrases e as:

$$P_p(u|h) = \sum_e P(u|e)P(e|h)$$

The translation probabilities $P(u|e)$ and $P(e|h)$ are obtained using an Urdu-English and an English-Hindi parallel corpus respectively.

This approach works reasonably well, but suffers from a couple of drawbacks. There are several common Hindi and Urdu words for which the translation is unsatisfactory. This is because the alignments for these words are not precise, they often do not align to any English word, or align to

an English words in combination with other Hindi words. A common example of this is with verbs, consider for example the English sentence
He works
which would translate into Hindi/Urdu as:
vah kaam karta hai
with word alignments *He* ↔ *vah*, *works* ↔ *kaam karta hai* . Automatic aligners often make mistakes on these multi-word alignments, and this create problems for words like *karta* and *hai* which often do not have direct equivalents in English. To deal with this issue we manually build a small phrase table for the most frequent Hindi and Urdu words by a consulting an online Hindi-Urdu-English dictionary (Platts, 1884). We also manually handle the frequent examples we observed of cases where we need to handle differences in tokenization between Hindi and Urdu (e.g *keliye* written as one word in Urdu and as *ke liye* in Hindi).

The other issue with the pivot language approach is that for word pairs which are rare in one of the languages, $\sum_e P(u|e)P(e|h)$ can easily work out to zero. This is exacerbated by alignment errors for rarer words. Thus, to strengthen our phrase table especially for infrequent words, we use a transliteration approach to build a phrase table. Note that for rare words like names of people and places, the words in Hindi and Urdu are transliterations of each other.

In light of the issues in transliterating between Hindi and Urdu (Malik et al., 2008; Malik et al., 2009) we take a statistical approach (Abdul-Jaleel and Larkey, 2003) to building a transliteration based phrase table.

We assume a generative model for producing Urdu words from Hindi words based on a character transliteration probability table P_c. The probability $P_t(u|h)$ of generating a Urdu word u from a Hindi word h is given by:

$$P_t(u|h) = \sum_{\mathbf{a}} \prod_i P_c(u_i|h_{a(i)})P(a_i|a_{i-1}),$$

where $\mathbf{a}$ represents the alignment between the Hindi and Urdu characters, $a(i)$ is the the index of the Hindi character that the i^{th} Urdu character is aligned to, $P_c(u_c|h_c)$ is the probability of an Urdu character u_c being generated by a Hindi character h_c and $P(a_i|a_{i-1})$ represents a distortion probability. Since transliteration is monotonic and we want to encourage small jumps we set: $P(a_i|a_{i-1}) = c\eta^{(a_i - a_{i-1})}$ for $a_i > a_{i-1}$ and 0 otherwise. To obtain P_c we use the EM algorithm and we can reuse standard machinery that is used to obtain HMM word alignments in Statistical Machine Translation (with the constraint of Monotone alignments). To calculate a transliteration based phrase table, for each Hindi word h we search over a large vocabulary of Urdu words and retain words u for which $P_t(u|h)$ is sufficiently high as possible transliterations of h. We set the probabilities in the transliteration based phrase table to be proportional to $P_t(u|h)$. Finding this table requires calculating $P_t(u|h)$ for every pair of words in the Urdu and Hindi vocabulary, we use the Forward-Backward algorithm for efficiency and parallelize the calculations over several machines.

The only remaining issue is how we get training data to train our transliteration model. To obtain such training data we use a table of consonant character conversions between Hindi and Urdu as given in (Malik et al., 2008). We look for words in our pivot language based translation table, where there are at least three consonants and at least 50% of the consonants are shared. We observed that this yields pairs of words that are transliterations of one another with high precision. These word pairs are used as training data to build our character transliteration model P_c.

Final word translation table is obtained by combining our three approaches as follows: If the word is present in our dictionary, we use the translation given in the dictionary and exclude all others, if not we linearly interpolate between the probability table we get based on using English as a pivot language and probability table we get based on transliteration.

4 Experimental results

In this section we report on experiments to evaluate the quality of our translation method described in Section 3 and report on the application of Hindi↔Urdu translation to the sharing of linguistic resources between the two languages.

Algorithm 1 Create Urdu-Hindi Phrase Table

4.1 Evaluation of Hindi-Urdu translation

We built a Hindi-Urdu transliteration system as explained in Section 3. For building a pivot language based translation table we used 70k sentences from the NIST MT-08 corpus training corpus for Urdu-English. For Hindi-English we used an internal corpus of 230k sentences. We built our statistical transliteration model on roughly 3k word pairs that we obtained as described in Section 3. For Urdu→Hindi translation, we used a five gram language model built from a crawl of archives from Hindi news web sites (the corpus size was about 60 million words). For Hindi→Urdu translation we use the MT-08 Urdu corpus (about 1.5 million words) to build a trigram LM.

We evaluated the translation system in translating from Urdu to Hindi. We asked an annotator to evaluate 100 sentences (2700 words), by marking an error on a word if it was a wrong translation or unnatural in Hindi. We compared our translation system against the Hindi Urdu Machine Transliteration (HUMT) system[3]. We found an error rate of 18% for our system as against 46% for the HUMT system.

4.2 Word alignments

In this section we describe experiments at improving a Hindi-English word aligner using hand alignments for an Urdu-English corpus. For the Urdu-English corpus we use a manually word aligned corpus of roughly 10k sentences, while for the Hindi-English corpus we had roughly 3k sentences out of which we set aside 300 sentences (5300 words) for a test set. In addition to these (relatively) small supervised corpora we also use a sentence parallel Hindi-English corpus (without manual word alignments) of roughly 250k sentences.

For word alignments we use the Maximum Entropy aligner described in (Ittycheriah and Roukos, 2005) that is trained using hand aligned training data. We first translate the Urdu sentences in the Urdu-English word aligned corpus to Hindi, and then transfer the alignments by simply replacing the alignment links to a Urdu word by links to the corresponding decoded Hindi word. The above procedure covers bulk of the cases since Urdu-Hindi translation is largely a word to word translation. The special case of a phrase of multiple Urdu words decoded to multiple Hindi words is handled as follows: we align each of the words in the Hindi phrase to the union of the sets of English words that each word in the Urdu phrase aligns to. Once we convert the Urdu-English manual alignments to an additional corpus we build two Hindi-English alignment models, one on the original corpus, the other on the (Urdu→Hindi)-English corpus. The MaxEnt aligner (Ittycheriah and Roukos, 2005) models the probability of a

particular set of links in the alignment L given the source sentence S and the target sentence T as: $P(L|S,T) = \prod_{i=1}^{M} p(l_i|t_1^M, s_1^K, l_1^{i-1})$. Let us denote by P_h and P_u the alignment models trained on the Hindi-English and the (Urdu→Hindi)-English corpora respectively. We combine these models log-linearly to obtain our final model for alignment:

$$P(L|S,T) = P_h^{\alpha}(L|S,T)P_u^{1-\alpha}(L|S,T).$$

To find the most likely alignment we use the same algorithm as in (Ittycheriah and Roukos, 2005) since the structure of the model is unchanged.

We report on the performance (Table 1) of a baseline Hindi-English word aligner built with varying amounts of Hindi-English manually word aligned training data compared against an aligner that combines in a model trained on the 10k (Urdu→Hindi)-English sentences. We observe large gains with small amounts of labelled Hindi-English alignment data, and even when we have 2800 sentences of Hindi-English data we see a gain in performance adding in the Urdu data. We note that the MaxEnt aligner we use (Ittycheriah and Roukos, 2005) defaults to (roughly) doing an HMM alignment using a word translation matrix obtained via unsupervised training. Thus the aligners reported on in Table 1 use a large amount of unsupervised data in addition to the small amounts of labelled data mentioned in the Table.

4.3 POS tagging

Unlike English for which there is an abundance of POS training data for Hindi and Urdu data is quite limited. For our experiments, we use the CRULP corpus (Hussain, 2008) for Urdu and a corpus from IITB (Dalal et al., 2007) for Hindi. The CRULP POS corpus has 150k words and uses a tagset of size 46 to tag the corpus. The IITB corpus has 50k words and uses a tagset of size 26. We set a side a test set of size 5k words from the IITB corpus. For part of speech tagging we use CRFs (Lafferty et al., 2001) with two types of features, $f(t_i, w_i)$ and $g(t_i, t_{i-1})$. With the small amounts of training data we have, adding additional feature templates degraded the performance.

In our POS tagging experiments we consider using the Urdu corpus to help POS tagging in Hindi. We first translate all of the CRULP Urdu data to Hindi. We cannot simply add in this data to the training data because of differences in the tagsets used in the data sets for the two languages. In order to make use of the additional Urdu POS tagged data (translated to Hindi), we build a separate POS tagger on this data, and use predictions from this model as a feature in training the Hindi POS tagger. We use these predictions via a feature template $h(t_i, t_i^u)$ where t_i^u denotes the tag assigned to the ith word by the POS tagger built from the CRULP Urdu data set translated into Hindi.

We present results in Table 2 with varying amounts of Hindi data used for training, in each case we present results with and without use of the Urdu resources. We see a small gain even when we use all of the available Hindi training data and as expected we see larger gains when smaller amounts of Hindi data are used.

We analyzed the type of errors and the error reduction when using the Urdu data for the case where we used only 5k words of Hindi data.

We find that the two frequent error types that were greatly reduced were noun being tagged as main verb (reduction of 65% relative) and main verb tagged as auxiliary verb (reduction of 71%). Reduction in confusion between nouns and main verbs is expected since these are open word classes that can most benefit from additional data. This also causes the reduction in errors of tagging main verbs as auxiliary verbs, since in Hindi, verbs are multi word groups with a main verb followed by one or more auxiliary verbs. Reduction of error rate in most of the other error types were close to the overall error rate reduction.

4.4 Sharing parallel corpora for machine translation

We experimented with using our internal Hindi-English parallel corpus (230k) sentences to obtain better translation for Urdu-English. The Urdu-English corpus we use is the NIST MT-08 training data set (70k sentences). We use the Direct Translation Model 2 (DTM) described in (Ittycheriah and Roukos, 2007) for all our translation experiments.

We build our baseline Urdu→English system using the NIST MT-08 training data. In training our DTM model we use HMM alignments, alignments with the MaxEnt aligner, and hand alignments for 10k sentences (the hand alignments were used to train the MaxEnt aligner).

We translated the Hindi in our Hindi-English corpus to Urdu, creating an additional Urdu-English corpus. We then use a MaxEnt aligner to align the Urdu-English words in this corpus. Since we expect this corpus to be relatively noisy due to incorrect translation from Urdu to Hindi we do not include this corpus while generating HMM alignments. We add the synthetic Urdu-English data with MaxEnt alignments to our baseline data and train a DTM model. Results comparing to the baseline are given Table 3, which shows an improvement of 0.8 in BLEU score over the baseline system by using data from the Hindi-English corpus.

This improvement is not due to unknown words being covered (the vocabulary covered is the same). Also note that in the bridge language approach we cannot get alternative translations for single words that were not already present in the Urdu-English phrase table. Thus, we believe that the improvement is due to longer phrases being seen more often in training. An example improved translation is shown below:

Corpus	MT08 Eval
Urdu	23.1
+Hindi	23.9

Table 3: *Improvement in Urdu-English machine translation using Hindi-English data* .

Ref: *just as long as its there they feel safe*

Baseline: *as long as this they just think there are safe*

Improved: *just as long as they are there they feel safe*

5 Conclusions

In this paper, we showed that we can translate between Hindi and English *without* a parallel corpus and improve upon previous efforts at transliterating between the two languages. We also showed that Hindi-Urdu translation can be useful to the sharing of linguistic resources between the two languages. We believe this approach to sharing linguistic resources will be of immense value especially with resources like treebanks which require a large effort to develop.

Acknowledgments

We thank Salim Roukos and Abe Ittycheriah for discussions that helped guide our efforts.

Phrase Structure Parsing with Dependency Structure

Zhiguo Wang and **Chengqing Zong**

Institute of Automation, Chinese Academy of Sciences
{zgwang, cqzong}@nlpr.ia.ac.cn

Abstract

In this paper we present a novel phrase structure parsing approach with the help of dependency structure. Different with existing phrase parsers, in our approach the inference procedure is guided by dependency structure, which makes the parsing procedure flexibly. The experimental results show our approach is much more accurate. With the help of golden dependency trees, F1 score of our parser achieves 96.08% on Penn English Treebank and 90.61% on Penn Chinese Treebank. With the help of N-best dependency trees generated by modified MSTParser, F1 score achieves 90.54% for English and 83.93% for Chinese.

1 Introduction

Over the past few years, several high-precision phrase parsers have been presented, and most of them are employing probabilistic context-free grammar (PCFG). As we all know, the basic PCFG has the problems that the independence assumption is too strong and lacks of lexical conditioning (Jurafsky and Martin, 2007). Although researchers have proposed various models and inference algorithms aiming to solve these problems, the performance of existing phrase parsers is still remained to further improve. Most of the existing approaches can be classified into two categories: unlexicalized PCFG based (Johnson, 1998; Klein and Manning, 2003; Levy and Manning, 2003; Matsuzaki et al., 2005; Petrov et al., 2006) and lexicalized PCFG based (Collins, 1999a; Charniak, 1997; Bikel, 2004; Charniak and Johnson, 2005).

Unlexicalized PCFG based approach attempts to weaken the independence assumption by annotating non-terminal symbols with labels of ancestor, siblings and even the latent annotations encoded by local information. In lexicalized PCFG based approach, researchers believe that the forms of a constituent and its sub-constituents are determined more by the constituent's head than any other of its lexical items (Charniak, 1997), so they annotate non-terminal symbols with the head words information.

Both of the two PCFG based approaches have improved the basic PCFG based parsers significantly. However, neither of them has been guided by enough linguistic priori knowledge. Their parsing procedures are too mechanical. Because of this, the efficiency is always worse, and much more artificial ambiguities, which are different from linguistic ambiguities (Krotov et al., 1998; Johnson, 1998), are generated. We believe parsing procedure guided by more linguistic priori knowledge will help to overcome the drawbacks in some extent. From our intuition, dependency structure, another type of syntactic structure with much linguistic knowledge, will be a good candidate to guide phrase parsing procedure.

In this paper we present a novel approach to using dependency structure to guide phrase parsing. This novel approach has its virtues from multiple angles. First, dependency structure offers a good compromise between the conflicting demands of analysis depth, which makes it much easier to get through hand annotating than phrase structure (Nivre, 2004). So, when we want to build a phrase structure corpus, we can build a dependency structure corpus first, and get the corresponding phrase structure automatically with the help of dependency structure. Second, many parsing algorithms with linear-time complexity used in dependency parsers can still achieve the state-of-the-art results (Johansson, 2007), but almost all phrase parsers with high-precision have no efficient algorithms superior to cubic-time complexity. So, in order to get an efficient

Coling 2008: Poster Volume, pages 1292–1300,
Beijing, August 2010

parser, we can first get a dependency structure through linear-time algorithm, and then obtain the phrase structure with the help of dependency structure more efficiently. Third, the lexicalized PCFG based parsers which just bring the head words into account have got a highly improved performance. It gives us reasons to believe dependency structure which takes the relationship of all the words will bring phrase parser a great help.

Remainder of this paper is organized as follows: Section 2 introduces the related work. Section 3 gives a consistency between dependency structure and phrase structure, and presents an approach to parsing phrase structure with dependency structure. In Section 4, we discuss the experiments and analysis. Finally, we conclude this paper and point out some future work in Section 5.

2 Related work

Unlexicalized PCFG based parsers (Johnson, 1998; Klein and Manning, 2003; Levy and Manning, 2003; Matsuzaki et al., 2005; Petrov et al., 2006) are the most successful parsing tools. They regard parsing as a pure machine learning question. However, they haven't taken any extra linguistic priori knowledge directly into account. Lexicalized PCFG based parsers (Collins, 1999a; Charniak, 1997; Bikel, 2004; Charniak and Johnson, 2005) just bring a little linguistic priori knowledge (head word information) into learning phase. In inference phase, both of the unlexicalized PCFG based approach and lexicalized PCFG based approach are using the pure searching algorithms, which try to parse a sentence monotonously, either from left to right or from right to left. From these states, we can find that manners of current parsers are too mechanical. Because of this, the efficiency of phrase parsers is always worse, and much more artificial ambiguities are generated.

There have been some work (Collins et al., 1999b; Xia and Palmer, 2001) about converting dependency structures to phrase structures. Collins et al. (1999b) proposed an algorithm to convert the Czech dependency Treebank into a phrase structure Treebank and do dependency parsing through Collins (1999a)'s model. Results showed the accuracy of dependency parsing for Czech was improved largely. Xia and Palmer (2001) proposed a more generalized algorithm according to X-bar theory and Collins et al. (1999b), and they did some experiments on Penn Treebank. The results showed their algorithm produced phrase structures that were very close to the ones in Penn Treebank. However, we have to point out that they only computed the unlabeled performance but lost all the exact syntactic symbols. Different from tree-transformed PCFG based approach and lexicalized PCFG based approach, both of Collins et al. (1999b) and Xia and Palmer (2001) attempted to build some heuristic rules through linguistic theory, but didn't try to learn anything from Treebank.

Li and Zong (2005) presented a hierarchical parsing algorithm for long complex Chinese sentences with the help of punctuations. They first divided a long sentence into short ones according to punctuation marks, then parsed the short ones into sub-trees individually, and at last combined all the sub-trees into a whole tree. Experimental results showed the parsing time was reduced largely, and performance was improved too. Although the procedure of their parser is more close to human beings' manner, it appears a little shallow just using the punctuation marks.

In this paper our motivations are to bring more linguistic priori knowledge into phrase parsing procedure with the help of dependency structure, and make the parsing procedure flexibly.

Matsuzaki et al. (2005) defined a generative model called PCFG with latent annotations (PCFG-LA). Using EM-algorithm each non-terminal symbols was annotated with a latent variable, and a fine-grained model can be got. In order to get a more compact PCFG-LA model, Petrov et al. (2006) presented a split-and-merge method which can get PCFG-LA model hierarchically, and their final result outperformed state-of-the-art phrase parsers. To make the parsing process of hierarchical PCFG-LA model more efficient, Petrov and Klein (2007) presented a coarse-to-fine inference algorithm. In Section 4 of this paper, we try to combine the hierarchical PCFG-LA model in learning phase and coarse-to-fine method in inference phase into our parser in order to get an accurate and efficient parser.

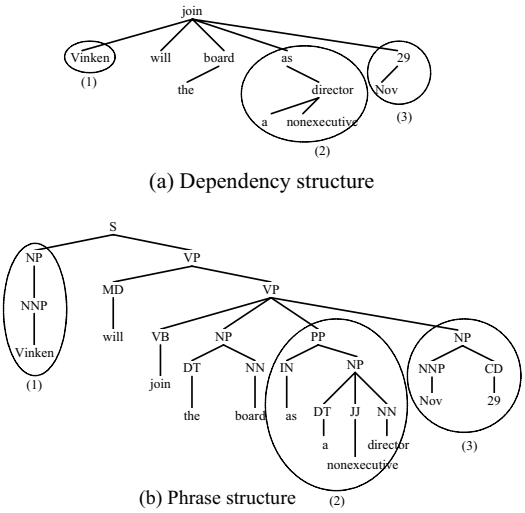

Figure 1. The consistency between phrase structure and dependency structure

3 Our framework

In this section, we first compare phrase structure with dependency structure of the same sentence, and get a consistent relationship among them. Then, based on this relationship, we present an inference framework to make the parsing procedure flexible and more efficient.

3.1 Analysis on consistency between phrase structure and dependency structure

Phrase structure and dependency structure are two different ways to represent syntactic structures of sentences. Phrase structure represents sentences by nesting of multi-word constituents, while dependency structure represents sentences as trees, whose nodes are words and edges represent the relations among words.

As we know, there are two kinds of dependency structures, projective structure and non-projective structure. For free-word order languages, non-projectivity is a common phenomenon, e.g. Czech. For languages like English and Chinese, the dependency structures are often projective trees. In this paper, we only consider English parsing based on Penn Treebank (PTB) and Chinese parsing based on Penn Chinese Treebank (PCTB), so we just research the consistency between phrase structure and projective dependency structure through PTB/PCTB.

Information carried by the two structures isn't equal. Phrase structure is more flexible, carries more information, and even contains all the information of dependency structure. So the task to convert a phrase structure to dependency structure is more straight, e.g. Nivre and Scholz (2004), Johansson and Nugues (2007). However, the reverse procedure is much more difficult, because dependency structure lacks the syntactic symbols, which are indispensable in phrase structure.

Although the two structures are completely different, they have consistency in some deep level. In this paper we analyze the consistency from a practical perspective in order to do phrase parsing with the help of dependency structure. Having investigated the two kinds of trees with dependency structure and phrase structure, we find a consistency[1] that each sub-tree in dependency structure must correspond to a sub-tree in phrase structure who dominates all the words appearing in dependency sub-tree. Figure 1 shows this relationship more intuitively. The dependency sub-tree surrounded by circle (1) in Figure 1(a) is a one-layer sub-tree, and has a corresponding phrase sub-tree surrounded by circle (1) in Figure 1(b). Both of the two sub-trees dominate the same word "Vinken". This consistency is also satisfied in other cases, e.g. two-layer sub-tree surrounded by circle (3) and three-layer sub-tree surrounded by circle (2) in Figure 1(a). These dependency sub-trees respectively have their corresponding phrase sub-trees dominating the same words in Figure 1(b).

This consistency brings us inspiration to make use of dependency structure for phrase parsing. In other words, in our method when a phrase sub-tree is generated from a dependency sub-tree, it must dominate all the same words with ones in the corresponding dependency sub-tree.

3.2 Inference framework

[1] Be aware that the consistency is irreversible and not every phrase sub-tree has its corresponding dependency sub-tree.

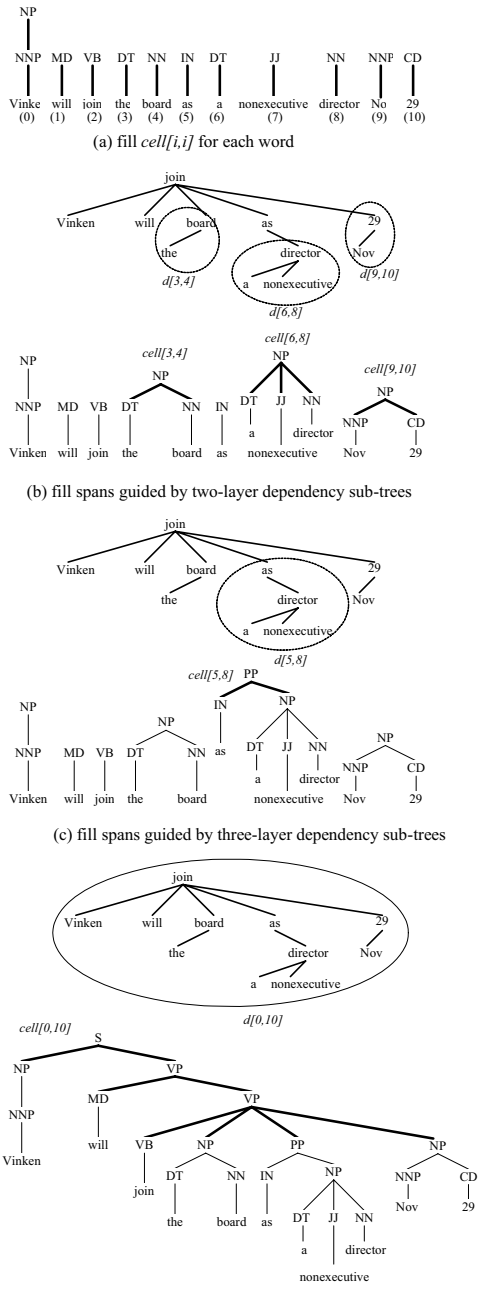

Figure 2. Parsing procedure of our inference framework guided by dependency structure

As we mentioned in Section 2, most of current inference algorithms are monotonous, which generate much more artificial ambiguities. For example, in Figure 1, if a sub-tree only dominating "board" and "as" is built (actually it is not occurred in golden tree) an artificial ambiguity is generated, and it thus will further bring a worse effect to other parts. The final precision will certainly descend. However, if we are given a corresponding dependency structure, those errors will be avoided. The consistency analyzed above tells us that there isn't a sub-tree dominating only "board" and "as" in dependency tree, so the two words can't build a sub-tree independently in phrase parsing. According to this strategy, we design an inference framework for phrase parsing.

Our inference framework parses a sentence flexibly with a traditional inference algorithm. The following terms will help to explain our work. A key data structure is *cell[i,j]*, which is used to store phrase sub-trees spanning words from positions i to j of the input sentence. *d[i,j]* is a dependency sub-tree spanning words from positions i to j. *cells[i,j]* is an array to store all the *cell*s which can be combined to build *cell[i,j]*. The pseudo-code of our inference framework is shown in Algorithm1. The line indicated by (1) and (2) gives us freedom to select any kinds of inference algorithms and matching parsing models.

Algorithm 1
InferenceFramework(sentence *S*, dependency tree *D*)

```
▷ initialize a List for the input sentence
for each word w_i in S do
      fill cell[i, i] and add it to a list L

▷ parse the cells[] hierarchically
for each d[s, t] of D in topological order do
      fill cells[s, t] with spans in L
      fill cell[s, t] with cells[s, t] through
                traditional inference algorithm   (1)
      add cell[s, t] to L

▷ extract the best tree
estimate all trees in cell[0, n]
                through parsing model             (2)
return the best phrase tree
```

Now, let's illustrate the flexible parsing procedure step by step through an example. Please see Figure 2. For simplicity, we just draw sub-trees of the final best tree, and ignore all the others. Figure 2(a) shows the procedure of filling *cell[i,i]* for each word. In Figure 2(b), there are three two-layer dependency sub-trees *d[3,4]*, *d[6,8]* and *d[9,10]*. So we try to generate phrase sub-trees for *cell[3,4]*, *cell[6,8]* and *cell[9,10]*, which have been annotated with bold edges. For example, we use sub-trees contained in *cell[6,6]*, *cell[7,7]* and *cell[8,8]* to

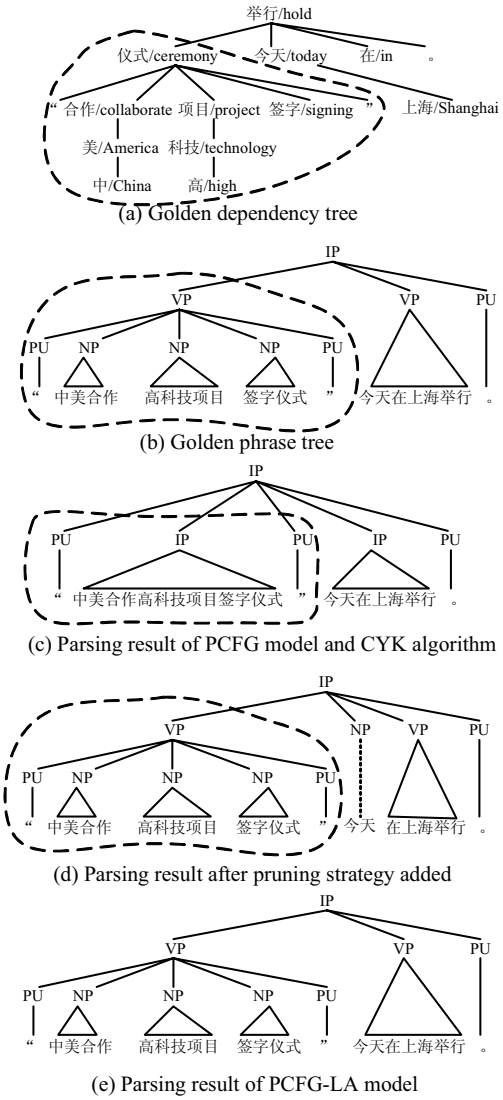

Figure 4. An example showing experimental results

build new sub-trees for *cell[6,8]*. Figure 2(c) and Figure 2(d) show the same procedure for parsing with the help of three-layer dependency sub-trees and four-layer dependency sub-trees individually. The generated phrase sub-trees are all annotated with bold edges in the figure. Obviously, the biggest dependency sub-tree is the whole dependency tree of sentence. In this example, when the four-layer dependency sub-tree is processed, the whole phrase trees are built. Usually, more than one phrase trees with the similar skeletons are generated. So we use a model to evaluate candidate results, and get out the one with the highest score as the final result.

Benefiting from the dependency structure, we can parse a sentence flexibly. Comparing with previous work on converting dependency structure to phrase structure (Collins et al., 1999b; Xia and Palmer, 2001), we make use of Treebank knowledge more sufficient with the help of traditional parsing technology. The search space has been pruned tremendously. As we know, the traditional parsing approach often tries to search all the n*(n+1)/2 cells for input sentence which has n words, but our parsing framework search cells intelligently with the help of corresponding dependency structure. Let's get a view of this through the sentence shown in Figure 2. From the whole parsing procedure shown in Figure 2, our framework just tries to fill 16 cells, which are *cell[i,i]* for each word, *cell[3,4]*, *cell[6,8]*, *cell[9,10]*, *cell[5,8]* and *cell[0,10]* hierarchically, but traditional parsing approach would try to fill all 66 cells. So 75.76% searching space has been pruned.

Table 1. Experimental settings

4 Experiments and results

In order to evaluate the effectiveness of our approach, we have done some experiments both for English parsing and Chinese parsing.

4.1 Preparation

To make comparison with previous work fairly, our experiments are based on general Treebank according to standard settings. We choose Penn English Treebank for English parsing experiments and Penn Chinese Treebank for Chinese. Table 1 shows the standard settings we take.

Because the two Treebanks are in type of phrase structure, we should get dependency structures corresponding with them. There are two ways to accomplish this work. First, use converting tools to get dependency trees directly through converting the original Treebanks, and the generated trees are always considered as golden trees during dependency parsing. Second, use a dependency parser with state-of-the-art

performance to parse all the sentences automatically. In this paper, we design two groups of experiments, as following:

(1) Phrase parsing with the help of golden dependency trees.
(2) Phrase parsing with the help of N-best dependency trees generated automatically.

4.2 Phrase parsing with golden dependency trees

In order to verify how much dependency structure can help phrase parsing and get an upper bound of our approach, we do phrase parsing with the help of golden dependency trees in this subsection.

Based on the parsing framework shown in Figure 3, we only use the basic PCFG in learning phase and our inference framework with basic CYK algorithm in inference phase. The parsing results are shown with the mark (1) in Table 2 for English and Table 3 for Chinese respectively.

Having investigated the generated trees with golden trees, we find the consistency of dependency structure and phrase structure is broken by some trees. Let's get a view of this through an example from Penn Chinese Treebank. In Figure 4(a), the dependency sub-tree surrounded by circle tells us that there must be a phrase sub-tree which dominate the word sequence of "中 美 合作 高 科技 项目 签字 仪式" (the signing ceremony of collaborating in high technology between America and China), and the golden phrase tree shown in Figure 4(b) has a corresponding sub-tree surrounded by circle indeed. However, the parsing tree generated by our approach shown in Figure 4(c) doesn't conform. There are three sub-trees dominating the word sequence mutually, but they don't construct a whole one. In our opinion, the contradiction derived from binarizing process of CYK[2]. The binary trees generated by our algorithm have consisted with the consistency originally, but after debinarizing process the consistency is broken.

Trying to check our opinion, we add a pruning strategy to the original inference algorithm to prune all the medial nodes which may break the consistency during parsing procedure. With the help of pruning strategy, the performances of English and Chinese are all improved further. Corresponding figures are shown in Table 2 and Table 3 with the mark (2). The parsing result of above example is shown in Figure 4(d) and the error appearing in Figure 4(c) is corrected naturally after the pruning strategy added.

Comparing with previous work which have done much work in learning phase, our algorithm achieves such amazing results only using basic PCFG model. From this aspect, our inference framework is much more effective. However, there are still some errors our approach can't deal with. For example, in Figure 4(d) the sub-tree rooted at NP and dominating word sequence of "今天 在 上海 举行" (hold in Shanghai today) is separated by two sub-trees. The reason is that the model (basic PCFG) we use in learning phase is too coarse to disambiguate sufficiently. So we don't pin all hopes in inference phase. We also modify the model in learning phase. PCFG-LA is one of the most successful models in phrase parsing, so we choose PCFG-LA as the model in learning phase. After this modification, performance of our approach has been improved delightedly. F1 score is 96.08% for English and 90.06% for Chinese. The line marked with (3) in Table 2 and Table 3 shows more details.

4.3 Phrase parsing with N-best dependency trees generated automatically

The experimental results shown in subsection 4.2 bring us confidence that do phrase parsing with the help of dependency structure is a highly effective approach. However, we don't usually have golden dependency structures, and a more acceptable way is using a dependency parser to generate dependency trees automatically. In this subsection we explore feasibility and effectiveness of phrase parsing with the help of dependency trees generated automatically. As we all know, even state-of-the-art dependency parser cannot generate totally correct result. So in order to make our system more robust we use N-best dependency structures to guide phrase parsing procedure.

[2] The premise of using CYK is that all the rules must have CNF form. So we usually bring some medial nodes to binarize rules gathered from Treebank.

	length<=40			all sentences		
	Precision	Recall	F1	Precision	Recall	F1
(1) Using PCFG and CYK	90.28	88.41	89.34	90.11	88.32	89.21
(2) Using pruning strategy	90.69	89.53	90.11	90.51	89.45	89.97
(3) Using PCFG-LA	96.28	95.97	96.13	96.25	95.91	96.08

Table 2. Parsing performance (%) for English with the help of golden dependency tree.

	length<=40			all sentences		
	Precision	Recall	F1	Precision	Recall	F1
(1) Using PCFG and CYK	86.89	78.25	82.34	85.56	77.43	81.29
(2) Using pruning strategy	87.65	82.33	84.91	86.39	81.45	83.85
(3) Using PCFG-LA	91.51	91.26	91.38	90.43	90.79	90.61

Table 3. Parsing performance (%) for Chinese with the help of golden dependency tree.

We choose MSTParser[3] which is the most famous dependency parser and modify it to generate N-best dependency trees. The oracle unlabeled accuracy of N-best dependency trees generated from 1-order model is shown in Table 4. To show the effectiveness of our approach, we choose Berkeleyparser[4] as the baseline parser, take the same configuration and combine it into our general parsing framework shown in Figure 3.

Considering the number of dependency structures (N-best) will affect the final result, we make use of the development set shown in Table1 to turning parameters. We parse the development set many times with different number of dependency structures. The F1 scores are shown in Figure 5 for English and Figure 6[5] for Chinese. From Figure 5 and Figure 6, we can find when we use 10-best dependency structures the performance is better. So we choose 10-best dependency trees for the test set.

The final performances of test set comparing with previous work are shown in Table 5 and Table 6. We can easily find that our approach has outperformed all the parsers which aren't improved through reranking stage or semi-supervised approach. Although there is still a margin between our parser and reranked parser or semi-supervised parser, we believe that the parsing performance can be improved further if we bring the reranking or semi-supervised approaches into our parsing framework.

4.4 Discussion

The experiment of parsing with golden dependency structure gets an amazing performance. It brings us a new way to build PTB/PCTB style phrase structure corpus. Because dependency structure is much easier to get through hand annotating than phrase structure, we can build a dependency structure corpus first, and then get phrase structure corpus through our approach guided by the dependency structure corpus.

The experiment of parsing with N-best dependency structures generated automatically uplifts the parsing performance to a new height. It brings us a more applied parsing tool for other NLP applications.

From the experiments in Section 4.2, we can find that even using the golden dependency structure we can't get totally correct phrase structure. The reason is that although every dependency sub-tree has its corresponding phrase sub-tree, not every phrase sub-tree has its corresponding dependency sub-tree. So the remainder errors can't be solved only by dependency structure and a better way is to modify the parsing model.

5 Conclusion and Future work

In this paper, we present a novel phrase parsing approach with the help of dependency structure. Based on the consistency between phrase structure and dependency structure, we propose a novel inference framework. Guided by the inference framework, inference algorithms parse sentences hierarchically with the help of dependency structures. Experimental results show that our approach can efficiently get better performance with both golden dependency structure and N-best dependency

structures generated automatically.

However, there are still some problems remaining to further study. First, in our approach we just use the unlabeled dependency trees. The relationship labels carry some useful information too, and we can make use of them to further improve phrase parsing. Second, phrase structure can also help the process of dependency parsing (McDonald et al., 2006), so

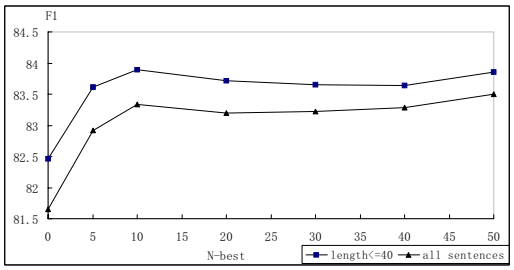

Figure 6. F1 scores (%) of Dev Set for Chinese with the help of N-best dependency trees

we can combine phrase parsing process and dependency parsing process together and make them help each other.

Abstract

The overwhelming amounts of multimedia contents have triggered the need for automatically detecting the semantic concepts within the media contents. With the development of photo sharing websites such as Flickr, we are able to obtain millions of images with user-supplied tags. However, user tags tend to be noisy, ambiguous and incomplete. In order to improve the quality of tags to annotate web images, we propose an approach to build Semantic Fields for annotating the web images. The main idea is that the images are more likely to be relevant to a given concept, if several tags to the image belong to the same Semantic Field as the target concept. Semantic Fields are determined by a set of highly semantically associated terms with high tag co-occurrences in the image corpus and in different corpora and lexica such as WordNet and Wikipedia. We conduct experiments on the NUS-WIDE web image corpus and demonstrate superior performance on image annotation as compared to the state-of-the-art approaches.

1 Introduction

The advancement in computer processor, storage and the growing availability of low-cost multimedia recording devices has led to an explosive growth of multimedia data. In order to effectively utilize such a huge amount of multimedia contents, we need provide tools to facilitate their management and retrieval. One of the most important tools is the automatic media concept detectors, which aim to assign high-level semantic concepts such as "bear" to the multimedia data. More formally, the concept detection for an web image is defined as: given a set of predefined concepts $\vec{C}$: [C_1, C_2 ...C_n], we assign a semantic concept C_i to the image if it appears visually in the image. Traditionally, such concept detectors are built by the classifier approaches. The performance of such detectors depends highly on the quality of training data. However, preparing a set of high quality training data usually needs a large amount of human labors. On the other hand, the social web is changing the way people create and use information. For example, users started to develop novel strategies to annotate the massive amount of multimedia information from the web. In image annotation, Kennedy et al. (2006) explored the trade-offs in acquiring training data by automated web image search as opposed to manual human labeling. Although the performance of systems with training data obtained by manual human labeling is still better than those whose training data is acquired by automated web search, the latter approaches have attracted many researchers' interest due to their potential in reducing human label efforts. However, the tags in the web images are known to be ambiguous and overly personalized (Matusiak 2006).

Figure 1 gives four examples to illustrate the relationships between the visual concept "bear" and the annotation tag "bear". Generally speaking, there are four types of relationships:

Coling 2008: Poster Volume, pages 1301–1309,
Beijing, August 2010

- The relevant tag: The user-tag "bear" properly reflects the content of an image, as shown in Figure 1(a). While "bear" has multiple senses, the visual concept corresponds directly to the most common sense of "bear".
- The ambiguous tag: The user-tag "bear" is ambiguously related to the visual content, as shown in Figure 1(b). In this example, the visual content is related to another sense of "bear": "a surly, uncouth, burly, or shambling person" (Merriam-Webster dictionary, 2010).
- The noisy tag: The user-tag "bear" is a noisy tag, as shown in Figure 1(c). In this example, the visual content is irrelevant to the concept "bear".
- The incomplete tag: The user-tag "bear" doesn't occur in the tag list of Figure 1(d). However, many human annotators believe that the visual concept "bear" exist in the Figure 1(d). Also, in Wikipeida, a panda is defined as a kind of a bear.

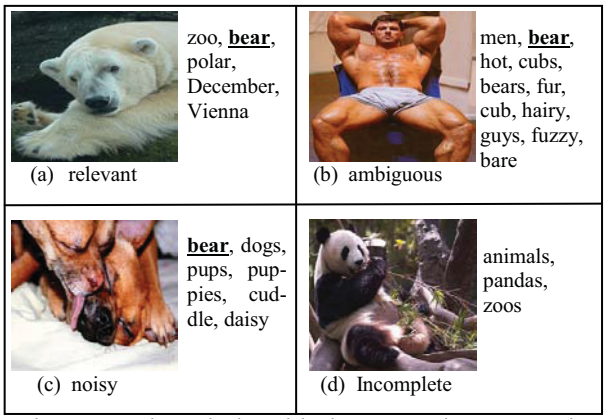

Figure 1: The relationship between the tags and the visual concept "bear" in NUS-Wide corpus.

In this paper, we aim to assign relevant tags to images in order to reduce the effects of ambiguous, noisy and incomplete tags. To distinguish relevant tags from other sense of tags, a common practice is to perform word sense disambiguation (WSD) to predict the right sense of a tag. Nevertheless, performing a WSD on a noisy and sparse set of tags, where the order and position of tags do not matter, is by no means easy. Most existing works on WSD, such as Navigli (2009) are based on clean data and word neighborhood statistics. They cannot be directly applied to address this problem. Although there are some works such as Wang et al. (2003) on capturing the semantics of noisy data, the problem of ambiguous words has not been considered. In addition, some semantic models such as PLSA (Hofmann 1999), LDA (David et al. 2003) have been proposed to capture the semantics. However, one challenge of employing such models is that there are many noisy tags in the web image domain. The reason for noisy tags is that the purpose of tagging is not only for content description, but also for other factors such as getting attention and so on (Ame and Naaman, 2007, Bischoff et al. 2008).

Given a web image with a tag list, we propose an approach to predict the "Semantic Field" of the image. Semantic Field (Jurafsky and Martin 2000) is designed to capture a more integrated relationship among the entire sets of tags. In our work, we consider four different cases of examples, as shown in Figure 1. In 1(a), the concept "bear" will be assigned to the image with relatively high probability, because "zoo", "bear", and "polar" provide clues that "bear" is the major focus of the image. In 1(b), the concept "bear" could possibly be disambiguated as not related to "animal", the most common sense of "bear", by investigating other tags such as "men","guys". In 1(c), the image will not be labeled as "bear", since the surrounding tags such as "dogs", "pups" do not support the existence of "bear" in the image. In 1(d), although the concept "bear" is missing, the image will be still labeled as "bear" since the surrounding tags such as "pandas", "animals", and "zoos" jointly suggest that "bear" appears in the image. The significance of user tags towards a target concept can be modeled from three different sources: the statistics from the web image corpus, Wordnet and Wikipedia. In summary, instead of directly matching the keywords and tags, we consider tags of an image collectively to predict the underlying semantic field. Ideally, the semantic field can highlight the major visual concepts in images so that we can assign the correct semantic labels to the images.

In the rest of this paper, we discuss related work in Section 2, while Section 3 reports the building of Semantic Fields and its application to web image ranking. Section 4 discusses the experimental setup and results. Finally, Section 5 contains our concluding remarks.

2 Related Work

In this section, we report the works on Semantic Field theory, text analysis in multimedia and the existing systems for a web image corpus.

2.1 Semantic Fields

Semantic Fields have been hotly debated in linguistics community (Grandy 1992, Garret 1992). Compared to lexical analysis, it considers the entire sets of words instead of a single word. The FrameNet project (Baker et al. 1998) is an attempt to realize the Semantic Field. However, the problem with FrameNet project is that it needs extensive human efforts to define the thematic roles for each domain and each frame, and hence it is domain specific.

2.2 Text Analysis in Multimedia

In multimedia, one of the important tasks is concept detection, which attempts to find the visual appearance of a concept such as "bear" in an image. However, due to the large variations in the low level visual feature space such as color, texture etc, in many cases, researchers are hardly able to capture the concept by visual information alone. Some researchers attempted to employ natural language analysis to detect the visual concept. Rowe (1994) explored the syntax of images' captions to infer the visual concepts present in images. For example, he found that the primary subject noun phrase usually denotes the most significant information in the media datum or its "focus". He assumed that both visual and text features will describe the same focus of the content. Wang et al. (2008) employed the similar idea to infer visual concepts in news video. They first aligned text information with visual information, and then captured the text focus to infer the visual concept. These works suggest that we can transfer the problem of visual concept detection to that of finding a text focus.

In addition, researchers proposed statistical models to combine text and visual features, such as the translation model (Duygulu et al. 2002, Jin et al. 2005), cross media relevance model (Jeon et al. 2003) and continuous relevance model (Lavrenko and Jeon, 2003). However, no matter what models we used, the annotation accuracy is still quite low, partially because of the existence of noise in tags. Jin et al. (2005) provided a solution to tackle such a noisy tag problem. They first investigated various semantic similarity measures between each keyword pairs in the tag list based on Wordnet. They then regarded non-correlated keywords as noises and discarded them. In this paper, there are three major differences between our work and the above work. First, because tags from Internet are not always included in Wordnet, we employ multi-resources of information to analyze the semantics. Second, we extend the analysis of the word pair relationship to the Semantic Field analysis. Third, since it is not easy to identify the noise in the tag list directly, we only analyze the tags which are highly relevant to the concept with a specific sense.

2.3 The State of the Art Systems

NUS-WIDE (Chua et al. 2009) is a large scale Web image corpus. It provides not only social tags from the web, but also the "gold" labels (or ground truth) for 81 concepts from large human labeling efforts. As far as we know, there are two reported systems that used the whole NUS-WIDE corpus to test their proposed methods. In Chua et al. (2009), the 81 concepts are detected by k nearest neighbor using the visual features of: color moments, color auto-correlogram, color histogram, edge direction histogram, wavelet texture, and a bag of visual words. The mean average precision (MAP) for the 81 concepts reaches 0.1569. Gao et al. (2009) extended the k-NN approach to use both text tags and visual information. For the tag information, they made use of the co-occurrence information to compute the probability of an image belonging to a contain concept. They used the same visual features as in (Chua et al. 2009). In their work, the taxonomy in WordNet is exploited to identify whether a target concept is generic or specific. The co-occurrence tag analysis is employed for generic concepts, while visual analysis is used for specific concepts. The MAP for this approach reaches 0.2887.

3 Building Semantic Fields for Annotating Web Images

In this paper, we attempt to capture text semantics collectively from the tag list of images to annotate their visual contents. Semantic Fields consist of a selected subset of the tag list and

the choice of these tags is based on their relevance to the contents of the targeted image with a specific sense. There are three characteristics in our Semantic Field model. First, the Semantic Field is built by only a subset of tag list. For example, the Semantic Field in Figure 1(a) is {zoo, bear, polar}. It could partially reduce the effect of the noise. Second, because inferring the visual concept of an image is more reliable by joint analysis of tags in the Semantic Field, rather than investigating one tag at a time in the whole tag list, we analyze the whole Semantic Field as a unit. By utilizing the context information in Semantic Field, the problems of ambiguous, noisy and incomplete tags are partially tackled. Third, we perform normalization to estimate the importance of Semantic Field, which is discussed in Section 3.1. If the value is large, it suggests that most of the tags in the image support the Semantic Field; that is, the probability that the target concept is the focus of the image is high, and vice versa. Such a design aims to minimize the effects of noisy and ambiguous tags.

3.1 A Probabilistic Model

We denote C_x as a target concept that appears in the content of an image. We want to determine the set of tags that are related to C_x from the user-supplied tags by building a Semantic Field SF_i for each image. The probability of the appearance of concept $P(C_x \mid SF_i)$ can be computed as:

$$P(C_x \mid SF_i) = \frac{P(SF_i \mid C_x) \times P(C_x)}{P(SF_i)} \qquad (1)$$

For the purpose of collecting and annotating images and simplifying the model, we did not consider the prior knowledge for each image. Thus, the prior probability $P(C_x)$ can be viewed as a constant with respect to a concept C_x. In addition, the range of the normalization factor $P(SF_i)$ is expected to be small, which will not affect the annotation of web images. This assumption is reasonable due to the fact that there are a large number of different tags, and these tags can be combined to form any Semantic Field in an arbitrary manner. The number of combinations is exponential to the number of possible tags available. This is also evident by the observation that most tag lists associated with the images are unique. In other words, two images with the same Semantic Field are seldom found in reality. With these in mind, Equation (1) can be approximated and simplified to:

$$P(C_x \mid SF_i) \propto P(SF_i \mid C_x) \qquad (2)$$

Given a Semantic Field SF_i, it may include n related tags $T_1, T_2, T_3, ..., T_n$. Thus Equation (2) is expanded to:

$$P(SF_i \mid C_x) = P(T_1, T_2, ...T_n \mid C_x) \qquad (3)$$

Two obvious approaches to compute Equation (3) are using the product of the individual terms or chain rule decomposition. However, we consider the individual terms to be interdependent and the chain rule decomposition is not easy to compute. To simplify the model, we employ the normalized linear fusion to expand Equation (3) as follows:

$$\mathrm{P}(T_1, T_2, ...T_n \mid C_x) = \frac{\sum_{i=1}^{n} P(T_i \mid C_x)}{\mathrm{TN}} \qquad (4)$$

The normalization factor is the total number (TN) of tags in the image tag list.

3.2 Using Multiple External Sources

To estimate the probability of a tag T_i given a target concept C_x, i.e., $P(T_i|C_x)$, we consider both the domain knowledge and general knowledge acquired from Internet. For the former, we utilize the co-occurrence statistics of tags in images which can be computed offline from any web image corpus. For the latter, we employ WordNet and Wikipedia for inferring the relatedness between tags and a target concept. Combining different knowledge sources, the probability is estimated as:

$$P(T_i \mid C_x) = P(T_{i\_wd} \mid C_x) \times P(T_{i\_wiki} \mid C_x) \times P(T_{i\_co} \mid C_x) \quad (5)$$

where T_{i_wd}, T_{i_wiki}, T_{i_co} represent the tag occurrences in WordNet, Wikipedia and co-occurrence statistics, respectively.

To compute Equation (5), we query different information sources using the target concept C_x. In WordNet, because the sense of the concept usually refers to the most common sense in our corpus, we choose the most common sense (noun) as the target. Using Figure 2 as an example, the concept "bear" is defined in WordNet as “massive plantigrade carnivorous or omnivorous mammals with long shaggy coats and strong claws”. In Wikipedia, with Figure 3 as an example, the related page is downloaded to

describe the concept "bear". For the co-occurrence statistics of the tag lists, we estimate their values from co-occurrence information from the image corpus. With the above knowledge, we compute the conditional probability of a tag being related to C_x as:

$$P(T_j \mid C_x) = \frac{\#(T_j, C_x)}{\#(C_x)} \qquad (6)$$

where j = {wd, wiki, co}, $\#(T_j, C_x)$ indicates the number of times the tag and the concept co-occur in an information source, and $\#(C_x)$ denotes the number of times the concept C_x appear in the information source. In addition, we employ an add-one smoothing approach [Jurafsky and Martin 2000] to further process the results.

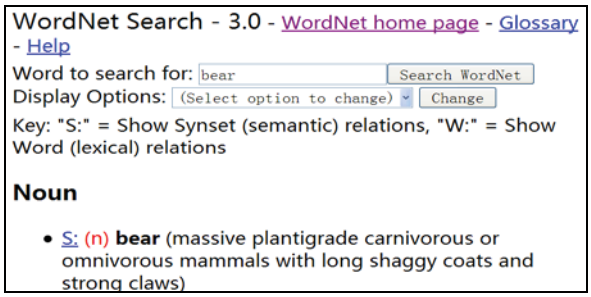

Figure 2: The information in WordNet

Figure 3: The information in Wikipedia.

Given a concept with a special sense, for all the tags in the corpus, we can obtain the conditional probabilities of each tag T_i based on Equation (5). We rank the tags according to $P(T_i \mid C_x)$. To reduce computations, we select the top N (N=200) tags as the highly related tags to a given concept and place them in a dictionary.

3.3 Building Semantic Field for Image Annotation

We now build the Semantic Fields to rank the images with respect to concept C_x. The detailed algorithm is shown in Figure 4.

Input:
1) Given a target concept, we rank all the tags in the corpus based on Equation (5).
2) Given a web image, we have a list of annotation tags ($l_1, l_2, ...l_{n1}$).

Step 1: Generate a dictionary (D) based on top N tags

Step 2: For (i=1; i<n1; i++)
If ($l_i \in D$) then put l_i into the Semantic Field for the image.

Step 3: Annotate the images and compute the probability of the occurrence of the concept via Equation (4)

Figure 4: The algorithm for building the Semantic Fields and annotating the images.

The algorithm comprises three steps:

1. bear	2. bears	3. polar	4. species
5. panda	6. cubs	7. giant	8. grizzly
9.teddy	10. pandas	…	…

Table 1: The top 10 tags for concept "bear" in most common sense.

First, given a target concept with a specific sense, we generate a dictionary based on the top N candidate tags as discussed in Section 3.2. Table 1 shows the top 10 tags in the dictionary for the concept "bear" with the most common sense. As we want to distinguish single and plural noun for different visual concepts, we do not employ the stemming algorithm. Although the results are not ideal, we find that many highly related words are included in the dictionary.

Second, we infer the annotation tags of the image from the dictionary and use that to build the Semantic Fields. Figure 1 demonstrates the resulting of Semantic Fields for images in Table 2.

Third, we assign the tags to images based on their Semantic Fields. Because most of the tags in Figure 1(a) and 1(d) are highly relevant to "bear" with the most common sense, we assign the semantics to these two images with high probabilities. Thus, the problem of incomplete tags is tackled in this case. On the other hand, since most of the tags in Figure 1(b) and 1(c) fail to support the concept "bear" with the most

common sense (the Semantic Field obtains less than 20% of tags' support), we only assign the semantics with very low probabilities. Thus, the ambiguous and noisy problem can be partially tackled.

Semantic Field for Figure 1 (a)	{zoo, bear, polar}
Semantic Field for Figure 1 (b)	{bear, bears}
Semantic Field for Figure 1 (c)	{bear}
Semantic Field for Figure 1 (d)	{animals, pandas, zoos}

Table 2: Semantic Fields of images in Figure 1.

4 Experiments

In this section, we first introduce the test-bed and measurement of the experiments. We then report the results and compare them with the state-of-the-art systems tested on NUS-WIDE corpus.

The NUS-Wide corpus (Chua et al. 2009) includes 269,648 images with 5,018 user-provided tags, and the ground-truth for 81 concepts for the entire database. These concepts are grouped into six different categories: graph, program, scene /location, event/activities, people and object. The choice of concepts is based on the generality and popularity in Flickr, the distributions in different categories and the common interests of the multimedia community. This corpus includes two parts. The first part contains 161,789 images to be used for training and the second part contains 107,859 images is used for testing.

The performance of the system is measured using the mean average precision (MAP) based on all the test images for all the 81 concepts. This is the same as the evaluation used in TRECVID. The MAP combines precision and recall into one performance value. Let $p^k = \{i_1, i_2, ..., i_k\}$ be a ranked version of the resulting set A. At any given rank k, let $R \bigcap p^k$ be the number of relevant images in the top k of p, where |R| is the total number of relevant images. Then MAP for the 81 concepts C_i is defined as:

$$MAP = \frac{1}{81}\sum_{C_i=1}^{81}[\frac{1}{|R|}\sum_{k=1}^{A}\frac{R \bigcap p^k}{k}\varphi(i_k)] \quad (6)$$

where the indictor function $\varphi(i_k) = 1$ if $i_k \in R$ and 0 otherwise.

4.1 Comparison with the State-of-the-Art Systems

We compare our approach against the reported systems on NUS-WIDE corpus.

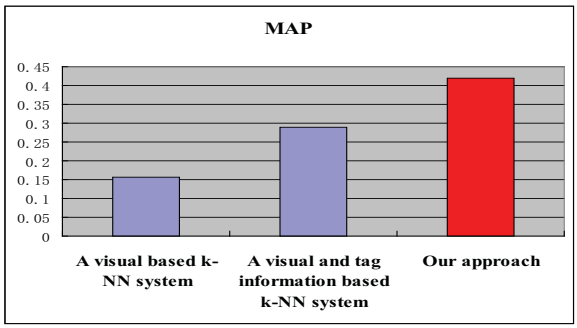

Figure 5: The comparison with the state-of-the-art system

In our approach, we employ the Semantic Field to annotate the images, which requires neither training data nor visual analysis, and is running directly on the test data. In contrast to the two previous approaches in Section 2.3, the input to Semantic Field is simply the tag list of an image. Figure 5 shows the performance comparisons among the three tested approaches. As compared to (Chua et al. 2009) and (Gao et al. 2009), which exhibit the best performance on NUS-WIDE so far, Semantic Field achieves a MAP of 0.4198 which shows a 45.4% improvement.

The reason for the superior performance of our approach is that there is insufficient training data, which means that most learning-based systems could not perform well. As seen in Figure 6(a), 44% of concepts have less than 1,000 positive training data. This is insufficient for training the classifiers for the visual concepts. Take the visual concept "flag" as the example. Considering that there are at least 200 national flags from different countries and regions, not to mention other types of flags such as holiday flag, there are large variations in concept "flag" as shown in Figure 6(b). Hence it is difficult to train a classifier with visual analysis by having only 214 positive training samples. This suggests that there may be a large

gap between the training and test data. On the other hand, because web images include not only visual features but also text information, we could employ text analysis to infer the visual concept. The advantages of our Semantic Field approach are that we could analyze multiple information sources to reduce the text variations and the performance of our approach is independent of the training data and visual features. With the increasing size of the corpus, the problems of few positive training data and large visual diversity between training and test data will be exacerbated. This is the reason why our approach is more robust than those based on visual analysis and traditional learning-based approaches.

(b) Different color and different shapes for the concept "flag" in NUS-Wide corpus.

Figure 6: Various visual patterns need a lot of training data

4.2 The Noisy, Ambiguous and Incomplete Tag Problems

We design the second experiment to evaluate the ability of our algorithm to tackle the noisy and ambiguous and incomplete tag problem in user-supplied tags. The baseline system is a keyword (tag) matching algorithm. That is, if the image contains the keyword in the tag list, the algorithm will regard it as relevant to the concept; otherwise, it is irrelevant. The results are shown in Figure 7.

We found that our approach achieves a relative improvement of 38% as compared to the keyword matching approach. This is because the Semantic Field approach selects and analyzes a group of tags as a whole, which provides essential context information and reduces the effects of noisy, ambiguous and incomplete tags.

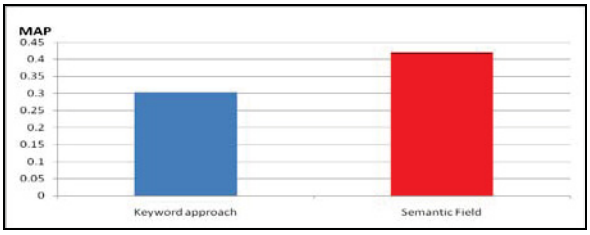

Figure 7: Comparison with keyword matching approach

For completeness, we also evaluate the system using the Equations (7) and (8) according to the top k images (k=1000, 2000, 3000, 4000, 5000).

$$P(tag) = \frac{\sum_{i=1}^{N} \frac{\#(p_i)}{\#(A_i)}}{N} \quad (7)$$

$$R(tag) = \frac{\sum_{i=1}^{N} \frac{\#(p_i)}{\#(T_i)}}{N} \quad (8)$$

We use p_i to represent the number of images with the target concept and A_i to represent the number of retrieved images for tag i. N denotes the number of different detected concepts (tags) in the ground truth set. In this corpus, the value of the N is 81. T_i is the number of the ground truth for a certain target concept.

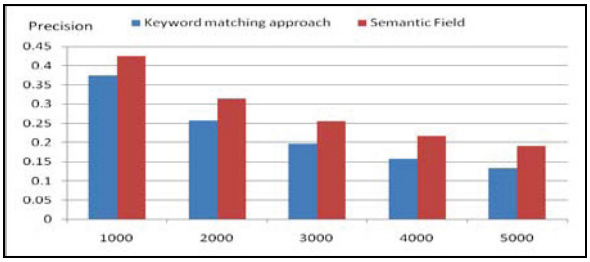

Figure 8: Comparison in precision on top-k image ranking. The x-axis indicates the value of k, while the y-axis shows the P(tag).

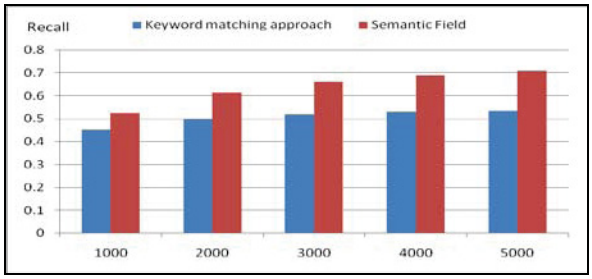

Figure 9: Comparison in recall on top-k image ranking. The x-axis indicates the value of k, while the y-axis shows the R(tag).

Figures 8 and 9 report the performance in precision and recall respectively. From the results, we find that our approach is better than that of the baseline system in both precision and recall. This is because on one hand the Semantic Field tackles the ambiguous and noisy tag problems so that we could improve the precision. On the other hand, the Semantic Field analysis includes many highly related tags, which tackle the incomplete tags problem so that it could improve the performance in recall.

4.3 Importance of Multi-source Information

Semantic Fields combine three information sources: WordNet, Wikipedia and the tag's co-occurrence information in the NUS-Wide corpus. We design the third experiment to evaluate the contribution of each information source. The results are shown in Figure 10.

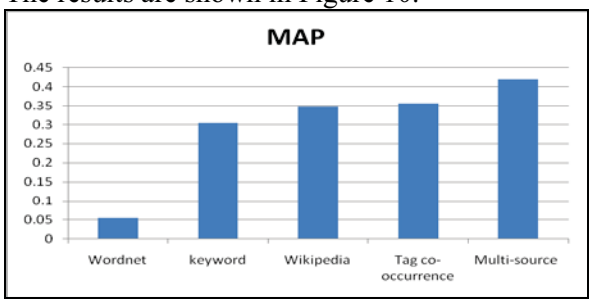

Figure 10: The comparison between using single information source and fusion of multiple information sources.

From Figure 10, we find that the performance of using WordNet alone obtains the worst result. This is because the number of tags carries the most common sense is limited and there are some noisy words in the description. For example, in Figure 2, the occurrence of the word "long" does not imply the occurrence of the concept "bear". Due to the lack of further information, using WordNet alone can hardly remove the noisy tag "long". The test result shows that such noisy information significantly degrade the performance of the system. This suggests the importance of incorperating other sources of informaiton to provide more complete information for the analysis.

We can also observe that using Wikipedia or tag co-occurrence shows comparatively better performance. This is because both information sources include abundance information for analysis. Thus, compared to the keyword-based approach, the performance of the systems shows around 17% improvement. Finally, fusing the three information sources results in the best MAP performance. This is because information from different sources complements each other and helps in reducing the effects of the noisy, ambiguous and incomplete tags.

5 Conclusion

In this paper, we proposed the use of Semantic Field to annotate web images. It could reduce the influences of noisy, ambiguous and incomplete tags so that the quality of the tags assigned to the web image can be improved. Our experiments showed that our approach is more robust and could achieve 38% improvement in MAP as compared to the learning-based and visual analysis approaches when there is sufficient text information. Also the fusion of multiple information sources could further boost the performance of the system.

The work is only the beginning. Future works include the followings. First, as multimedia data includes multiple modality features, how to fuse them to improve the performance of the system is an important problem. Second, current version of our algorithm only could identify one sense of the concept. How to distinguish among different senses of the concept is also an urgent task. Third, we will explore more semantic relations from Wordnet, Wikipedia and so on.

Automatic Extraction of Cue Phrases for Cross-Corpus Dialogue Act Classification

Nick Webb and **Michael Ferguson**
ILS Institute, SUNY Albany
nwebb@albany.edu, ferguson@cs.albany.edu

Abstract

In this paper, we present an investigation into the use of cue phrases as a basis for dialogue act classification. We define what we mean by cue phrases, and describe how we extract them from a manually labelled corpus of dialogue. We describe one method of evaluating the usefulness of such cue phrases, by applying them directly as a classifier to unseen utterances. Once we have extracted cue phrases from one corpus, we determine if these phrases are general in nature, by applying them directly as a classification mechanism to a different corpus to that from which they were extracted. Finally, we experiment with increasingly restrictive methods for selecting cue phrases, and demonstrate that there are a small number of core cue phrases that are useful for dialogue act classification.

1 Motivation

In this paper we present a recent investigation into the role of linguistic cues in dialogue act (DA) classification. Dialogue acts (Bunt, 1994) are annotations over segments of dialogue that characterise the function of those segments. Linguistic cues, which can take many forms including lexical and syntactic structures, are features that can serve as useful indicators of discourse structure (Hirschberg and Litman, 1993; Grosz and Sidner, 1986). In prior work, several researchers have shown that cue phrases can be a powerful feature for DA classification (Samuel et al., 1999; Webb et al., 2005a). Webb and Liu (2008) have previously shown that cue phrases automatically extracted from one corpus can be used to classify utterances from a new corpus. We take this approach and apply it to two established corpora with manually encoded dialogue act annotations, to investigate both the existence and the usefulness of cue phrases shared between the two corpora.

2 Related Work

In parallel with the increased availability of manually annotated dialogue corpora there has been a proliferation of literature detailing dialogue act labelling as a classification task. Prior work describes the selection of features from the corpus (including word n-grams, cue phrases, syntactic structures, dialogue history and prosodic cues) which are then passed to some machine learning algorithm. Most studies have concentrated on a single corpus, and optimised feature selection and learning algorithm accordingly. In this work we focus on two corpora, Switchboard and ICSI-MRDA, and discuss prior classification efforts relating to these two corpora.

2.1 Switchboard Corpus

The Switchboard corpus contains a large number of approximately 5-minute conversations between two people who are unknown to each other, who were asked to converse about a range of everyday topics with little or no constraint. The DA annotated portion of the Switchboard corpus (Jurafsky et al., 1997) consists of 1155 annotated conversations, containing some 225,000 utterances, of which we use 200,000 utterances, the rest being held out for separate experiments. The dialogues are annotated with a non-hierarchical variant of the DAMSL annotation scheme (Core et al., 1999). The resulting Switchboard-DAMSL annotation was a set of more than 220 distinct labels. To obtain enough data per class for statistical modelling purposes, a clustered tag set was devised, which distinguishes 42 mutually exclu-

Coling 2008: Poster Volume, pages 1310–1317,
Beijing, August 2010

sive DA types. Classification over the Switchboard corpus has been demonstrated using Decision Trees (Verbree et al., 2006), Memory-Based Learning (Rotaru, 2002) and Hidden Markov Models (HMM) (Stolcke et al., 2000). The work of Stolcke et al. (2000) is often cited as the best performing, achieving a classification accuracy of 71% over the 42 labels, although there is no cross-validation of these results. The approach of Stolcke et al. (2000) combines HMM modelling of utterances with a tri-gram model of DA sequences. Webb et al. (2005a) report a slightly lower cross-validated score (of 69%) containing an individual classification high of 72%, using an intra-utterance, cue-based classification model.

2.2 ICSI-MRDA Corpus

Like the Switchboard corpus, the ICSI Meeting Room DA (MRDA) corpus (Shriberg et al., 2004) was annotated using a variant of the DAMSL tagset, similar but not identical to the Switchboard-DAMSL annotation. The differences (and a translation between the two sets) can be seen in Shriberg et al. (2004). The underlying domain of the dialogues in the ICSI-MRDA corpus was that of multi-party meetings, with multiple participants discussing an agenda of items in a structured meeting. This application required the introduction of new tags specifically for this scenario, such as a label introduced to indicate when an utterance was used to take control of the meeting. The ICSI-MRDA corpus comprises 75 naturally occurring meetings, each around an hour in length. The section of the corpus we use consists of around 105,000 utterances. For each utterance in the corpus, one general tag was assigned, with zero or more additional specific tags. Excluding non-labelled cases, there are 11 general tags and 39 specific tags resulting in 1,260 unique dialogue acts used in the annotation. As with the Switchboard corpus, processing steps were introduced that compressed the number of unique DAs to 55. In later work, the dimensionality was further reduced, resulting in a subset of just 5 labels.

Over the ICSI-MRDA corpus, we also see DA classification efforts using Decision Trees (Verbree et al., 2006) and Memory-Based Learning (Lendvai and Geertzen, 2007), in addition to Graph Models (Ji and Bilmes, 2006) and Maximum Entropy (Ang et al., 2005). Comparatively few approaches have been applied to the 55-label annotated corpus, with most choosing to focus on the 5-label clustering, presumably for the resulting increase in score. When Ji and Bilmes (2005) apply a Graph Model to the 55 category corpus, they achieve a classification accuracy of 66%. However, when they apply the exact same method to the 5-label corpus (Ji and Bilmes, 2006), classification accuracy is boosted to 81%. The best reported classification score on the the 5-label version of the corpus is reported by Verbree et al. (2006), who achieve 89% classification accuracy by modelling the words of the utterance, the DA history and some orthographic information (such as the presence of question marks).

It remains very difficult to directly compare approaches, even when applied to the *same* corpus, so cross-corpora comparisons must be carefully considered. There are issues of the DA label set used, the labels considered and those ignored, the pre-processing of the corpus, the use of orthographic information, or prosody and so on. What seems clear is that there are no obvious leading contender for algorithm best suited to the DA classification task. Instead, we focus on the features used for DA classification.

3 Automatic Cue Extraction

When examining prior approaches, we noticed that they used a range of different features for the DA classification task, including lexical, syntactic, prosodic and dialogue context features. Most classifiers used some lexical features (the words in the utterances under consideration), frequently employing some kind of Hidden Markov Modelling to every utterance (Levin et al., 2003; Stolcke et al., 2000; Reithinger and Klesen, 1997), a technique popular in speech processing. We were inspired by the work of Samuel et al. (1999), who instead of modelling entire utterances, extract significant *cue phrases* from the VerbMobil corpus of dialogues. We use a method for cue extraction unused by Samuel et al. (1999).

What defines a good cue phrase? We are looking for words or phrases in a corpus that regularly co-occur with individual dialogue acts. We use

the term *predictivity* to indicate how predictive a phrase is of a particular DA. We want to select phrases that are highly indicative, and so concern ourselves with the highest predictivity of a particular cue phrase. We call this score the maximal predictivity. There are several other thresholds that should also be apparent. First, below some maximal predictivity score, we assume that phrases will no longer be discriminative enough to be useful for labelling DAs. Second, the number of occurrences of each phrase in the corpus as a whole is important. In their experiments, Samuel et al. (1999) constructed all n-grams of lengths 1 through 3 from the corpus, and then applied a range of measures which pruned the n-gram list until only candidate cue phrases remained. In order to test the effectiveness of these automatically acquired cue phrases, Samuel et al. (1999) passed them as features to a machine learning method, in their case transformation-based learning.

More formally, we can describe our criteria, predictivity, for selecting cue phrases from the set of all possible cue phrases in the following way. The predictivity of phrase c for DA d is the conditional probability $P(d|c)$, where:

$$P(d|c) = \frac{\#(c\&d)}{\#(c)}$$

We represent the set of all *possible* cue phrases (all n-grams length 1–4 from the corpus) as C, so given $c \in C : c$ represents some possible cue phrase. Similarly, D is the set of all dialogue act labels, and $d \in D : d$ represents some dialogue act label. Therefore $\#(c)$ is the count of (possible) cue phrase c in corpus, and $\#(c\&d)$ is the count of occurrences of phrase c in utterances with dialogue act d in the training data. The *maximal predictivity* of a cue phrase c, written as $mp(c)$, is defined as:

$$mp(c) = \max_{d \in D} P(d|c)$$

In their experiments, Samuel et al. (1999) also experimented with conditional probability, using $P(c|d)$, or the probability of some phrase occurring given some Dialogue Act. For our experiments, the word n-grams used as potential cue phrases during are automatically extracted from training data. All word n-grams of length 1–4 within the data are considered as candidates. The maximal predictivity of each cue phrase can be computed directly from the corpus. We can use this value as one threshold for pruning potential cue phrases from our model. Removing n-grams below some predictivity threshold will improve the compactness of the model produced. Another reasonable threshold would appear to be the frequency count of each potential cue phrase. Phrases which have a low frequency score are likely to have very high predictivity scores, possibly skewing the model as a whole. For example, any potential cue phrase which occurs only once will de-facto have a 100% predictivity score. We can use a minimal count value ($t_{\#}$) and minimal predictivity thresholds (t_{mp}) to prune the set C^* of 'useful' cue phrases derived from the training data, as defined by:

$$C^* = \{c \in C \mid mp(c) \geq t_{mp} \wedge \#(c) \geq t_{\#}\}$$

The n-grams that remain after this thresholding process are those we identify as cue phrases. For our initial experiments, we used a predictivity of 30% and a frequency of 2 as our thresholds for cue extraction.

4 Cue-Based DA Classification

Having defined our mechanism to extract cue phrases from a corpus, we need some way to evaluate their effectiveness. Samuel et al. (1999) passed their cue phrases as a feature to a machine learning method. We chose instead a method where the cue phrases extracted from a corpus could be used *directly* as a method of classification. If our extracted cues are indeed reliable predictors of dialogue acts, then a classifier that uses these cues directly should perform reasonably well. If, on the other hand, this mechanism did not work, it would not necessarily mean that our cue phrases are not effective, only that we need to pass them to a subsequent machine learning process as others had done. The benefit of our direct classification approach is that it is very fast to evaluate, and gives us immediate feedback as to the possible effectiveness of our automatically extracted cue phrases.

The predictivity of a cue phrase can be exploited directly in a simple model of Dialogue Act classification. We can extract potential cue phrases as described in Section 3. The resulting cue phrases selected using our measure of predictivity are then used directly to classify unseen utterances in the following manner. We identify all the potential cue phrases a target utterance contains, and determine which has the highest predictivity of some dialogue act category, then assign that category. Given the notation we define earlier, we can obtain the DA predicted by a particular cue ($dp(c)$) by:

$$dp(c) = \underset{d \in D}{\mathsf{argmax}}\, P(d|c)$$

If multiple cue phrases share the same maximal predictivity, but predict different categories, we select the DA category for the phrase which has the higher number of occurrences (that is, the n-gram with the highest frequency). If the combination of predictivity and occurrence count is insufficient to determine a single DA, then a random choice is made amongst the remaining candidate DAs. If $ng(u)$ defines the set of ngrams of length 1..4 in utterance u, and C_u^* is the set of n-grams in the utterance u that are also in the threshold model C^* then C_u^* is defined as:

$$C_u^* = ng(u) \cap C^*$$

Given our thresholds, the $mpu(u)$ (the utterance maximal prediction, or mp value for the highest scoring cue in utterance u) is defined as:

$$mpu(u) = \underset{c \in C_u^*}{\mathsf{max}}\, mp(c)$$

The maximally predictive cues of an utterance ($mpcu(u)$) are:

$$mpcu(u) = \{c \in C_u^* \mid mp(c) = mpu(u)\}$$

Then the maximal cue of utterance ($mcu(u)$), i.e. one of its maximally predictive cues that has a maximal count (from within that set), is:

$$mcu(u) = \underset{c \in mpcu(u)}{\mathsf{argmax}}\, \#(c)$$

Finally, for our classification model, $dpu(u)$ utterance DA prediction — the DA predicted by model for utterance u, is defined as:

$$dpu(u) = dp(mcu(u))$$

If no cue phrases are present in the utterance under consideration, then a default tag is assigned.

To this basic model, we added three further elaborations. The first used models sensitive to utterance length. When examining the ICSI-MRDA corpus, Ji and Bilmes (2006) found that the mean length of <STATEMENT> utterances was 8.60 words, <BACKCHANNEL> utterances were 1.04 words, <PLACE-HOLDERS> utterances were 1.31 words and <QUESTIONS> utterances were 6.50 words. Taking this as a start point, we grouped utterances into those of length 1 (i.e. short, or one word utterances), those with lengths 2–4 (we call medium length utterances), and those of length 5+ (the long length model, that comprises everything else), and produced separate cue-based models for each group.

Second, we introduced <*start*> and <*finish*> tags to each utterance (independent of the calculation of utterance length), to capture position specific information for particular cues. For example "<*start*> *okay*" identifies the occurrence of the word *'okay'* as the first word in the utterance. Finally, in the Switchboard annotation, there are other markers dealing with various linguistic issues, as outlined in Meteer (1995). A primary example is the label <+>, which indicated the presence of overlapping speech. One approach to better utilise this data is to 'reconnect' the divided utterances, i.e. appending any utterance assigned tag <+> to the last utterance by the *same* speaker. We base the selection of these model elaborations and the values for the parameters of frequency and predictivity on prior research (cf. (Webb et al., 2005a; Webb et al., 2005b; Webb et al., 2005c)).

5 Cue-Based Classification Results

Ultimately, we want to compare classification performance of a set of automatically extracted cue phrases across the two corpora, Switchboard and ICSI-MRDA. Both are annotated with similar variants of the DAMSL annotation scheme,

Condition	Cue Source	Cue Count	Accuracy
(1)	Switchboard training data	136,942	80.72%
(2)	ICSI-MRDA training data	48,856	70.78%
(3)	Intersection of Switchboard and ICSI-MRDA Training Data	25,053	72.34%
(4)	As above, discard <STATEMENT> cue phrases	577	72.62%
(5)	As above, retain only cue phrases containing <*start*> tags	242	72.52%
(6)	As above, retain only cue phrases appearing in every training intersection	148	72.09%

Table 1: Switchboard Classification Results

but there are differences. For example, the ICSI-MRDA corpus introduces several new labels that do not exist in the Switchboard annotation. Some labels in the Switchboard annotation are clustered into a single corresponding label in the ICSI-MRDA corpus, such as the two labels from Switchboard, <STATEMENT-OPINION> and <STATEMENT-NON-OPINION>, which are represented by a single label <STATEMENT> in the ICSI-MRDA corpus. To facilitate cross-corpus classification, we will cluster these labels as described in Shriberg et al. (2004). Of course, any clustering of labels has an impact on classifier performance, usually resulting in an increase. Webb et al. (2005c) indicate that clustering statement labels in the Switchboard corpus should improve performance by 8-10% percentage points.

5.1 Baseline Results

We need to establish baseline classification performance for both corpora. Our baseline for this classification task is to the most frequently occurring label for all utterances. For a number of dialogue corpora, the most frequently occurring label is some sort of statement or assertion, which is true for both the Switchboard and ICSI-MRDA corpora, where <STATEMENT> is the most frequent label. For the Switchboard corpus, selecting this label results in 51.05% accuracy. Remember that we are working with a version of the Switchboard corpus where we have clustered the original labels <STATEMENT-OPINION> and <STATEMENT-NON-OPINION> into a single label. In the original Switchboard annotation, the most frequently occurring label is <STATEMENT-NON-OPINION>, which occurs 36% of the time. Further analysis on the Switchboard corpus by Webb et al. (2005c) highlights that a significant number of <STATEMENT-OPINION> utterances in Switchboard are mislabelled as <STATEMENT-NON-OPINION> by human annotators. For the ICSI-MRDA corpus, an accuracy of 31.77% is achieved by labelling each utterance as <STATEMENT>.

Now we have established a simple baseline of performance, we want to know how well our cue-based classification method works applied to these corpora, as an evaluation of how well our cue extraction method works for each of these corpora. We ran a 10-fold stratified cross-validation exercise (referred to as Condition (1) in Tables 1 and 2) using the cue-based extraction mechanism described in Section 3, selecting cue phrases from the training data (which averaged 180k utterances for Switchboard, and 95k utterances for ICSI-MRDA), resulting in an average of 135k cue phrases from Switchboard and 50k cue phrases from ICSI-MRDA. We then applied these cue-based models to the held out test data as described in Section 4, applying Switchboard extracted cue phrases to Switchboard test data, and likewise with the ICSI-MRDA data. This establishes the best performance by our algorithm over these data sets. For Switchboard, we achieve 80.72% accuracy, as predicted by the work reported in Webb et al. (2005c). For ICSI-MRDA we obtain an accuracy of 58.14%. Remember, this model is applied to the 55-label annotated ICSI-MRDA corpus. Best reported classification accuracy for this corpus is the 66% reported by Ji and Bilmes (2005), using a graph-based model that models both utterances and sequences of DA labels. For both corpora, the cue-based model of classification outperforms the baseline, using no dialogue context whatsoever.

Condition	Cue Source	Cue Count	Accuracy
(1)	ICSI-MRDA training data	48,856	58.14%
(2)	Switchboard training data	136,942	47.07%
(3)	Intersection of Switchboard and ICSI-MRDA Training Data	25,053	47.86%
(4)	As above, discard <STATEMENT> cue phrases	577	48.05%
(5)	As above, retain only cue phrases containing <*start*> tags	242	47.30%
(6)	As above, retain only cue phrases appearing in every training intersection	148	46.34%

Table 2: ICSI-MRDA Classification Results

5.2 Cross-Corpus Results

The focus of our effort is not to maximise raw performance over individual corpora, but to examine the effectiveness of our automatically extracted cue phrases, and one mechanism to do this is to compare classification *cross-corpora*. If our cue phrases are sufficiently general predictors of DA labels across corpora, we believe that to be a powerful claim for cue phrases as a DA classification feature. Therefore, our next step was to take the cue-phrases generated from each fold of the Switchboard experiment, and apply them to the held out test data from the corresponding fold of the ICSI-MRDA experiment, and vice-versa. This is a test to see how generally applicable are the cue phrases extracted from each corpus.

When we take cues extracted from the Switchboard corpus, and apply them to the held out portion of the ICSI-MRDA corpus, we achieve an average classification accuracy (over our 10-folds) of 47.07%. This score represents 81% of the accuracy achieved by our prior result when ICSI-MRDA test data is classified using ICSI-MRDA training data. It also represents 71% of the best published score on this corpus (Ji and Bilmes, 2005). When we classify held out Switchboard test data with cue phrases extracted from the ICSI-MRDA corpus, we achieve an average classification accuracy of 70.78%, which corresponds to 88% of our best score on this corpus using Switchboard training data. These results correspond to Condition (2) in Tables 1 and 2.

These are very positive results for both directions of classification, indicating that the cue phrases we automatically extract from our corpora are generally applicable as a feature for DA classification.

5.3 Cue Phrase Reduction

We have successfully shown that we can use cue phrases extracted from one corpus to classify utterances from a different corpus. We used an inclusive approach, using all cue phrases extracted from the source corpus training data. Intuitively however, we might expect to get comparable performance by using only those cue phrases that appear in both corpora. For these intersection cue phrases, we require a strict overlap. Once the cues phrases are extracted from each individual training fold for each corpus, they are compared and retained if and only if:

- the cue phrase itself is a direct match, including any position specific label
- the DA the phrases predicts is a match
- the model number (as defined in Section 4) is a match

For each fold of our cross-validation, we take cues phrases extracted from the training data that appear in *both* corpora, pruning out cue phrases that only appear in one of the corpora. We then retain *only* those cue phrases that meet these criteria from both corpora for each specific fold, and apply them to the held out test data from that fold for each corpus.

Average classification performance for both corpora rises very slightly in comparison to using all extracted cue phrases. These results can be seen as Condition (3) in Tables 1 and 2. When applying the intersection cue phrases to the Switchboard test data, we achieve an average classification accuracy score of 72.34%. When we apply the intersection cues to the ICSI-MRDA test data, the average score is 47.86%. The average number of cue phrases that are used in this experiment

(i.e that appear in all training folds for both corpora, with matching model information) is around 25k. This represents 50% of the average number of cues extracted from the ICSI-MRDA corpus, and only 19% of the average number of cue phrases extracted from the Switchboard corpus.

We describe earlier that our default label as applied by our classifier when no cue phrase can be found is the <STATEMENT> label, the most frequent single label in both corpora. Given this, we can safely remove cue phrases that predict <STATEMENT> labels from our cue phrase set. The absence of such cue phrases should have no impact on our classification performance, but should reduce our total number of cue phrases. As can be seen in Condition (4) in Tables 1 and 2, this is indeed the case, with no statistical significance between the results with and without <STATEMENT> cue phrases. However, there is a drop in the number of cue phrases. When we remove all <STATEMENT> cue phrases from the intersection of cue phrases, we are left with an average of 577 cue phrases.

Further analysis of classifier performance indicates that a high percentage of actual labelling is performed using a subset of even the cue phrases extracted under Condition (4). We observed that cue phrases that contain a <*start*> tag (as described in Section 4) were used in the majority of cases. Our final experiment was to extract, from the 577 cue phrases, only those phrases that contain the <*start*> tag. This reduced the average number of cue phrases to 242. Classification performance remains unaffected, scoring an average of 72.52% for Switchboard and 47.30% for ICSI-MRDA, as seen in Condition (5) in the results tables. We note that of those 242 phrases, 148 appear in the intersection of *every* training fold of our 10-fold cross-validation. When we use only those 148 cue phrases for classification, as seen in Condition (6), average classification accuracy remains the same; 72.09% for Switchboard, and 46.34% for ICSI-MRDA.

6 Conclusions

In this paper, we investigate a cue-based approach to DA classification, applied to two corpora, Switchboard and ICSI-MRDA. We automatically extracted cue phrases from both corpora, and used them directly to classify unseen utterances from the corresponding corpus, demonstrating that our automatically discovered cue phrases are a sufficiently useful feature for this task.

We then explored the generality of our cue phrases, by applying them directly as a classifier to data from the alternate corpus. Whilst there was some expected drop in performance, the classification accuracy for both experiments is good, given such a small number of features and the simple design of the classifier. The result indicates that cue phrases are a highly useful feature for DA classification, and can be used to classify data from new corpora, possibly as some part of some quasi-automatic first annotation effort.

We experimented with reducing the set of cue phrases, using increasingly restrictive measures of retaining our automatically discovered cues. We found that we did not have a drop in performance compared to the cross-corpus classification accuracy, even when the cue set is drastically reduced (to 0.001% of the original Switchboard cue phrases, and 0.003% of the ICSI-MRDA cue phrases). This appears to be a strong indicator of the discriminative power of some small number of automatically discovered core cue phrases.

Abstract

Search with synonyms is a challenging problem for Web search, as it can easily cause intent drifting. In this paper, we propose a practical solution to this issue, based on co-clicked query analysis, i.e., analyzing queries leading to clicking the same documents. Evaluation results on Web search queries show that synonyms obtained from this approach considerably outperform the thesaurus based synonyms, such as WordNet, in terms of keeping search intent.

1 Introduction

Synonym discovery has been an active topic in a variety of language processing tasks (Baroni and Bisi, 2004; Fellbaum, 1998; Lin, 1998; Pereira et al., 1993; Sanchez and Moreno, 2005; Turney, 2001). However, due to the difficulties of synonym judgment (either automatically or manually) and the uncertainty of applying synonyms to specific applications, it is still unclear how synonyms can help Web scale search task. Previous work in Information Retrieval (IR) has been focusing mainly on related words (Bai et al., 2005; Wei and Croft, 2006; Riezler et al., 2008). But Web scale data handling needs to be precise and thus synonyms are more appropriate than related words for introducing less noise and alleviating the efficiency concern of query expansion. In this paper, we explore both manually-built thesaurus and automatic synonym discovery, and apply a three-stage evaluation by separating synonym accuracy from relevance judgment and user experience impact.

The main difficulties of discovering synonyms for Web search are the following:

1. Synonym discovery is context sensitive. Although there are quite a few manually built thesauri available to provide high quality synonyms (Fellbaum, 1998), most of these synonyms have the same or nearly the same meaning only in some senses. If we simply replace them in search queries in all occurrences, it is very easy to trigger search intent drifting. Thus, Web search needs to understand different senses encountered in different contexts. For example, "baby" and "infant" are treated as synonyms in many thesauri, but "Santa Baby" has nothing to do with "infant". "Santa Baby" is a song title, and the meaning of "baby" in this entity is different than the usual meaning of "infant".

2. Context can not only limit the use of synonyms, but also broaden the traditional definition of synonyms. For instance, "dress" and "attire" sometimes have nearly the same meaning, even though they are not associated with the same entry in many thesauri; "free" and "download" are far from synonyms in traditional definition, but "free cd rewriter" may carry the same query intent as "download cd rewriter".

3. There are many new synonyms developed from the Web over time. "Mp3" and "mpeg3" were not synonyms twenty years ago; "snp newspaper" and "snp online" carry the same query intent only after snponline.com was published. Manually editing synonym list is prohibitively expensive. Thus, we need an automatic synonym discovery system that can learn from huge amount of data and update the dictionary frequently.

Coling 2008: Poster Volume, pages 1318–1326,
Beijing, August 2010

In summary, synonym discovery for Web search is different from traditional thesaurus mining; it needs to be context sensitive and needs to be updated timely. To address these problems, we conduct context based synonym discovery from co-clicked queries, i.e., queries that share similar document click distribution. To show the effectiveness of our synonym discovery method on Web search, we use several metrics to demonstrate significant improvements: (1) synonym discovery accuracy that measures how well it keeps the same search intent; (2) relevance impact measured by Discounted Cumulative Gain (DCG) (Jarvelin and Kekalainen., 2002); and (3) user experience impact measured by online experiment.

The rest of the paper is organized as follows. In Section 2, we first discuss related work and differentiate our work from existing work. Then we present the details of our synonym discovery approach in Section 3. In Section 4 we show our query rewriting strategy to include synonyms in Web search. We conduct experiments on randomly sampled Web search queries and run the three-stage evaluation in Section 5 and analyze the results in Section 6. WordNet based synonym reformulation and a current commercial search engine are the baselines for the three-stage evaluation respectively. Finally we conclude the paper in Section 7.

2 Related Works

Automatically discovering synonyms from large corpora and dictionaries has been popular topics in natural language processing (Sanchez and Moreno, 2005; Senellart and Blondel, 2003; Turney, 2001; Blondel and Senellart, 2002; van der Plas and Tiedemann, 2006), and hence, there has been a fair amount of work in calculating word similarity (Porzel and Malaka, 2004; Richardson et al., 1998; Strube and Ponzetto, 2006; Bollegala et al., 2007) for the purpose of discovering synonyms, such as information gain on ontology (Resnik, 1995) and distributional similarity (Lin, 1998; Lin et al., 2003). However, the definition of synonym is application dependent and most of the work has been applied to a specific task (Turney, 2001) or restricted in one domain (Baroni and Bisi, 2004). Synonyms extracted using these traditional approaches cannot be easily adopted in Web search where keeping search intent is critical.

Our work is also related to semantic matching in IR: manual techniques such as using handcrafted thesauri and automatic techniques such as query expansion and clustering all attempts to provide a solution, with varying degrees of success (Jones, 1971; van Rijsbergen, 1979; Deerwester et al., 1990; Liu and Croft, 2004; Bai et al., 2005; Wei and Croft, 2006; Cao et al., 2007). These works focus mainly on adding in loosely semantically related words to expand literal term matching. But related words may be too coarse for Web search considering the massive data available.

3 Synonym Discovery based on Co-clicked Queries

In this section, we discuss our approach to synonym discovery based on co-clicked queries in Web search in detail.

3.1 Co-clicked Query Clustering

Clustering has been extensively studied in many applications, including query clustering (Wen et al., 2002). One of the most successful techniques for clustering is based on distributional clustering (Lin, 1998; Pereira et al., 1993). We adopt a similar approach to our co-clicked query clustering. Each query is associated with a set of clicked documents, which in turn associated with the number of views and clicks. We then compute the distance between a pair of queries by calculating the Jensen-Shannon(JS) divergence (Lin, 1991) between their clicked URL distributions. We start with that every query is a separate cluster, and merge clusters greedily. After clusters are generated, pairs of queries within the same cluster can be considered as co-clicked/related queries with a similarity score computed from their JS divergence.

$$Sim(q_k|q_l) = D_{JS}(q_k||q_l) \quad (1)$$

3.2 Query Pair Alignment

To make sure that words are replacement for each other in the co-clicked queries, we align words in the co-clicked query pairs that have the same length (number of terms), and have the same terms for all positions except one. This is a simplification for complicated aligning processes. Previous work on machine translation (Brown et al., 1993) can be used when complete alignment is needed for modeling. However, as we have tremendous amount of co-clicked query data, our restricted version of alignment is sufficient to obtain a reasonable number of synonyms. In addition, this restricted approach eliminates much noise introduced in those complicated aligning processes.

3.2.1 Synonym Discovery from Co-clicked Query Pair

Synonyms discovered from co-clicked queries have two aspects of word meaning: (1) general meaning in language and (2) specific meaning in the query. These two aspects are related. For example, if two words are more likely to carry the same meaning in general, then they are more likely to carry the same meaning in specific queries; on the other hand, if two words often carry the same meaning in a variety of specific queries, then we tend to believe that the two words are synonyms in general language. However, neither of these two aspects can cover the other. Synonyms in general language may not be used to replace each other in a specific query. For example, "sea" and "ocean" have nearly the same meaning in language, but in the specific query "sea boss boat", "sea" and "ocean" cannot be treated as synonyms because "sea boss" is a brand; also, in the specific query "women's wedding attire", "dress" can be viewed as a synonym to "attire", but in general language, these two words are not synonyms. Therefore, whether two words are synonyms or not for a specific query is a synthesis judgment based on both of general meaning and specific context.

We develop a three-step process for synonym discovery based on co-clicked queries, considering the above two aspects.

Step 1: Get all synonym candidates for word w_i in general meaning.

In this step, we would like to get all synonym candidates for a word. This step corresponds to Aspect (1) to catch the general meaning of words in language. We consider all the co-clicked queries with the word and sum over them, as in Eq. 2

$$P(w_j|w_i) = \frac{\sum_k sim_k(w_i \to w_j)}{\sum_{w_j} \sum_k sim(w_i \to w_j)} \quad (2)$$

where $sim_k(w_i \to w_j)$ represents the similarity score (see Section 3.1) of a query q_k that aligns w_i to w_j. So intuitively, we aggregate scores of all query pairs that align w_i to w_j, and normalize it to a probability over the vocabulary.

Step 2: Get synonyms for word w_i in query q_k.

In this step, we would like to get synonyms for a word in a specific query. We define the probability of reformulating w_i with w_j for query q_k as the similarity score shown in Eq. 3.

$$P\left(w_j|w_i, q_k\right) = sim_k(w_i \to w_j) \quad (3)$$

Step 3: Combine the above two steps.

Now we have two sets of estimates for the synonym probability, which is used to reformulate w_i with w_j. One set of values are based on general language information and another set of values are based on specific queries. We apply three combination approaches to integrate the two sets of values for a final decision of synonym discovery: (1) two independent thresholds for each probability, (2) linear combination with a coefficient, and (3) linear combination in log scale as in Eq. 4, with λ as a mixture coefficient.

$$\begin{aligned} P_{q_k}(w_j|w_i) \propto \lambda \log P(w_j|w_i) \\ +(1-\lambda) \log P(w_j|w_i, q_k) \end{aligned} \quad (4)$$

In experiments we found that there is no significant difference with the results from different combination methods by finely tuned parameter setting.

3.2.2 Concept based Synonyms

The simple word alignment strategy we used can only get the synonym mapping from single

term to single term. But there are a lot of phrase-to-phrase, term-to-phrase, or phrase-to-term synonym mappings in language, such as “babe in arms” to “infant”, and “nyc” to ”new york city”. We perform query segmentation on queries to identify concept units from queries based on an unsupervised segmentation model (Tan and Peng, 2008). Each unit is a single word or several consecutive words that represent a meaningful concept.

4 Synonym Handling in Web Search

The automatic synonym discovery methods described in Section 3 generate synonym pairs for each query. A simple and straightforward way to use the synonym pairs would be “equalizing” them in search, just like the “OR” function in most commercial search engines.

Another method would be to re-train the whole ranking system using the synonym feature, but it is expensive and requires a large size training set. We consider this to be future work.

Besides general equalization in all cases, we also apply a restriction, specially, on whether or not to allow synonyms to participate in document selection. For the consideration of efficiency, most Web search engines has a document selection step to pre-select a subset of documents for full ranking. For the general equalization, the synonym pair is treated as the same even in the document selection round; in a conservative variation, we only use the original word for document selection but use the synonyms in the second phase finer ranking.

5 Experiments

In this section, we present the experimental results for our approaches with some in-depth discussion.

5.1 Evaluation Metrics

We have several metrics to evaluate the synonym discovery system for Web search queries. They corresponds to the three stages during the system development. Each of them measures a different aspect.

Stage 1: accuracy. Because we are more interested in the application of reformulating Web search queries, our guideline to the editorial judgment focuses on the query intent change and context-based synonyms. For example, “transporters” and “movers” are good synonyms in the context of “boat” because “boat transporters” and “boat movers” keep the same search intent, but “ocean” is not a good synonym to “sea” in the query of “sea boss boats” because “sea boss” is a brand name and “ocean boss” does not refer to the same brand. Results are measured with accuracy by the number of discovered synonyms (which reflects coverage).

Stage 2: relevance. To evaluate the effectiveness of our semantic features we use DCG, a widely-used metric for measuring Web search relevance.

Stage 3: user experience. In addition to the search relevance, we also evaluate the practical user experience after logging all the user search behaviors during a two-week online experiment.

Web CTR: the Web click through rate (Sherman and Deighton, 2001; Lee et al., 2005) is defined as

$$CTR = \frac{\text{number of clicks}}{\text{total page views}},$$

where a page view (PV) is one result page that a search engine returns for a query.

Abandon rate: the percentage of queries that are abandoned by user neither clicking a result nor issuing a query refinement.

5.2 Data

A period of Web search query log with clicked URLs are used to generate co-clicked query set. After word alignment that extracts the co-clicked query pairs with same number of units and with only one different unit, we obtain 12.1M unsegmented query pairs and 11.9M segmented query pairs.

Since we run a three-stage evaluation, there are three independent evaluation set respectively:

1. accuracy test set. For the evaluation of synonym discovery accuracy, we randomly sampled 42K queries from two weeks of query log, and

evaluate the effectiveness of our synonym discovery model with these queries. To test the synonym discovery model built on the segmented data, we segment the queries before using them as evaluation set.

2. relevance test set. To evaluate the relevance impact by the synonym discovery approach, we run experiments on another two weeks of query log and randomly sampled 1000 queries from the affected queries (queries that have differences in the top 5 results after synonym handling).

3. user experience test set. The user experience test is conducted online with a commercial search engine.

5.3 Results of Synonym Discovery Accuracy

Here we present the results of WordNet thesaurus based query synonym discovery, co-clicked based term-to-term query synonym discovery, and co-click concept based query synonym discovery.

5.3.1 Thesaurus-based Synonym Replacement

The WordNet thesaurus-based synonym replacement is a baseline here. For any word that has synonyms in the thesaurus, thesaurus-based synonym replacement will rewrite the word with synonyms from the thesaurus.

Although thesaurus often provides clean information, synonym replacement based on thesaurus does not consider query context and introduces too many errors and noise. Our experiments show that only **46%** of the discovered synonyms are correct synonyms in query. The accuracy is too low to be used for Web search queries.

5.3.2 Co-clicked Query-based Context Synonym Discovery

Here we present the results from our approach based on co-clicked query data (in this section the queries are all original queries without segmentation). Figure 1 shows the accuracy of synonyms by the number of discovered synonyms. By applying different thresholds as cut-off lines to Eq. 4, we get different numbers of synonyms from the same test set. As we can see, loosening the threshold can give us more synonym pairs, but it could hurt the accuracy.

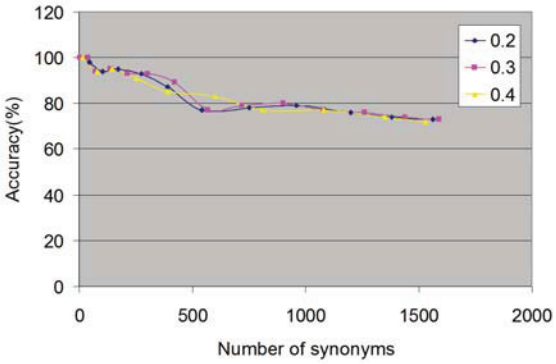

Figure 1: Accuracy versus number of synonyms with term based synonym discovery

Figure 1 demonstrates how accuracy changes with the number of synonyms. Y-axis represents the percentage of correctly discovered synonyms, and X-axis represents the number of discovered synonyms, including both of correct ones and wrong ones. The three different lines represents three different parameter settings of mixture weights (λ in Eq. 4, which is 0.2, 0.3, or 0.4 in the figure). The figure shows accuracy drops by increasing the number of synonyms. More synonym pairs lead to lower accuracy.

From Figure 1 we can see: Firstly, three curves with different thresholds almost overlap, which means the effectiveness of synonym discovery is not very sensitive to the mixture weight. Secondly, accuracy is monotonically decreasing as more synonyms are detected. By getting more synonyms, the accuracy decreases from **100%** to less than **80%** (we are not interested in accuracies lower than 80% due to the high precision requirement of Web search tasks, so the graph contains only high-accuracy results). This trend also confirms the effectiveness of our approach (the accuracy for a random approach would be a constant).

5.3.3 Concept based Context Synonym Discovery

We present results from our model based on segmented co-clicked query data in this section.

Original Query	New Query with Synonyms	Intent
Examples of thesaurus-based based synonym replacement		
basement window wells drainage billabong boardshorts sale bigger stronger faster documentary	basement window wells drain billabong boardshorts sales event larger stronger faster documentary	same
yahoo maryland judiciary case search free cell phone number lookup	hayseed maryland judiciary pillowcase search free cell earpiece number lookup	different
Examples of term-to-term synonym discovery		
airlines jobs area code finder acai berry	airlines careers area code search acai fruit	same
acai berry ace crest toothpaste coupon	acai juice hardware crest whitestrips coupon	different
Examples of concept based synonym discovery		
ae apartments_for_rent arizona time_zone	american_eagle outfitters apartment_rentals arizona time	same
cortrust bank credit_card david_beckham dodge_caliber	cortrust bank mastercard beckham dodge	different

Table 1: Examples of query synonym discovery: the first section is thesaurus based, second section is co-clicked data based term-to-term synonym discovery, and the last section is concept based synonym discovery.

The modeling part is the same as the one for Section 5.3.2, and the only difference is that the data were segmented. We have shown in Section 5.3.2 that the mixture weight is not an crucial factor within a reasonable range, so we present only the result with one mixture weight in Figure 2. As in Section 5.3.2, the figure shows that the accuracy of synonym discovery is sensitive to the threshold. It confirms that our model is effective and setting threshold to Eq. 4 is a feasible and sound way to discover not only single term synonyms but also phrase synonyms.

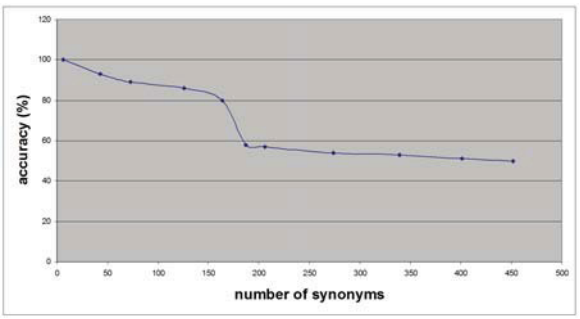

Figure 2: Accuracy versus number of synonyms with concept based synonym discovery

Table 1 shows some anecdotal examples of query synonyms with the thesaurus-based synonym replacement, context sensitive synonym discovery, and concept based context sensitive synonym discovery. In contrast, the upper part of each section shows positive examples (query intents remain the same after synonym replacement) and the lower part shows negative examples (query intents change after synonym replacement).

5.4 Results of Relevance Impact

We run relevance test on 1000 randomly sampled affected queries. With the automatic synonym discovery approach we apply our synonym handling method described in Section 4. Results of DCG improvements by different thresholds and synonym handling settings are presented in Table 2. Thresholds are selected empirically from the accuracy test in Section 5.3 (we run a small size relevance test on the accuracy test set and set the range of thresholds based on that). Note that in our relevance experiments we use term-to-term synonym pairs only. For the relevance impact of concept-based synonym discovery, we would like to study it in our future work.

From Table 2 we can see that the automatic synonym discovery approach we presented significantly improves search relevance on various settings, which confirms the effectiveness of our synonym discovery for Web search queries. We conjecture that avoiding synonym in document selection is of help. This is because precision is more important to Web search than recall for the huge amount of data available on the Web.

Relevance impact with synonym handling			
threshold1	threshold2	doc-selection participation	DCG
0.8	0.02	no	**+1.7%**
0.8	0.02	yes	**+1.3%**
0.8	0.05	no	**+1.8%**
0.8	0.05	yes	**+1.4%**

Table 2: Relevance impact with synonym handling by different parameter settings. "Threshold1" is the threshold for context-based similarity score–Eq. 3; "threshold2" is the threshold for general case similarity score–Eq. 2; "doc-selection participation" refers to whether or not let synonym handling participate in document selection. All improvements are statistically significant by Wilcox significance test.

5.5 Results of User Experience Impact

In addition to the relevance impact, we also evaluated the practical user experience impact by CTR and abandon rate (defined in Section 5.1) through a two-week online run. Results show that the synonym discovery method presented in this paper improves Web CTR by **2%**, and decreases abandon rate by **11.4%**. All changes are statistically significant, which indicates synonyms are indeed beneficial to user experience.

6 Discussion and Error Analysis

From Table 1, we can see that our approach can catch not only traditional synonyms, which are the synonyms that can be found in manually-built thesaurus, but also context-based synonyms, which may not be treated as synonyms in a standard dictionary or thesaurus. There are a variety of synonyms our approach discovered:

1. Synonyms that are not considered as synonyms in traditional thesaurus, such as "berry" and "fruit" in the context of "acai". "acai berry" and "acai fruit" refer to the same fruit.

2. Synonyms that have different part-of-speech features than the corresponding original words, such as "finder" and "search". Users searching "area code finder" and users searching "area code search" are looking for the same content. In the context of Web search queries, part-of-speech is not an important factor as most queries are not grammatically perfect.

3. Synonyms that show up in recent concepts, such as "webmail" and "email" in the context of "cox". The new concept of "webmail" or "email" has not been added to many thesauri yet.

4. Synonyms not limited by length, such as "crossword puzzles" and "crossword", "homes for sale" and "real estate". The segmenter helps our system discover synonyms in various lengths.

With these many variations, the synonyms discovered by our approach are not the "synonyms" in the traditional meaning. They are context sensitive, Web data oriented and search effective synonyms. These synonyms are discovered by the statistical model we presented and based on Web search queries and clicked data.

However, the click data themselves contain a huge amount of noise. Although they can reflect the users' intents in some big picture, in many specific cases synonyms discovered from co-clicked data are biased by the click noise. In our application—Web search query reformulation with synonyms, accuracy is the most important thing and thus we are interested in error analysis. The errors that our model makes in synonym discovery are mainly caused by the following reasons:

(1) There are some concepts well accepted such as "cnn" means "news" and "amtrak" means "train". And users searching "news" tend to click CNN Web site; users searching "train" tend to click Amtrak Web site. With our model, "cnn" and "news", "amtrak" and "train" are discovered to be synonyms, which may hurt the search of "news" or "train" in general meaning.

(2) Same clicks by different intents. Although clicking on same documents generally indicates same search intent, different intents could result in same or similar clicks, too. For example, the queries of "antique style wedding rings" and "antique style engagement rings" carry different intents, but very usually, these two different intents lead to the clicks on the same Web site. "Booster seats" and "car seats", "brighton handbags" and "brighton shoes" are other two examples in the same case. For these examples, clicking on Web URLs are not precise enough to reflect the subtle difference of language concepts.

(3) Bias from dominant user intents. Most people searching "apartment" are looking for an apartment to rent. So "apartment for rent" and "apartment" have similar clicked URLs. But these two are not synonyms in language. In these cases, popular user intents dominate and bias the meaning of language, which causes problems. "Airline baggage restrictions" and "airline travel restrictions" is another example.

(4) Antonyms. Many context-based synonym discovery methods suffer from the antonym problem, because antonyms can have very similar contexts. In our model, the problem has been reduced by integrating clicked-URLs. But still, there are some examples, such as "spyware" and "antispyware", resulting in similar clicks. To learn how to "protect a Web site", a user often needs to learn what are the main methods to "attack a Web site", and these different-intent pairs lead to the same clicks because different intents do not have to mean different interests in many specific cases.

Although these problems are not common, but when they happen, they cause a bad user search experience. We believe a solution to these problems might need more advanced linguistic analysis.

7 Conclusions

In this paper, we have developed a synonym discovery approach based on co-clicked query data, and improved search relevance and user experience significantly based on the approach.

For future work, we are investigating more synonym handling methods to further improve the synonym discovery accuracy, and to handle the discovered synonyms in more ways than just the query side.

Abstract

Recent years have witnessed a large body of research works on cross-domain sentiment classification problem, where most of the research endeavors were based on a supervised learning strategy which builds models from only the labeled documents or only the labeled sentiment words. Unfortunately, such kind of supervised learning method usually fails to uncover the full knowledge between documents and sentiment words. Taking account of this limitation, in this paper, we propose an iterative reinforcement learning approach for cross-domain sentiment classification by simultaneously utilizing documents and words from both source domain and target domain. Our new method can make full use of the reinforcement between documents and words by fusing four kinds of relationships between documents and words. Experimental results indicate that our new method can improve the performance of cross-domain sentiment classification dramatically.

1 Introduction

Sentiment classification is the task of determining the opinion (e.g., negative or positive) of a given document. In recent years, it has drawn much attention with the increasing reviewing pages and blogs etc., and it is very important for many applications, such as opinion mining and summarization (e.g., (Ku et al., 2006; McDonald et al., 2007)).

In most cases, a variety of supervised classification methods can perform well in sentiment classification. This kind of methods requires a condition to guarantee the accuracy of classification: training data should have the same distribution with test data so that test data could share the information got from training data. So the labeled data in the same domain with test data is considered as the most valuable resources for the sentiment classification. However, such resources in different domains are very imbalanced. In some traditional domains or domains of concern, many labeled sentiment data are freely available on the web, but in other domains, labeled sentiment data are scarce and it involves much human labor to manually label reliable sentiment data. The challenge is how to utilize labeled sentiment data in one domain (that is, source domain) for sentiment classification in another domain (that is, target domain). This raises an interesting task, cross-domain sentiment classification (or sentiment transfer). In this work, we focus on one typical kind of sentiment transfer problem, which utilizes only training data from source domain to improve sentiment classification performance for target domain, without any labeled data for the target domain (e.g., (Andreevskaia and Bergler, 2008)).

In recent years, some studies have been conducted to deal with sentiment transfer problems. However, most of the attempts rely on only the labeled documents (Aue and Gamon, 2005; Tan et al., 2007; Tan et al., 2009; Wu et al., 2009) or the labeled sentiment words (Gamon and Aue, 2005) to improve the performance of sentiment transfer, so this kind of methods fails to uncover the full knowledge between the documents and the sentiment words.

In fact, the opinion of a document can be determined by the interrelated documents as well as by the interrelated words, and this rule is also tenable when determining the opinion of a sentiment word. This rule is based on the following intuitive observations:

(1) A document strongly linked with other positive (negative) documents could be considered as positive (negative); in the same way, a word strongly linked with other positive (negative) words could be considered as positive (negative).

Coling 2008: Poster Volume, pages 1327–1335,
Beijing, August 2010

(2) A document containing many positive (negative) words could be considered as positive (negative); similarly, a word appearing in many positive (negative) documents could be considered as positive (negative).

Inspired by these observations, we aim to take into account all the four kinds of relationships among documents and words (i.e. the relationships between documents, the relationships between words, the relationships between words and documents, and the relationships between documents and words) in both source domain and target domain under a unified framework for sentiment transfer.

In this work, we propose an iterative reinforcement approach to implement the above idea. The proposed approach makes full use of all the relationships among documents and words from both source domain and target domain to transfer information between domains. In our approach, the opinion of a document (word) is reinforced by the opinion of all its interrelated documents and words; and the updated opinion of the document (word) will conversely reinforce the opinions of its interrelated documents and words. That is to say, it is an iterative reinforcement process until it converges to a final result.

The contribution of our work is twofold. First, we extend the traditional sentiment-transfer methods by utilizing the full knowledge between interrelated documents and words. Second, we present a reinforcement approach to get the opinions of documents by making use of graph-ranking algorithm.

The proposed approach is evaluated on three domain-specific sentiment data sets. The experimental results show that our approach can dramatically improve the accuracy when transferred to another target domain. And we also conduct extensive experiments to investigate the parameters sensitivity. The results show that our algorithm is not sensitive to these parameters.

2 Proposed Methods

2.1 Problem Definition

In this paper, we have two document sets: the test documents $D^U = \{d_1,\ldots,d_{nd}\}$ where d_i is the term vector of the i^{th} text document and each $d_i \in D^U (i = 1,\ldots,nd)$ is unlabeled; the training documents $D^L = \{d_{nd+1},\ldots,d_{nd+md}\}$ where d_j represents the term vector of the j^{th} text document and each $d_j \in D^L (j = nd+1,\ldots,nd+md)$ should have a label from a category set C = {negative, positive}. We assume the training dataset D^L is from the interrelated but different domain with the test dataset D^U. Also, we have two word sets: $W^U = \{w_1,\ldots,w_{nw}\}$ is the word set of D^U and each $w_i \in W^U$ $(i = 1,\ldots,nw)$ is unlabeled; $W^L = \{w_{nw+1},\ldots,w_{nw+mw}\}$ is the word set of D^L and each $w_j \in W^L (j = nw+1,\ldots,nw+mw)$ has a label from C. Our objective is to maximize the accuracy of assigning a label in C to $d_i \in D^U$ $(i = 1,\ldots,nd)$ utilizing the training data D^L and W^L in another domain.

The proposed algorithm is based on the following presumptions:

(1) $W^L \cap W^U \neq \Phi$.

(2) The labels of documents appear both in the training data and the test data should be the same.

2.2 Overview

The proposed approach is inspired by graph-ranking algorithm whose idea is to give a node high score if it is strongly linked with other high-score nodes. Graph-ranking algorithm has been successfully used in many fields (e.g. PageRank (Brin et al, 1999), LexRank (Erkan and Radev, 2004)). We can get the following thoughts based on the ideas of PageRank and HITS (Kleinberg, 1998):

(1) If a document is strongly linked with other positive (negative) documents, it tends to be positive (negative); and if a word is strongly linked with other positive (negative) words, it tends to be positive (negative).

(2) If a document contains many positive (negative) words, it tends to be positive (negative); and if a word appears in many positive (negative) documents, it tends to be positive (negative).

Given the data points of documents and words, there are four kinds of relationships in our problem:

- DD-Relationship: It denotes the relationships between documents, usually computed by their content similarity.
- WW-Relationship: It denotes the relationships between words, usually computed by knowledge-based approach or corpus-based approach.
- DW-Relationship: It denotes the relationships between documents and words, usu-

ally computed by the relative importance of a word in a document.

- WD-Relationship: It denotes the relationships between words and documents, usually computed by the relative importance of a document to a word.

Meanwhile, our problem refers to both source domain and target domain, so our approach considers eight relationships altogether: DDO-Relationship (the relationships between D^U and D^L), DDN-Relationship (the relationships between D^U), WWO-Relationship (the relationships between W^U and W^L), WWN-Relationship (the relationships between W^U and W^U), DWO-Relationship (the relationships between D^U and W^L), DWN-Relationship (the relationships between D^U and W^U), WDO-Relationship (the relationships between W^U and D^L), WDN-Relationship (the relationships between W^U and D^U). The first four relationships are used to compute the sentiment scores of the documents, and the others are used to compute the sentiment scores of the words.

The iterative reinforcement approach could make full use of all the relationships in a unified framework. The framework of the proposed approach is illustrated in Figure 1.

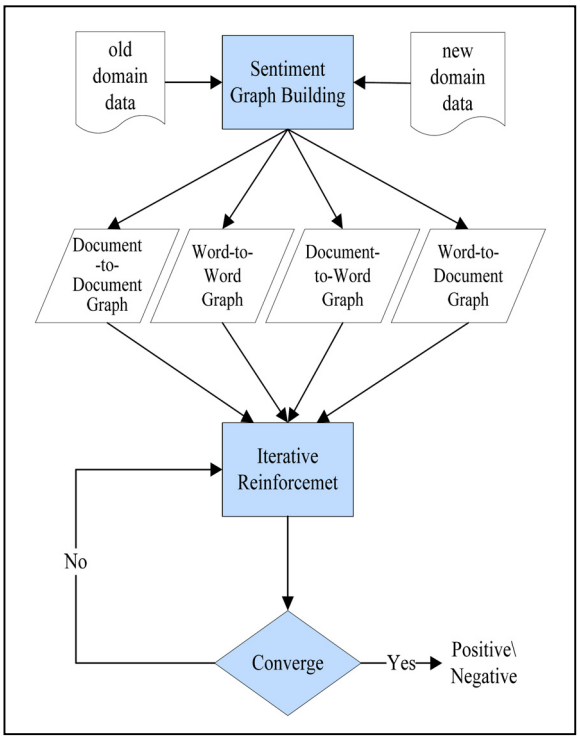

Figure 1. Framework of the proposed approach

The framework consists of a graph-building phase and an iterative reinforcement phase. In the graph-building phase, the input includes both the labeled data from source domain and the unlabeled data from target domain. The proposed approach builds four graphs based on these data to reflect the above relationships respectively. For source-domain data, we initialize every document and word a score ("1" denotes positive, and "-1" denotes negative) to represent its degree of sentiment orientation, and we call it sentiment score; for target-domain data, we set the initial sentiment scores to 0.

In the iterative reinforcement phase, our approach iteratively computes the sentiment scores of the documents and words based on the graphs. When the algorithm converges, all the documents get their sentiment scores. If its sentiment score is between 0 and 1, the document should be classified as "positive". The closer its sentiment score is near 1, the higher the "positive" degree is. Otherwise, if its sentiment score is between 0 and -1, the document should be classified as "negative". The closer its sentiment score is near -1, the higher the "negative" degree is.

The algorithms of sentiment graph building and iterative reinforcement are described in details in the next sections, respectively.

2.3 Sentiment-Graph Building

Symbol Definition

In this section, we build four graphs to reflect eight relationships, and the meanings of symbols are shown in Table 1.

Relationship	Similarity matrix	Normalized form	Neighbor matrix
DDO	$U^L=[U^L_{ij}]_{ndxmd}$	$\hat{U}^L$	$Un^L=[Un^L_{ij}]_{nd\times K}$
DDN	$U^U=[U^U_{ij}]_{ndxnd}$	$\hat{U}^U$	$Un^U=[Un^U_{ij}]_{nd\times K}$
WWO	$V^L=[V^L_{ij}]_{nwxmw}$	$\hat{V}^L$	$Vn^L=[Vn^L_{ij}]_{nw\times K}$
WWN	$V^U=[V^U_{ij}]_{nwxnw}$	$\hat{V}^U$	$Vn^U=[Vn^U_{ij}]_{nw\times K}$
DWO	$M^L=[M^L_{ij}]_{ndxmw}$	$\hat{M}^L$	$Mn^L=[Mn^L_{ij}]_{nd\times K}$
DWN	$M^U=[M^U_{ij}]_{ndxnw}$	$\hat{M}^U$	$Mn^U=[Mn^U_{ij}]_{nd\times K}$
WDO	$N^L=[N^L_{ij}]_{nwxmd}$	$\hat{N}^L$	$Nn^L=[Nn^L_{ij}]_{nw\times K}$
WDN	$N^U=[N^U_{ij}]_{nwxnd}$	$\hat{N}^U$	$Nn^U=[Nn^U_{ij}]_{nw\times K}$

Table 1: Symbol definition

In this table, the first column denotes the name of the relationship; the second column denotes

the similarity matrix to reflect the corresponding relationship; in consideration of convergence, we normalize the similarity matrix, and the normalized form is listed in the third column; in order to compute sentiment scores, we find the neighbors of a document or a word and the neighbor matrix is listed in the fourth column.

Document-to-Document Graph

We build an undirected graph whose nodes denote documents in both D^L and D^U and edges denote the content similarities between documents. If the content similarity between two documents is 0, there is no edge between the two nodes. Otherwise, there is an edge between the two nodes whose weight is the content similarity. The edges in this graph are divided into two parts: edges between D^U and D^L; edges between D^U itself, so we build the graph in two steps.

(1) Create D^U and D^L Edges

The content similarity between two documents is computed with the cosine measure. We use an adjacency matrix U^L to denote the similarity matrix between D^U and D^L. $U^L=[U^L_{ij}]_{ndxmd}$ is defined as follows:

$$U^L_{ij} = \frac{d_i \bullet d_{j+nd}}{\|d_i\| \times \|d_{j+nd}\|},\ i = 1,...,nd, j = 1,...,md \qquad (1)$$

The weight associated with word w is computed with $tf_w idf_w$ where tf_w is the frequency of word w in the document and idf_w is the inverse document frequency of word w, i.e. $1+\log(N/n_w)$, where N is the total number of documents and n_w is the number of documents containing word w in a data set.

In consideration of convergence, we normalize U^L to $\hat{U}^L$ by making the sum of each row equal to 1:

$$\hat{U}^L_{ij} = \begin{cases} U^L_{ij} \Big/ \sum_{j=1}^{md} U^L_{ij}, & if \sum_{j=1}^{md} U^L_{ij} \neq 0 \\ 0, & otherwise \end{cases} \qquad (2)$$

In order to find the neighbors (in another word, the nearest documents) of a document, we sort every row of $\hat{U}^L$ to $\tilde{U}^L$ in descending order. That is: $\tilde{U}^L_{ij} \geq \tilde{U}^L_{ik}$ ($i = 1,\ldots,nd; j,k = 1,\ldots,md; k \geqslant j$).

Then for $d_i \in D^U$ ($i = 1,\ldots,nd$), $\tilde{U}^L_{ij}$ ($j = 1,\ldots,K$) corresponds to K neighbors in D^L. We use a matrix $Un^L = [Un^L_{ij}]_{nd \times K}$ to denote the neighbors of D^U in source domain, with Un^L_{ij} corresponding to the j^{th} nearest neighbor of d_i.

(2) Create D^U and D^U Edges

Similarly, the edge weight between D^U itself is computed by the cosine measure. We get the similarity matrix $U^U=[U^U_{ij}]_{ndxnd}$, the normalized similarity matrix $\hat{U}^U$, and the neighbors of D^U in target domain: $Un^U = [Un^U_{ij}]_{nd \times K}$.

Word-to-Word Graph

Similar to the Document-to-Document Graph, we build an undirected graph to reflect the relationship between words in W^L and W^U, in which each node corresponds to a word and the edge weight between any different words corresponds to their semantic similarity. The edges in this graph are divided into two parts: edges between W^U and W^L; edges between W^U itself, so we also build the graph in two steps.

(1) Create W^U and W^L Edges

We compute the semantic similarity using corpus-based approach which computes the similarity between words utilizing information from large corpora. There are many measures to identify word semantic similarity, such as mutual information (Turney, 2001), latent semantic analysis (Landauer et al., 1998) etc. In this study, we compute word semantic similarity based on the sliding window measure, that is, two words are semantically similar if they co-occur at least once within a window of maximum K_{win} words, where K_{win} is the window size. We use an adjacency matrix V^L to denote the similarity matrix between W^U and W^L. $V^L=[V^L_{ij}]_{nwxmw}$ is defined as follows:

$$V^L_{ij} = \begin{cases} \log \frac{N \times p(w_i, w_{j+nw})}{p(w_i) \times p(w_{j+nw})}, & if\ w_i \neq w_{j+nw} \\ 0, & otherwise \end{cases} \qquad (3)$$

where N is the total number of words in D^U; $p(w_i, w_j)$ is the probability of the co-occurrence of w_i and w_j within a window, i.e. $num(w_i, w_j)/N$, where $num(w_i, w_j)$ is the number of the times w_i and w_j co-occur within the window; $p(w_i)$ and $p(w_j)$ are the probabilities of the occurrences of w_i and w_j respectively, i.e. $num(w_i)/N$ and $num(w_j)/N$, where $num(w_i)$ and $num(w_j)$ are the

numbers of the times w_i and w_j occur. We normalize V^L to $\hat{V}^L$ to make the sum of each row equal to 1. Then we sort every row of $\hat{V}^L$ to $\tilde{V}^L$ in descending order, and we use a matrix $Vn^L = [Vn^L{}_{ij}]_{nw \times K}$ to denote the neighbors of W^U in source domain.

(2) Create W^U and W^U Edges

Then we also compute the edge weight between any different nodes which denote words in W^U by the sliding window measure. We get the similarity matrix $V^U=[V^U{}_{ij}]_{nwxnw}$, the normalized similarity matrix $\hat{V}^U$, and the neighbors of W^U in target domain: $Vn^U = [Vn^U{}_{ij}]_{nw \times K}$.

Document-to-Word Graph

We can build a weighted directed bipartite graph from documents in D^U and words in W^L and W^U in the following way: each node in the graph corresponds to a document in D^U or a word in W^L and W^U; if word w_j appears in document d_i, we create an edge from d_i to w_j. The edges in this graph are divided into two parts: edges from D^U to W^L; edges from D^U to W^U, so we also build the graph in two steps.

(1) Create D^U to W^L Edges

The edge weight from a document in D^U to a word in W^L is proportional to the importance of word w_j in document d_i. We use an adjacency matrix M^L to denote the similarity matrix from D^U to W^L. $M^L=[M^L{}_{ij}]_{ndxmw}$ is defined as follows:

$$M^L_{ij} = \frac{tf_{w_{j+nw}} \times idf_{w_{j+nw}}}{\sum_{w \in d_i} tf_w \times idf_w} \tag{4}$$

where w represents a unique word in d_i and tf_w, idf_w are respectively the term frequency in the document and the inverse document frequency. We normalize M^L to $\hat{M}^L$ to make the sum of each row equal to 1. Then we sort every row of $\hat{M}^L$ to $\tilde{M}^L$ in descending order, and we use a matrix $Mn^L = [Mn^L{}_{ij}]_{nd \times K}$ to denote the neighbors of D^U in W^L.

(2) Create D^U to W^U Edges

Similarly, we can also compute the edge weight from a document in D^U to a word in W^U in the same way. We get the similarity matrix $M^U=[M^U{}_{ij}]_{ndxnw}$, the normalized similarity matrix $\hat{M}^U$, and the neighbors of D^U in W^U: $Mn^U = [Mn^U{}_{ij}]_{nd \times K}$.

Word-to-Document Graph

In this section, we build a weighted directed bipartite graph from words in W^U and documents in D^L and D^U in which each node in the graph corresponds to a word in W^U and a document in D^L or D^U; if word w_j appears in document d_i, we create an edge from w_j to d_i. The edges in this graph are also divided into two parts: edges from W^U to D^L; edges from W^U to D^U.

(1) Create W^U to D^L Edges

Similar to 3.3.4, the edge weight from a word in W^U to a document in D^L is proportional to the importance of word w_i in document d_j. We use an adjacency matrix $N^L=[N^L{}_{ij}]_{nwxmd}$ to denote the similarity matrix from W^U to D^L. We normalize N^L to $\hat{N}^L$ to make the sum of each row equal to 1. Then we sort every row of $\hat{N}^L$ to $\tilde{N}^L$ in descending order, and we use a matrix $Nn^L = [Nn^L{}_{ij}]_{nw \times K}$ to denote the neighbors of W^U in D^L.

(2) Create W^U to D^U Edges

We can also compute the edge weight from a word in W^U to a document in D^U in the same way. We get the similarity matrix $N^U=[N^U{}_{ij}]_{nwxnd}$, the normalized similarity matrix $\hat{N}^U$, and the neighbors of W^U in D^U: $Nn^U = [Nn^U{}_{ij}]_{nw \times K}$.

2.4 Proposed Method

Based on the two thoughts introduced in Section 2.2, we fuse the eight relationships abstracted from the four graphs together to iteratively reinforce sentiment scores, and we can obtain the iterative equation as follows:

$$\begin{aligned} ds_i = {} & \varphi \sum_{g \in Un^L{}_{i\bullet}} (\hat{U}^L{}_{ig} \times ds_g) + \mu \sum_{h \in Un^U{}_{i\bullet}} (\hat{U}^U{}_{ih} \times ds_h) \\ & + \gamma \sum_{l \in Mn^L{}_{i\bullet}} (\hat{M}^L{}_{il} \times ws_l) + \delta \sum_{r \in Mn^U{}_{i\bullet}} (\hat{M}^U{}_{ir} \times ws_r) \end{aligned} \tag{5}$$

$$\begin{aligned} ws_j = {} & \varphi \sum_{g \in Vn^L{}_{j\bullet}} (\hat{V}^L{}_{jg} \times ws_g) + \mu \sum_{h \in Vn^U{}_{j\bullet}} (\hat{V}^U{}_{jh} \times ws_h) \\ & + \gamma \sum_{l \in Nn^L{}_{j\bullet}} (\hat{N}^L{}_{jl} \times ds_l) + \delta \sum_{r \in Nn^U{}_{j\bullet}} (\hat{N}^U{}_{jr} \times ds_r) \end{aligned} \tag{6}$$

where $i\bullet$ means the i^{th} row of a matrix; $Ds = \{ds_1,\ldots,ds_{nd}, ds_{nd+1},\ldots, ds_{nd+md}\}$ represents the sentiment scores of D^U and D^L; $Ws = \{ws_1,\ldots,ws_{nw}, ws_{nw+1},\ldots, ws_{nw+mw}\}$ represents the sentiment scores of W^U and W^L; φ and μ show

the relative contributions to the final sentiment scores from source domain and target domain when calculating DD-Relationship and WW-Relationship, and $\varphi + \mu = 1$; γ and δ show the relative contributions to the final sentiment scores from source domain and target domain when calculating DW-Relationship and WD-Relationship, and $\gamma + \delta = 1$.

For simplicity, we merge the relationships from source domain and target domain. That is, for formula (5), we merge the first two items into one, the last two items into one; for formula (6), we merge its first two items into one, its last two items into one. Thus, (5) and (6) are transformed into (7) and (8) as follows:

$$ds_i = \alpha \times \sum_{g \in Un_{i\bullet}} (\hat{U}_{ig} \times ds_g) + \beta \times \sum_{l \in Mn_{i\bullet}} (\hat{M}_{il} \times ws_l) \quad (7)$$

$$ws_j = \alpha \times \sum_{g \in Nn_{j\bullet}} (\hat{N}_{jg} \times ds_g) + \beta \times \sum_{l \in Vn_{j\bullet}} (\hat{V}_{jl} \times ws_l) \quad (8)$$

where α and β show the relative contributions to the final sentiment scores from document sets and word sets, and $\alpha + \beta = 1$.

In consideration of the convergence, Ds and Ws are normalized separately after each iteration as follows to make the sum of positive scores equal to 1, and the sum of negative scores equal to -1:

$$ds_i = \begin{cases} ds_i \Big/ \sum_{j \in D^U_{neg}} (-ds_j), & if \quad ds_i < 0 \\ ds_i \Big/ \sum_{j \in D^U_{pos}} ds_j, & if \quad ds_i > 0 \end{cases} \quad (9)$$

$$ws_j = \begin{cases} ws_j \Big/ \sum_{i \in W^U_{neg}} (-ws_i), & if \quad ws_j < 0 \\ ws_j \Big/ \sum_{i \in W^U_{pos}} ws_i, & if \quad ws_j > 0 \end{cases} \quad (10)$$

where D^U_{neg} and D^U_{pos} denote the negative and positive document set of D^U respectively; W^U_{neg} and W^U_{pos} denote the negative and positive word set of W^U respectively.

Here is the complete algorithm:

1. Initialize the sentiment score *vector* ds_i of $d_i \in D^L$ ($i = nd+1,\ldots, nd+md$) with 1 when d_i is labeled "positive", and with -1 when d_i is labeled "negative", and initialize the sentiment score *vector* ws_i of $w_i \in W^L$ ($i = nw+1,\ldots, nw+mw$) with 1 when w_i is labeled "positive", and with -1 when w_i is labeled "negative". And we normalize ds_i ($i = nd+1,\ldots, nd+md$) (ws_i ($i = nw+1,\ldots, nw+mw$)) to make the sum of positive scores of D^L (W^L) equal to 1, and the sum of negative scores of D^L (W^L) equal to -1. Also, the initial sentiment scores of D^U and W^U are set to 0.
2. Alternate the following two steps until convergence:
   2.1. Compute and normalize ds_i ($i = 1,\ldots, nd$) using formula (7) and (9):
   2.2. Compute and normalize ws_j ($j=1,\ldots,nw$) using formula (8) and (10):

   where $ds_i^{(k)}$ and $ws_j^{(k)}$ denote the ds_i and ws_j at the k^{th} iteration.
3. According to $ds_i \in Ds$ ($i = 1,\ldots,nd$), assign each $d_i \in D^U$ ($i = 1,\ldots,nd$) a label. If ds_i falls in the range [-1,0], assign d_i the label "negative"; if ds_i falls in the range [0,1], assign d_i the label "positive".

3 Experiments

In this section, we evaluate our approach on three different domains and compare it with some state-of-the-art algorithms, and also evaluate the approach's sensitivity to its parameters. Note that we conduct experiments on Chinese data, but the main idea in the proposed approach is language-independent in essence.

3.1 Data Preparation

We use three Chinese domain-specific data sets from on-line reviews, which are: Book Reviews[1] (B, www.dangdang.com/), Hotel Reviews[2] (H, www.ctrip.com/) and Notebook Reviews[3] (N, www.360buy.com/). Each dataset has 4000 labeled reviews (2000 positives and 2000 negatives).

We use ICTCLAS (http://ictclas.org/), a Chinese text POS tool, to segment these Chinese reviews. Then, utilizing the part-of-speech tagging function provided by ICTCLAS, we take all adjectives, adverbs and adjective-noun phrases as candidate sentiment words. After removing the repeated words and ambiguous words, we get a list of words in each domain.

For the list of words in each domain, we manually label every word as "negative", "posi-

[2] www.searchforum.org.cn/tansongbo/corpus/Ctrip_htl_4000.rar
[3] www.searchforum.org.cn/tansongbo/corpus/Jingdong_NB_4000.rar

tive" or "neutral", and we take those "negative" and "positive" words as a sentiment word set.

Note that we use the sentiment word set only for source domain, while using the candidate sentiment words for target domain.

Lastly, the documents are represented by vector space model. In this model, each document is converted into bag-of-words presentation in the remaining term space. We compute term weight with the frequency of the term in the document.

We choose one of the three data sets as source-domain data D^L, and its corresponding sentiment word set as W^L; we choose another data set as target-domain data D^U, and its corresponding candidate sentiment words as W^U.

3.2 Baseline Methods

In this paper we compare our approach with the following baseline methods:

Proto: This method applies a traditional supervised classifier, prototype classifier (Tan et al., 2005), for the sentiment transfer. And it only uses source domain documents as training data.

LibSVM: This method applies a state-of-the-art supervised learning algorithm, Support Vector Machine, for the sentiment transfer. In detail, we use LibSVM (Chang and Lin, 2001) with a linear kernel and set all options as default. This method only uses source domain documents as training data.

TSVM: This method applies transductive SVM (Joachims, 1999) for the sentiment transfer which is a widely used method for improving the classification accuracy. In our experiment, we use Joachims's SVM-light package (http://svmlight.joachims.org/) for TSVM. We use a linear kernel and set all parameters as default. This method uses both source domain data and target domain data.

3.3 Overall Performance

In this section, we compare proposed approach with the three baseline methods. There are three parameters in our algorithm, K, K_{win}, α (β can be calculated by 1-α). We set K to 50, and K_{win} to 10 respectively. With different α, our approach can be considered as utilizing different relative contributions from document sets and word sets. In order to identify the importance of both document sets and word sets for sentiment transfer, we separately set α to 0, 1, 0.5 to show the accuracy of utilizing only word sets (referred to as WORD), only document sets (referred to as DOC), and both the document and word sets (referred to as ALL). It is thought that the algorithm achieves the convergence when the changing between the sentiment score ds_i computed at two successive iterations for any $d_i \in D^U$ (i = 1,…,nd) falls below a given threshold, and we set the threshold 0.00001 in this work. The parameters will be studied in parameters sensitivity section.

Table 2 shows the accuracy of Prototype, LibSVM, TSVM and our algorithm when training data and test data belong to different domains.

As we can observe from Table 2, our algorithm produces much better performance than supervised baseline methods. Compared with the traditional classifiers, our approach outperforms them by a wide margin on all the six transfer tasks. The great improvement compared with the baselines indicates that our approach performs very effectively and robustly.

	Traditional Classifier		TSVM	Our Approach		
	Proto	LibSVM		DOC	WORD	ALL
B->H	0.735	0.747	0.749	**0.772**	0.734	0.763
B->N	0.651	0.652	0.769	0.714	0.785	**0.795**
H->B	0.645	0.675	0.614	0.671	0.668	**0.703**
H->N	0.729	0.669	0.726	**0.749**	0.727	0.734
N->B	0.612	0.608	0.622	0.638	0.667	**0.726**
N->H	0.724	0.711	0.772	0.764	0.740	**0.792**
Average	0.683	0.677	0.709	0.718	0.720	**0.752**

Table 2: Accuracy comparison of different methods

Table 2 shows the average accuracy of TSVM is higher than both traditional classifiers, since it utilizes the information of both source domain and target domain. However, the proposed approach outperforms TSVM: the average accuracy of the proposed approach is about 4.3% higher than TSVM. This is caused by two reasons. First, TSVM is not dedicated for sentiment-transfer learning. Second, TSVM requires the ratio between positive and negative examples in the test data to be close to the ratio in the training data, so its performance will be affected if this requirement is not met.

Results of "DOC" and "WORD" are shown in column 4 and 5 of Table 2. As we can observe, they produce better performance than all the baselines. This is caused by two reasons. First, "DOC" and "WORD" separately utilize the sen-

timent information of documents and words. Second, both "DOC" and "WORD" involve an iterative reinforcement process to improve their performance. The great improvement indicates that the iterative reinforcement approach is effective for sentiment transfer.

Besides, Table 2 also shows both document sets and word sets are important for sentiment transfer. The approach "ALL" outperforms the approaches "DOC" and "WORD" on almost all the six transfer tasks except "B->H" and "H->N". The average increase of accuracy over all the six tasks is 3.4% and 3.2% respectively. The reason is: at every iteration, the classification accuracy of documents and words is improved by each other, and then the accuracy of sentiment transfer is improved by the documents and words that are classified more accurately. As for "B->H" and "H->N", the performance of utilizing only document sets is so good that the word sets couldn't improve the performance any more. The improvement of the approach "ALL" convinces us that not a single one of the four relationships can be omitted.

3.4 Parameters Sensitivity

The proposed algorithm has an important parameter, α (β can be calculated by 1-α). In this section, we conduct experiments to show that our algorithm is not sensitive to this parameter.

To investigate the sensitivity of proposed method involved with the parameter α, we set K to 50, and K_{win} to 10. And we change α from 0 to 1, an increase of 0.1 each. We also evaluate α on the six tasks mentioned in section 3.1, and the results are shown in figure 2.

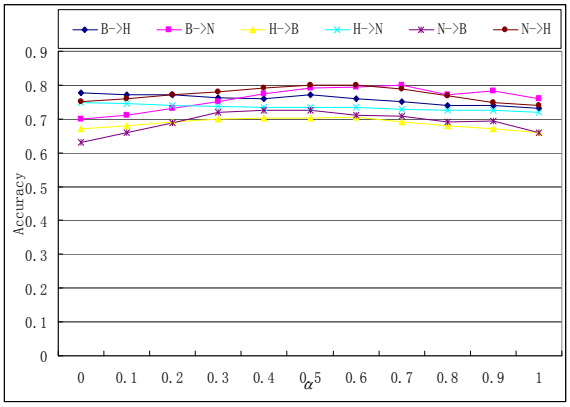

Figure 2: Accuracy for Different α

We can observe from Figure 2 that the accuracy first increases and then decreases when α is increased from 0 to 1. The accuracy changes gradually when α is near 0 or 1, and it changes less when α is between 0.2 and 0.8. It is easy to explain this phenomenon. When α is set to 0, this indicates our algorithm only uses word sets to aid classification, without the information of document sets. And if α is set to 1, our algorithm only uses document sets to calculate sentiment score, without the help of word sets. Both cases above don't use all information of four relationships, so their accuracies are worse than to equal the contributions of both document and word sets. This experiment shows that the proposed algorithm is not sensitive to the parameter α as long as α is not 0 or 1. We set α to 0.5 in our overall-performance experiment.

3.5 Convergence

Our algorithm is an iterative process that will converge to a local optimum. We evaluate its convergence on the six tasks mentioned above. Figure 3 shows the change of accuracy with respect to the number of iterations. We can observe from figure 3 that the curve rises sharply during the first 6 iterations, and it is very stable after 10 iterations are performed. This experiment indicates that our algorithm could converge very quickly to get a local optimum.

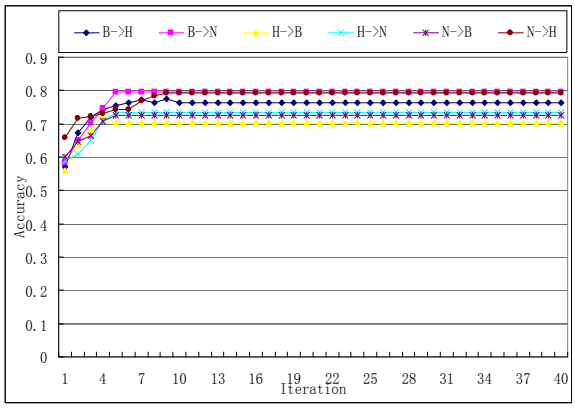

Figure 3: Performance for Iteration

4 Conclusions

In this paper, we propose a novel cross-domain sentiment classification approach, which is an iterative reinforcement approach for sentiment transfer by utilizing all the relationships among documents and words from both source domain and target domain to transfer information between domains. First, we build three graphs to reflect the above relationships respectively. Then,

we assign a score for every unlabelled document to denote its extent to "negative" or "positive". We then iteratively calculate the score by making use of the graphs. Finally, the final score for sentiment classification is achieved when the algorithm converges, so we can label the target-domain data based on these scores.

We conduct experiments on three domain-specific sentiment data sets. The experimental results show that the proposed approach could dramatically improve the accuracy when transferred to a target domain. To investigate the parameter sensitivity, we conduct experiments on the same data sets. It is observed that our approach is not very sensitive to its four parameters, and could converge very quickly to get a local optimum.

In this study, we employ only cosine measure, sliding window measure and vector measure to compute similarity. These are too general, and perhaps not so suitable for sentiment classification. In the future, we will try other methods to calculate the similarity. Furthermore, we experiment our approach on only three domains, and we will apply our approach to many more domains.

Exploring the Use of Word Relation Features for Sentiment Classification

Rui Xia and **Chengqing Zong**

Institute of Automation, Chinese Academy of Sciences
{rxia, cqzong}@nlpr.ia.ac.cn

Abstract

Word relation features, which encode relation information between words, are supposed to be effective features for sentiment classification. However, the use of word relation features suffers from two issues. One is the sparse-data problem and the lack of generalization performance; the other is the limitation of using word relations as additional features to unigrams. To address the two issues, we propose a generalized word relation feature extraction method and an ensemble model to efficiently integrate unigrams and different type of word relation features. Furthermore, aimed at reducing the computation complexity, we propose two fast feature selection methods that are specially designed for word relation features. A range of experiments are conducted to evaluate the effectiveness and efficiency of our approaches.

1 Introduction

The task of text sentiment classification has become a hotspot in the field of natural language processing in recent years (Pang and Lee, 2008). The dominating text representation method in sentiment classification is known as the bag-of-words (BOW) model. Although BOW is quite simple and efficient, a great deal of the information from original text is discarded, word order is disrupted and syntactic structures are broken. Therefore, more sophisticated features with a deeper understanding of the text are required for sentiment classification tasks.

With the attempt to capture the word relation information behind the text, word relation (WR) features, such as higher-order n-grams and word dependency relations, have been employed in text representation for sentiment classification (Dave et al., 2003; Gamon, 2004; Joshi and Penstein-Rosé, 2009).

However, in most of the literature, the performance of individual WR feature set was poor, even inferior to the traditional unigrams. For this reason, WR features were commonly used as additional features to supplement unigrams, to encode more word order and word relation information. Even so, the performance of joint features was still far from satisfactory (Dave et al., 2003; Gamon, 2004; Joshi and Penstein-Rosé, 2009).

We speculate that the poor performance is possibly due to the following two reasons: 1) in WR features, the data are sparse and the features lack generalization capability; 2) the use of joint features of unigrams and WR features has its limitation.

On one hand, there were attempts at finding better generalized WR (GWR) features. Gamon (2004) back off words in n-grams (and semantic relations) to their respective POS tags (e.g., *great-movie* to adjective-noun); Joshi and Rosé (2009) propose a method by only backing off the head word in dependency relation pairs to its POS tag (e.g., *great-movie* to *great*-noun), which are supposed to be more generalized than word pairs. Based on Joshi and Rosé's method, we back off the word in each word relation pairs to its corresponding POS cluster, making the feature space smarter and more effective.

On the other hand, we find that from unigrams to WR features, relevance between features is reduced and the independence is in-

Coling 2008: Poster Volume, pages 1336–1344,
Beijing, August 2010

creased. Although the discriminative model (e.g., SVM) is proven to be more effective on unigrams (Pang et al., 2002) for its ability of capturing the complexity of more relevant features, WR features are more inclined to work better in the generative model (e.g., NB) since the feature independence assumption holds well in this case.

Based on this finding, we therefore intuitively seek, instead of jointly using unigrams and GWR features, to efficiently integrate them to synthesize a more accurate classification procedure. We use the ensemble model to fuse different types of features under distinct classification models, with an attempt to overcome individual drawbacks and benefit from each other's merit, and finally to enhance the overall performance.

Furthermore, feature reduction is another important issue of using WR features. Due to the huge dimension of WR feature space, traditional feature selection methods in text classification perform inefficiently. However, to our knowledge, no related work has focused on feature selection specially designed for WR features.

Taking this point into consideration, we propose two fast feature selection methods (FMI and FIG) for GWR features with a theoretical proof. FMI and FIG regard the importance of a GWR feature as two component parts, and take the sum of two scores as the final score. FMI and FIG remain a close approximation to MI and IG, but speed up the computation by at most 10 times. Finally, we apply FMI and FIG to the ensemble model, reducing the computation complexity to a great extent.

The remainder of this paper is organized as follows. In Section 2, we introduce the approach to extracting GWR features. In Section 3, we present the ensemble model for integrating different types of features. In Section 4, the fast feature selection methods for WR features are proposed. Experimental results are reported in Section 5. Section 6 draws conclusions and outlines directions for future work.

2 Generalized Word Relation Features

A straightforward method for extracting WR features is to simply map word pairs into the feature vector. However, due to the sparse-data problem and the lack of generalization ability, the performance of WR is discounted. Consider the following two pieces of text:

1) *Avatar is a great movie. I definitely recommend it.*

2) *I definitely recommend this book. It is great.*

We lay the emphasis on the following word pairs: *great-movie, great-it, it-recommend*, and *book-recommend*. Although these features are good indicators of sentiment, due to the sparse-data problem, they may not contribute as importantly as we have expected in machine learning algorithms. Moreover, the effects of those features would be greatly reduced when they are not captured in the test dataset (for example, a new feature *great-song* in the test set would never benefit from *great-movie* and *great-it*).

Joshi and Rosé (2009) back off the head word in each of the relation pairs to its POS tag. Taking *great-movie* for example, the back-off feature will be *great*-noun. With such a transformation, original features like *great-movie*, *great-book* and other *great*-noun pairs are regarded as one feature, hence, the learning algorithms could learn a weight for a more general feature that has stronger evidence of association with the class, and any new test sentence that contains an unseen noun in a similar relationship with the adjective *great* (e.g., *great-song*) will receive some weight in favor of the class label.

With the attempt to make a further generalization, we conduct a POS clustering. Considering the effect of different POS tags in both unigrams and word relations, the POS tags are categorized as shown in Table 1.

POS-cluster	Contained POS tags
J	JJ, JJS, JJR
R	RB, RBS, RBR
V	VB, VBZ, VBD, VBN, VBG, VBP
N	NN, NNS, NNP, NNPS, PRP
O	The other POS tags

Table 1: POS Clustering (the Penn Corpus Style)

Since adjectives and adverbs have the highest correlation with sentiment, and some verbs and nouns are also strong indicators of sentiment, we therefore put them into separate clusters. All the other tags are categorized to one cluster because they contain a lot of noise rather than useful information. In addition, we assign pronouns to POS-cluster N, aimed at capturing the generality in WR features like *great-movie* and *great-it*, or *book-recommend* and *it-recommend*.

Taking "*Avatar is a great movie*" for example, different types of WR features are presented in Table 2, where Uni denotes unigrams; WR-Bi indicates traditional bigrams; WR-Dp indicates word pairs of dependency relation; GWR-Bi and GWR-Dp respectively denote generalized bigrams and dependency relations.

WR types	WR features
WR-Bi	*Avatar-is, is-a, a-great, great-movie*
WR-Dp	*Avatar-is, a-movie, great-movie, movie-is*
GWR-Bi	*Avatar*-V, *is*-O, *a*-J, *great*-N, N-*is*, V-*a*, O-*great*, J-*movie*
GWR-Dp	*Avatar*-V, *a*-N, *great*-N, *movie*-V, N-*is*, O-*movie*, J-*movie*

Table 2: Different types of WR features

3 An Ensemble Model for Integrating WR Features

3.1 Joint Features, Good Enough?

Although the unigram feature space is simple, and the WR features are more sophisticated, the latter was mostly used as extra features in addition to the former, rather than to substitute it. Even so, in most of the literature, the improvements of joint features are still not as good as we had expected. For example, Dave et al. (2003) try to extract a refined subset of WR pairs (adjective-noun, subject-verb, and verb-object pairs) as additional features to traditional unigrams, but do not get significant improvements. In the experiments of Joshi and Rosé (2009), the improvements of unigrams together with WR features (even generalized WR features) are also not remarkable (sometimes even worse) compared to simple unigrams.

One possible explanation might be that different types of features have distinct distributions, and therefore would probably yield vary performance on different machine learning algorithms. For example, the generative model is optimal if the distribution is well estimated; otherwise the performance will drop significantly (for instance, NB performs poorly unless the feature independence assumption holds well). While on the contrary, the discriminative model such as SVM is good at representing the complexity of relevant features.

Let us review the results reported by Pang and Lee (2002) that compare different classification algorithms: SVM performs significantly better than NB on unigrams; while the outcome is the opposite on bigrams. It is possibly due to that from unigrams to bigrams, the relevance between features is reduced (bigrams cover some relevance of unigram pairs), and the independence between features increases.

Since GWR features are less relevant and more independent in comparison, it is reasonable for us to infer that these features would work better on NB than on SVM. We therefore intuitively seek to employ the ensemble model for sentiment classification tasks, with an attempt to efficiently integrate different types of features under distinct classification models.

3.2 Model Formulation

The ensemble model (Kittler, 1998), which combines the outputs of several base classifiers to form an integrated output, has become an effective classification method for many domains.

For our ensemble task, we train six base classifiers (the NB and SVM model respectively on the Uni, GWR-Bi and GWR-Dp features). By mapping the probabilistic outputs (for C classes) of D base classifiers into the meta-vector

$$\hat{\mathbf{x}} = [o_{11},\ldots o_{1C},\ldots,o_{kj},\ldots,o_{D1},\ldots o_{DC}], \qquad (1)$$

the weighted ensemble is formulized by

$$O_j = g_j(\hat{\mathbf{x}}) = \sum_{k=1}^{D} \omega_k o_{kj} = \sum_{k=1}^{D} \omega_k \hat{x}_{k\times D+j}, \qquad (2)$$

where ω_k is the weight assigned to the k-th base classifier.

3.3 Weight Optimization

Inspired by linear regression, we use descent methods to seek optimization according to certain criteria. We employ two criteria, namely the perceptron criterion and the minimum classification error (MCE) criterion.

The perceptron cost function is defined as

$$J_p = \frac{1}{N}\sum_{i=1}^{N}\left[\max_{j=1,\ldots,C} g_j(\hat{\mathbf{x}}_i) - g_{y_i}(\hat{\mathbf{x}}_i)\right]. \qquad (3)$$

The minimization of J_p is approximately equal to seek a minimum misclassification rate.

The MCE criterion (Juang and Katagiri, 1992) is supposed to be more relevant to the classification error. A short version of MCE criterion function is given by

$$J_{mce} = \frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{C} I(y_i = j)\delta(-g_j(\hat{\mathbf{x}}) + \max_{k \neq j} g_k(\hat{\mathbf{x}})) \quad (4)$$

where $\delta(\bullet)$ is the sigmoid function.

For both criteria, stochastic gradient descent (SGD) is utilized for optimization. SGD uses approximate gradients estimated from subsets of the training data and updates the parameters in an online manner:

$$\omega_h(k+1) = \omega_h(k) - \eta(k)\frac{\partial J}{\partial \omega_h}. \quad (5)$$

The gradients of perceptron and MCE cost functions are respectively

$$\frac{\partial J_{\mathrm{p}}}{\partial \omega_h} = -\frac{1}{N}\sum_{i=1}^{N}(\hat{x}_{h\times D+s_i} - \hat{x}_{h\times D+y_i}) \quad (6)$$

where $s_i = \arg\max_{j=1,\ldots,C} g_j(\hat{\mathbf{x}}_i)$, and

$$\frac{\partial J_{\mathrm{MCE}}}{\partial \omega_h} = -\frac{1}{N}\sum_{i=1}^{N} l_{y_i}(\hat{\mathbf{x}}_i)(1 - l_{y_i}(\hat{\mathbf{x}}_i))(\hat{x}_{h\times D+s_i} - \hat{x}_{h\times D+y_i}) \quad (7)$$

where $l_j(\hat{\mathbf{x}}_i) = \delta(-g_{y_i}(\hat{\mathbf{x}}_i) + \max_{h \neq j} g_k(\hat{\mathbf{x}}_i))$ and $s_i = \arg\max_{j=1,\ldots,C; j\neq y_i} g_j(\hat{\mathbf{x}}_i)$.

As for perceptron criterion, we employ the average perceptron (AvgP) (Freund and Schapire, 1999), a variation of perceptron model that averages the weights of all iteration loops, to improve the generalization performance.

4 Feature Selection for WR Features

In the past decade, feature selection (FS) studies mainly focus on topical text classification. (Yang and Pedersen, 1997) investigate five FS metrics and reported that good FS methods (such as IG and CHI) can improve the categorization accuracy with an aggressive feature removal. In sentiment classification tasks, traditional FS methods were also proven to be effective (Ng et al., 2006; Li et al., 2009).

With regard to WR features, since the dimension of feature space has sharply increased, the amount of computation is considerably large when employing traditional FS methods.

4.1 Fast MI and Fast IG

In order to address this problem, we propose a fast feature selection method that is specially designed for GWR features. In our method, the importance of a GWR feature *ws* (e.g., *great-movie*) is considered as two component parts: the non-back-off word *w* (*great*) and the POS pairs *s* (J-N). We calculate the score of *w* and *s* respectively using existing FS methods, and take the sum of them as the final score. By assuming the two parts are mutually independent, the importance of a relation feature can be taken separately. We now give a theoretical support.

First, the mutual information between a relation feature ws and class c_k is defined as

$$I(ws, c_k) = \log\frac{P(ws, c_k)}{P(ws)P(c_k)}. \quad (8)$$

If *w* and *s* are independent, they are conditionally independent. Thus we have

$$\begin{aligned} I(ws, c_k) &= \log\frac{P(ws \mid c_k)}{P(ws)} \\ &\approx \log\frac{P(w \mid c_k)P(s \mid c_k)}{P(w)P(s)} \\ &= \log\frac{P(w \mid c_k)}{P(w)} + \log\frac{P(s \mid c_k)}{P(s)} \\ &= I(w, c_k) + I(s, c_k). \end{aligned} \quad (9)$$

Formula (9) indicates that under the assumption that two component parts *w* and *s* of a relation feature *ws* are mutually independent, the mutual information of the relation feature $I(ws, c_k)$ equals the sum of two component parts $I(w, c_k)$ and $I(s, c_k)$.

Since the average mutual information across all classes $I(ws)$ is the probabilistic sum of each class, it can be written as:

$$I(ws) \approx I(w) + I(s). \quad (10)$$

Yang and Pedersen (1997) show that the information gain $G(t)$ is the weighted average of $I(t, c_k)$ and $I(\overline{t}, c_k)$. Therefore, with the same reason, we can consider the information gain of a relation feature $G(ws)$ as the sum of two component parts:

$$G(ws) \approx G(w) + G(s) \quad (11)$$

We refer to Formula (10) and (11) as fast MI (FMI) and fast IG (FIG) respectively. Now let us look back at the rationality of the independence assumption. In fact in a relation feature, two component parts are hardly independent since they are "related". Nonetheless, if we con-

sider a GWR feature as a combination of the non-back-off word and the POS pairs, the assumption will be easier to satisfy. Taking *great-movie* (*great*-N) for example, compared to *great* and N, *great* and J-N are more independent (J-N covers some relation information), therefore it is more feasible to take $G(great)+G(\text{J-N})$ as an approximation of $G(great\text{-N})$.

Laying aside the assumption, we place emphasis on the advantage of FIG (FMI) in computational efficiency. Assuming the dimension of the unigrams feature space is N, and ignoring the data-sparse problem, the dimension of the GWR feature space is $2\times5\times N$ (backing off head/modifier word to 5 POS-cluster). Traditional IG (MI) feature selection needs to calculate the score of all $10\times N$ features, while FIG (FMI) only needs to compute for N words and 25 POS pairs. That is to say, FIG (FMI) can speed up the computation of traditional IG (MI) by at most 10 times.

4.2 Integration with the Ensemble Model

We now present how FMI (FIG) is applied to the ensemble model described in section 3.2. In each of the six base-classifiers described in Section 3.2, feature selection is performed (traditional IG on unigrams, FIG on GWR features).

Note that when performing FIG on individual GWR feature sets, the computation of non-back-off word $G(w)$, is taken care of by having already computed IG on unigrams. Thus, we only need to compute the score of 25 POS pairs. From this point of view, FIG (FMI) is quite suitable for the ensemble model.

5 Experiments

We first present the performance of system performance, and then demonstrate the effectiveness of fast feature selection.

5.1 Experimental Setup

Datasets: The Cornell movie-review dataset[1] introduced by (Pang and Lee, 2004) is used in our experiments. It is a document-level polarity dataset that contains 1,000 positive and 1,000 negative processed reviews.

We also use the dataset[2] introduced in (Joshi and Penstein-Rosé, 2009) for comparison. It is a subset (200 sentences each for 11 different products) of the product review dataset released by (Hu and Liu, 2004). We will refer to it E-product dataset.

The Movie dataset is a domain-specific document-level dataset and the E-product dataset is at sentence-level and cross-domain. We conduct experiments on both of them to evaluate our approach in a wide range of tasks.

Classifier: We implement the NB classifier based on a multinomial event model (McCallum and Nigam, 1998) with Laplace smoothing. The tool LIBSVM[3] is chosen as the SVM classifier. Setting of kernel function is linear kernel, the penalty parameter is set to one, and the Platt's probabilistic output for SVM is applied to approximate the posterior probabilities. Term presence is used as the feature weighting.

Implementation: The Movie dataset is evenly divided into 5 folds, and all the experiments are conducted with a 5-fold cross validation. Following the settings by Joshi and Rosé, an 11-fold cross validation is applied to E-product dataset, where each test fold contains all the sentences for one of the 11 products, and the sentences for the remaining 10 products are used for training.

For ensemble learning, the stacking framework (Džeroski and Ženko, 2004) is employed. Taking the Movie dataset for example, in each loop of the 5-fold cross validation, the probabilistic outputs of the test fold are considered as test samples for ensemble leaning; and an inner 4-fold leave-one-out procedure is applied to the training data, where samples in each fold are trained on the remaining three folds to obtain the probabilistic outputs which serve as training samples for ensemble learning.

All the performance in the remaining tables and figures is in terms of average accuracy.

5.2 Results of Classification Accuracy

The results of classification accuracy are organized in three parts. We first compare the performance of individual WR and GWR; secondly we compare joint features and the ensemble

[1] http://www.cs.cornell.edu/people/pabo/movie-review-data/

[2] http://www.cs.cmu.edu/~maheshj/datasets/acl09short.html

[3] http://www.csie.ntu.edu.tw/~cjlin/libsvm/

model; thirdly we compare different ensemble strategies; finally we make a comparison with some related work.

5.2.1 WR vs. GWR

Table 3 presents the results of individual WR feature sets. Four types of WR features, including WR-Bi, WR-Dp, GWR-Bi and GWR-Dp, are examined under two classification models on two datasets. For each of the results, we report the best accuracy under feature selection.

Model	WR Feature	Movie	E-product
SVM	WR-Bi	83.05	63.27
	GWR-Bi	85.55	65.17
	WR-Dp	82.15	65.14
	GWR-Dp	83.40	67.09
NB	WR-Bi	84.60	66.86
	GWR-Bi	85.45	67.50
	WR-Dp	83.90	65.68
	GWR-Dp	83.65	67.41

Table 3: Accuracies (%) of Individual WR Feature Sets

At first, we place the emphasis on the performance of individual GWR and WR. With the SVM model, the performance of GWR features is remarkable compared to traditional WR pairs. Specifically, on the Movie dataset, GWR-Bi outperforms WR-Bi by 2.50%, and GWR-Dp outperforms WR-Dp by 1.35%; on the E-product dataset, the improvements are 1.90% and 1.95%. Under the NB model, on the Movie dataset, GWR-Bi outperforms WR-Bi by 0.85%; on the E-product dataset, GWR-Bi outperforms WR-Bi by 0.64% and GWR-Dp outperforms WR-Dp by 1.73%. One exception is GWR-Dp on the Movie dataset, but the decline is slight (0.25%).

WR Feature	Movie	E-product
WR-Bi	386k	21k
GWR-Bi	152k	16k
WR-Dp	455k	24k
GWR-Dp	151k	16k

Table 4: Dimension of Individual Feature Space

Secondly, we compare the dimensions of different feature space. Table 4 presents the average size of different types of feature spaces on two datasets. On the Movie dataset, the size of GWR feature space has been significantly reduced (386k vs. 152k in Bi; 455k vs. 151k in Dp). On the E-product dataset, since the training set are made up by 10 different domains, data are quite sparse, therefore, the extent of dimension reduction is not as sound as that on Movie dataset, but still considerable (21k vs. 16k in Bi; 24k vs. 16k in Dp).

5.2.2 Joint Features vs. Ensemble Model

The performance of individual feature sets, joint feature set and ensemble model is reported in Table 5. Uni, GWR-Bi and GWR-Dp are used as individual features sets in the ensemble model, and Joint Features denote the union of three individual sets. For feature selection, IG is used in Joint Features, and FIG is used in the ensemble model. The reported results are in terms of the best accuracy under feature selection.

Feature and Model		Movie	E-product
Uni	SVM	85.20	67.77
	NB	84.10	66.18
GWR-Bi	SVM	85.55	65.17
	NB	85.45	67.50
GWR-Dp	SVM	83.40	67.09
	NB	83.65	67.41
Joint Features	SVM	86.10	66.55
	NB	85.20	67.64
Ensemble Model	AvgP	**88.60**	70.14
	MCE	88.55	**70.18**

Table 5: Accuracies (%) of Component Features, Joint Features and Ensemble Model

To begin with, we observe the results of individual feature sets. Although we have demonstrated that GWR features are more effective than WR, it is a pity that they do not show significant superiority (sometimes even worse) compared to unigrams. That is to say, although GWR features encode more generalized word relation information than WR features, the role of unigrams still can not be replaced. This is in accordance with that, WR (GWR) features are used as additional features to assist unigrams in most of the literature.

Secondly, we focus on the performance of two classification models on different feature sets. SVM seems to work better than NB on unigrams (more than 1%); while on GWR-Bi and GWR-Dp feature sets, NB tends to be overall effective. This has confirmed our speculation that WR features perform better under NB than under SVM (since independence between features increases) and strengthened the confidence

of our motivation to ensemble different types of features under distinct classification models.

Finally, we make a comparison of Joint Features and Ensemble model. Observing the results on the Movie dataset, Joint Features exceed individual feature sets, but the improvements are not remarkable (less than 1 percentage compared to the best individual score). While the results of the ensemble model, as we have expected, are fairly good. AvgP and MCE respectively get the scores of 0.886 and 0.8855, robustly higher than that of Joint Features (0.8610 and 0.8520 respectively under SVM and NB).

On the E-product dataset, it is quite surprising that the result of Joint Features is even worse than some of the individual features sets. This also confirms that Joint Features are sometimes not so effective at exploring different types of features. With regard to the ensemble model, AvgP gets an accuracy of 0.7014 and MCE achieves the best score (0.7018), consistently superior to the results of Joint Features.

5.2.3 Different Ensemble Strategies

We also examine the performance of different strategies. In Table 6, three ensemble strategies are compared, where "(Uni & Bi & Dp) @ SVM" denotes ensemble of three kinds of feature sets with the fixed SVM classifier, "Uni @ (NB & SVM)" denotes ensemble of two classifiers on fixed unigram features, and "(Uni & Bi & Dp) @ (NB & SVM)" denotes ensemble of both classifiers and feature sets.

Ensemble Strategy		Movie	E-product
(Uni & Bi & Dp) @ SVM	AveP	86.60	69.50
	MCE	86.60	69.59
Uni @ (NB & SVM)	AveP	87.75	68.95
	MCE	87.80	69.14
(Uni & Bi & Dp) @ (NB & SVM)	AveP	**88.60**	70.14
	MCE	88.55	**70.18**

Table 6: Accuracies (%) of Different Ensemble Strategies.

Seen from Table 5 and 6, the performance of ensemble of either feature sets or classifiers is robustly better than any individual classifier, as well as the joint features on both datasets. With regard to ensemble of both feature sets and classification algorithms, it is the most effective compared to the above two ensemble strategies. This is in accordance with our motivation described in Section 3.1.

5.2.4 Comparison with Related Work

We take the performance of SVM on unigrams as the baseline for comparison. On the Movie dataset, Pang and Lee (2004) and Ng et al. (2006) reported the baseline accuracy of 0.871. But our baseline is 2 percentages lower (0.852). It is mainly due to that: 1) 0.871 was obtained by a 10-fold cross validation, and our result is get by 5-fold cross validation; 2) the result of the tool LibSVM is inferior of SVM^{light} by almost 1-2 percentages, since the penalty parameter in LibSVM is fixed, while in SVM^{light}, the value is automatically adapted; 3) the baseline in Ng et al. (2006) is obtained with length normalization which play a role in performance.

Ng et al. reported the state of art best performance (0.905), which outperforms the baseline (0.871) by 3.4%. Our best result of ensemble model (0.886) gets a comparable improvement (3.40%) compared to our obtained baseline (0.852).

On the E-product dataset, Joshi and Rosé reported the best result (0.679) on joint features of unigrams and their proposed GWR features. This is in accordance with our result of Joint Features (0.6655 by SVM and 0.6764 by NB). The superiority of our ensemble result is quite significant (0.7014 by AvgP and 0.7018 by MCE).

5.3 Results of Feature Selection

In this part, we examine FMI and FIG for GWR feature selection. The performance of MI and IG are also presented for comparison. The results on the Movie and E-product datasets are displayed in Figures 1 and 2 respectively. Due to space limit, we only report the results of GWR-Bi features for Movie and GWR-Dp features for E-product. In each of the figures, the results under NB and SVM are both presented.

At first, we observe the results of feature selection for GWR-Bi features on the Movie dataset. At first glance, IG and FIG have roughly the same performance. IG-based methods are shown to be quite effective in GWR feature reduction. For example under the NB model, top 2.5% (4000) GWR-Bi features ranked by IG and FIG achieve accuracies of 0.849 and 0.842

respectively, even better than the score with all features (0.8415).

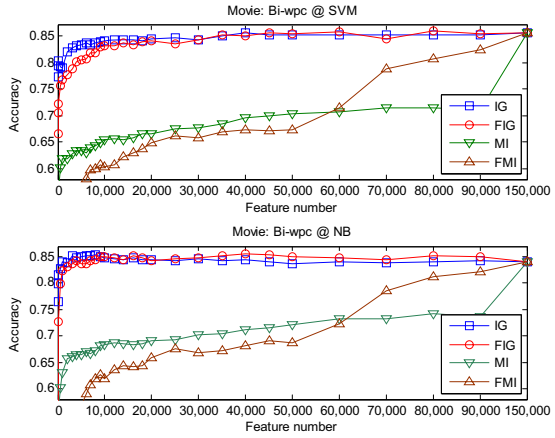

Figure 1: Feature Selection for GWR-Bi Features on the Movie Dataset

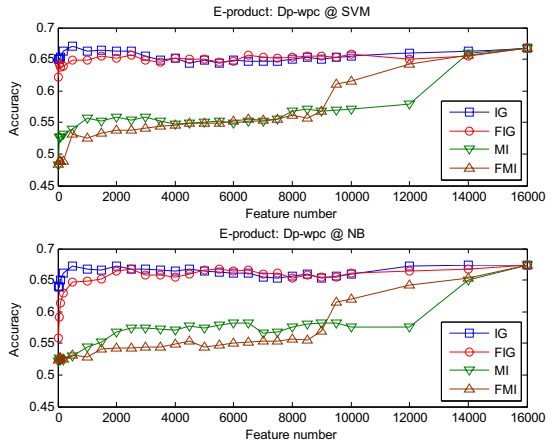

Figure 2: Feature Selection for GWR-Dp features on the E-product dataset

We then observe IG vs. FIG in a finer granularity. When the selected features are few (less than 5%), IG performs significantly better than FIG, while the latter gradually approaches the former when the feature number increases: as it comes to 10-15%, their performance is quite close. From then on, FIG is consistently comparable to IG, even sometimes slightly better.

With regard to MI and FMI, although the performance compared to IG and FIG is rather poor (the reason has been intensively studied by Yang and Pedersen, 1997). Our focus is the ability of FMI for approximating MI. From this point of view, FMI is by contrast effective, especially with more than 1/3 features.

Compared to the Movie dataset, the size of E-product dataset is much smaller, and the data are much sparser. Nevertheless, IG and FIG are still effective. On one hand, top 1.25% (2000) features ranked by IG yield a result better than (or comparable to) that with all features. On the other hand, FIG is still competent to be a good approximation to IG.

All of the above comparisons are made according to accuracies, and we now pay attention to computational efficiency. Taking the Movie dataset for example, IG needs to compute scores of information gain for all $152k$ features, while FIG only needs to compute $42k+5\times5$ scores, saving more than 70% of the computational load; on the E-product dataset, although the data are sparse, the rate of computation reduction is still significant (62.5%).

Note that in the ensemble model, when performing FIG for individual GWR feature set, part of its inherent complexity is already taken care of by having already computed IG on Uni feature set, and we only need to compute the scores for 25 POS pairs. From this perspective, FIG is even more attractive in the ensemble model.

6 Conclusions and Future Work

The focus of this paper is exploring the use of WR features for sentiment classification. We have proposed a GWR feature extraction approach and an ensemble model to efficiently integrate different types of features. Moreover, we have proposed two fast feature selection methods (FMI and FIG) for GWR features.

Individual GWR features outperform traditional WR features significantly, but they still can not totally substitute unigrams. The ensemble model is quite effective at integrating unigrams and different types of WR feature, and the performance is significantly better than joint features.

FIG is proved to be a good solution for selecting GWR features. It is also worthy noting that FIG is a general feature selection method for bigram features, even outside the scope of sentiment classification and text classification.

In the future, we plan to make an in-depth study about why individual WR features are inferior to unigrams, and how to make the joint features more effective. We also plan to extend the use of GWR features to the task of transfer learning, which we think is a promising direction for future work.

An Empirical Study of Translation Rule Extraction with Multiple Parsers

Abstract

Translation rule extraction is an important issue in syntax-based Statistical Machine Translation (SMT). Recent studies show that rule coverage is one of the key factors affecting the success of syntax-based systems. In this paper, we first present a simple and effective method to improve rule coverage by using multiple parsers in translation rule extraction, and then empirically investigate the effectiveness of our method on Chinese-English translation tasks. Experimental results show that extracting translation rules using multiple parsers improves a string-to-tree system by over 0.9 BLEU points on both NIST 2004 and 2005 test corpora.

1 Introduction

Recently various syntax-based models have been extensively investigated in Statistical Machine Translation (SMT), including models between source trees and target strings (Quirk et al., 2005; Liu et al., 2006; Huang et al., 2006), source strings and target trees (Yamada and Knight, 2001; Galley et al., 2006; Shen et al., 2008), or source trees and target trees (Eisner, 2003; Ding and Palmer, 2005; Cowan et al., 2006; Zhang et al., 2008; Liu et al., 2009). In these models, automatic extraction of translation rules is an important issue, in which translation rules are typically extracted using parse trees on source/target-language side or both sides of the bilingual text. Exploiting the syntactic information encoded in translation rules, syntax-based systems have shown to achieve comparable performance with phrase-based systems, even outperform them in some cases (Marcu et al., 2006).

Among all the factors contributing to the success of syntax-based systems, *rule coverage* has been proved to be an important one that affects the translation accuracy of syntax-based systems (DeNeefe et al., 2007; Shen et al., 2008). However, these systems suffer from a problem that translation rules are extracted using only 1-best parse tree generated by a single parser, which generally results in relatively low rule coverage due to the limited scope in rule extraction (Mi and Huang, 2008). To alleviate this problem, a straightforward solution is to enlarge the scope of rule extraction, and obtain translation rules by using a group of diversified parse trees instead of a single parse tree. For example, Mi and Huang (2008) used *k*-best parses and forest to extract translation rules for improving the rule coverage in their forest-based SMT system, and achieved promising results. However, most previous work used the parse trees generated by only one parser, which still suffered somewhat from the relatively low diversity in the outputs of a single parser.

Addressing this issue, we investigate how to extract diversified translation rules using multiple parsers. As different parsers (or parsing models) can provide us with parse trees having relatively large diversity, we believe that it is beneficial to employ multiple different parsers to obtain diversified translation rules and thus enlarge the rule coverage. Motivated by this idea, we propose a simple and effective method to improve rule coverage by using multiple parsers

Coling 2008: Poster Volume, pages 1345–1353,
Beijing, August 2010

in rule extraction. Furthermore, we conduct an empirical study to investigate the effectiveness of our method on Chinese-English translation in a string-to-tree system. Experimental results show that our method improves the baseline system by over 0.9 BLEU points on both NIST 2004 and 2005 test corpora, even achieves a +1 BLEU improvement when working with the *k*-best extraction method. More interestingly, we observe that the MT performance is not very sensitive to the parsing performance of the parsers used in rule extraction. Actually, the MT system does not show different preferences for different parsers.

2 Related Work

In machine translation, some efforts have been made to improve rule coverage and advance the performance of syntax-based systems. For example, Galley et al. (2006) proposed the idea of rule composing which composes two or more rules with shared states to form a larger, composed rule. Their experimental results showed that the rule composing method could significantly improve the translation accuracy of their syntax-based system. Following Galley et al. (2006)'s work, Marcu et al. (2006) proposed SPMT models to improve the coverage of phrasal rules, and demonstrated that the system performance could be further improved by using their proposed models. Wang et al. (2007) described a binarization method that binarized parse trees to improve the rule coverage on non-syntactic mappings. DeNeefe et al. (2007) analyzed the phrasal coverage problem, and compared the phrasal coverage as well as translation accuracy for various rule extraction methods (Galley et al., 2006; Marcu et al., 2006; Wang et al., 2007).

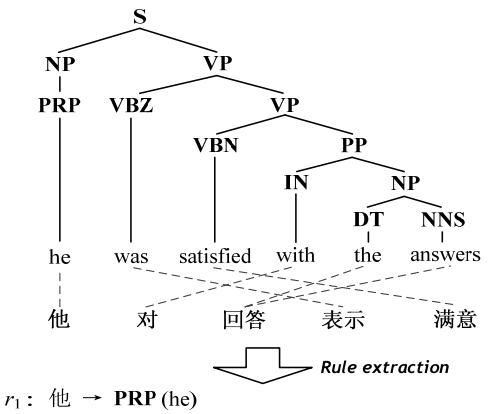
As another research direction, some work is focused on enlarging the scope of rule extraction to improve rule coverage. For example, (Venugopal et al., 2008) and (Mi and Huang, 2008) extracted rules from the *k*-best parses and forest generated by a single parser to alleviate the problem of the limited scope of 1-best parse, and achieved promising results.

Our work differs from previous work in that we are concerned with obtaining diversified translation rules using multiple different parsers (or parsing models) instead of a single parser (or parsing model). It can be regarded as an enhancement of previous studies. As shown in the following parts of this paper, it works very well with the existing techniques, such as rule composing (Galley et al., 2006), SPMT models (Marcu et al., 2006) and rule extraction with *k*-best parses (Venugopal et al., 2008).

3 Translation Rule Extraction

In this work, the issue of translation rule extraction is studied in the string-to-tree model proposed by Galley et al. (2006). We choose this model because it has been shown to be one of the state-of-the-art syntax-based models, and has been adopted in the most successful systems in NIST 2009 MT evaluation.

Typically, (string-to-tree) translation rules are learned from the word-aligned bilingual text whose target-side has been parsed using a syntactic parser. As the basic unit of translation, a translation rule consists of sequence words or variables in the source language, and a syntax tree in the target language having words (terminals) and variables (non-terminals) at leaves. Figure 1 shows the translation rules extracted from a word-aligned sentence pair with a target-side parse tree.



r_1: 他 → **PRP** (he)
r_2: 对 → **IN** (with)
r_3: 回答 → **NP** (**DT**(the) **NNS**(answers))
r_4: 表示 → **VBZ** (was)
r_5: 满意 → **VBN** (satisfied)
r_6: $x_1\,x_2$ → **PP** (x_1:**IN** x_2:**NP**)
r_7: 对 x_1 → **PP** (**IN**(with) x_1:**NP**)
r_8: $x_1\,x_2$ 表示 满意 →
S (x_1:**NP** **VP**(**VBZ**(was) **VP**(**VBN**(satisfied) x_2:**PP**)))

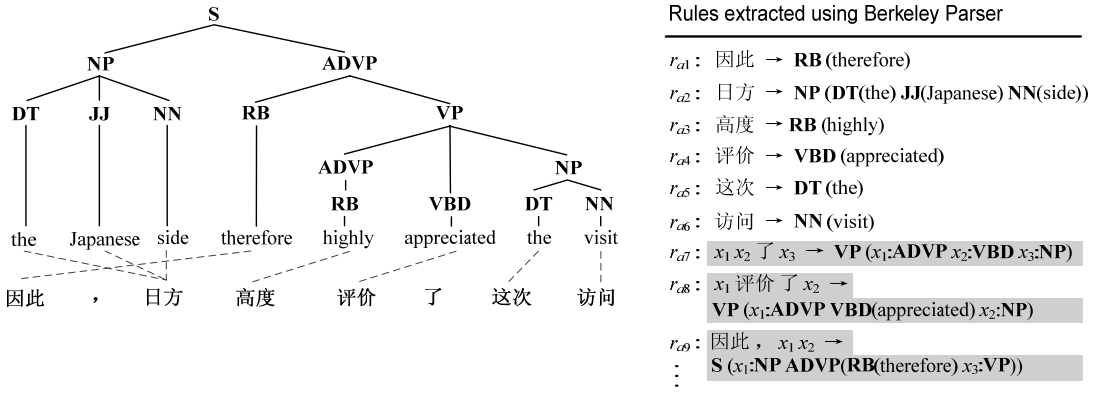
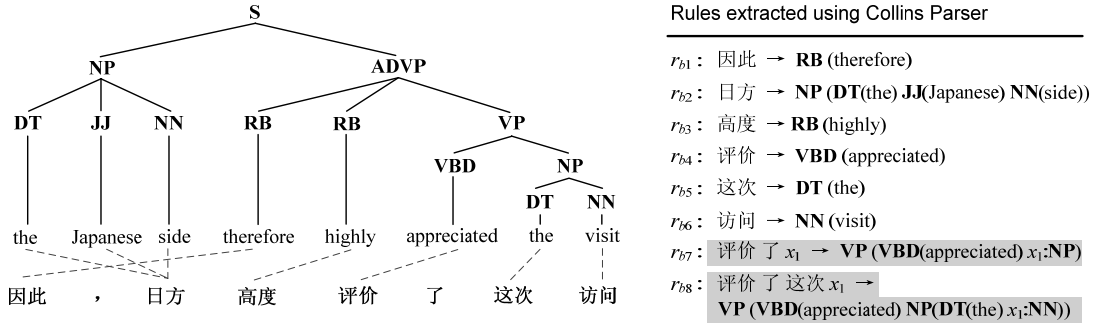
Figure 1: Translation rules extracted from a string-tree pair.



(a) rule extraction using Berkeley Parser



(b) rule extraction using Collins Parser (Model 2)

Figure 2: Rule extraction using two different parsers (Berkeley Parser and Collins Parser). The shaded rectangles denote the translation rules that can be extracted from the parse tree generated by one parser but cannot be extracted from the parse tree generated by the other parser.

To obtain basic translation rules, the (minimal) GHKM extraction method proposed in (Galley et al, 2004) is utilized. The basic idea of GHKM extraction is to compute the set of the minimally-sized translation rules that can explain the mappings between source-language string and target-language tree while respecting the alignment and reordering between the two languages. For example, from the string-tree pair shown at the top of Figure 1, we extract the minimal GHKM translation rules $r_{1\text{-}6}$. In addition to GHKM extraction, the SPMT models (Marcu et al., 2006) are employed to obtain *phrasal rules* that are not covered by GHKM extraction. For example, rule r_8 in Figure 1 is a SPMT rule that is not obtained in GHKM extraction. Finally, the rule composing method (Galley et al., 2006) is used to compose two or more minimal GHKM or SPMT rules having shared states to form larger rules. For example, rule r_7 in Figure 1 is generated by composing rules r_2 and r_6.

4 Differences in Coverage between Rule Extractions with Different Parsers

As described above, translation rule extraction relies on the outputs (parse trees) of parsers. As different parsers generally have large diversity between their outputs, rule extractions with different parsers generally result in very different sets of rules. For example, Figure 2 shows the rule extractions on a word-aligned sentence pair having two target-trees generated by Berkeley Parser and Collins Parser, respectively. It is observed that Figure 2 (a) and (b) cover different sets of rule due to the different target-trees used in rule extraction. Particularly, well-formed rules $r_{a7\text{-}a9}$ are extracted in Figure 2 (a), while they do not appear in Figure 2 (b). Also, rules $r_{b7\text{-}b9}$ in Figure 2 (b) have the similar situation. This observation gives us an intuition that there is a "complementarity" between the rules extracted using different parsers.

We also conduct a quantitative study to investigate the impact of using different parsers (Berkeley Parser and Collins Parser) on rule coverage. Tables 1 shows the statistics of the rules extracted from 370K Chinese-English parallel sentence pairs[1] using the method described in Section 3. In addition to the total number of rules extracted, the numbers of *phrasal rules* and *useful rules* are also reported to indicate the rule coverage of a rule set. Here *phrasal rule* refers to the rule whose source-side and the yield of its target-side contains only one phrase each, with optional surrounding variables. According to (DeNeefe et al., 2007), the number of phrasal rules is a good indicator of the coverage of a rule set. *useful rule* refers to the rule that can be applied when decoding the test sentences[2]. As shown in Table 1, the two resulting rule sets only have about 70% overlaps (Column 4), and the rule coverage increases by about 20% when we combine them together (Column 5). This finding confirms that the rule coverage can be improved by using multiple different parsers in rule extraction.

	# of rules	# of phrasal rules	# of useful rules
Berkeley	3,538,332	2,515,243	549,783
Collins	3,526,166	2,481,195	553,893
Overlap	2,542,380	1,907,521	386,983
Union	4,522,118	3,088,920	716,693

Table 1: Comparison of rule coverage between different rule sets.

5 Translation Rule Extraction with Multiple Parsers

5.1 Rule Extraction Algorithm

Motivated by the above observations, we propose a rule extraction method to improve the rule coverage by using multiple parsers.

Let $\langle f, e, a \rangle$ be a tuple of <source sentence, target sentence, bi-directional word alignments>, and $\{P_1, ..., P_N\}$ be N syntactic parsers in target-language. The following pseudocode formulizes the algorithm for extracting translation rules from $\langle f, e, a \rangle$ using parsers $\{P_1, ..., P_N\}$, where $P_i(e)$ returns the parse tree generated by the i-th parser P_i. Function GENERATERULES() computes the set of rules for $\langle f, t_i, a \rangle$ by using various rule extraction methods, such as the method described in Section 3.

Multi-Parser based Rule Extraction

Input: $\langle f, e, a \rangle$ and $P = \{P_1, ..., P_N\}$
Output: rule set R

Function MULTIPARERXTRACTOIN($\langle f, e, a \rangle$, P)
  for $i = 1$ **to** N **do** ◁ for each parser
    $t_i = P_i(e)$ ◁ target-tree
    R_i = GENERATERULES (f, t_i, a) ◁ rule extraction
    R.append(R_i)
  return R
Function GENERATERULES (f, t_i, a)
  return rules extracted from $\langle f, t_i, a \rangle$

5.2 Learning Rule Probabilities

In multi-parser based rule extraction, more than one parse trees are used, and each of them is associated with a parsing confidence (e.g. generative probability of the tree). Ideally, if the parse trees used in rule extraction can be accurately weighted, the rule probabilities will be better estimated according to the parse weights, for example, the rules extracted from a parse tree having a low weight should be penalized accordingly in the estimation of rule probabilities. Unfortunately, the tree probabilities are generally incomparable between different parsers due to the different parsing models used and ways of implementation. Thus we cannot use the posterior probability of a rule's target-side to estimate the *fractional count* (Mi and Huang, 2008; Liu et al., 2009), which is used in maximum-likelihood estimation of rule probabilities. In this work, to simplify the problem, we assume that all the parsers have the same and maximum degrees of confidence on their outputs. For a rule r extracted from a string-tree pair, the count of r is defined to be:

$$c(r) = \frac{\sum_{i=1}^{N} \tau(r,i)}{N} \quad (1)$$

where $\tau(r,i)$ is 1 if r is extracted by using the i-th parser, otherwise 0.

[1] LDC2005T10, LDC2003E07, LDC2003E14 and LDC2005T06

[2] In this experiment, the test sentences come from NIST 2004 and 2005 MT evaluation sets. It should be noted that due to the pruning in decoding we cannot count the exact number of rules that can be used during decoding. In this work, we use an alternative – the number of rules matched with test sentences – to estimate an upper-bound approximately.

Following Mi and Huang (2008)'s work, three conditional rule probabilities are employed for experimenting with our method.

$$\Pr(r \mid root(r)) = \frac{c(r)}{\sum_{r':root(r')=root(r)} c(r)} \quad (2)$$

$$\Pr(r \mid lhs(r)) = \frac{c(r)}{\sum_{r':lhs(r')=lhs(r)} c(r)} \quad (3)$$

$$\Pr(r \mid rhs(r)) = \frac{c(r)}{\sum_{r':rhs(r')=rhs(r)} c(r)} \quad (4)$$

where $lhs(r)$ and $rhs(r)$ are the source-hand and target-hand sides of r respectively, and $root(r)$ is the root of r's target-tree.

5.3 Parser Indicator Features

For each rule, we define N indicator features (i.e. $\tau(r,i)$) to indicate a rule is extracted by using which parsers, and add them into the translation model. By training the feature weights with Minimum Error Rate Training (MERT), the system can learn preferences for different parsers automatically.

6 Experiments

The experiments are conducted on Chinese-English translation in a state-of-the-art string-to-tree SMT system.

6.1 Experimental Setup

Our bilingual data consists of 370K sentence pairs (9M Chinese words + 10M English words) which have been used in the experiment in Section 4. GIZA++ is employed to perform the bidirectional word alignment between the source and target sentences, and the final word alignment is generated using the inter-sect-diag-grow method. A 5-gram language model is trained on the target-side of the bilingual data and the Xinhua portion of English Gigaword corpus. The development data set comes from NIST MT 2003 evaluation set. To speed up MERT, sentences with more than 20 Chinese words are removed. The test sets are the NIST MT evaluation sets of 2004 and 2005.

Our baseline MT system is built based on the string-to-tree model proposed in (Galley et al., 2006). In this system, both of minimal GHKM (Galley et al., 2004) and SPMT rules (Marcu et al., 2006) are extracted from the bilingual corpus, and the composed rules are generated by composing two or three minimal GHKM and SPMT rules[3]. We use a CKY-style decoder with cube pruning (Huang and Chiang, 2007) and beam search to decode new Chinese sentences. By default, the beam size is set to 30. For integrating n-gram language model into decoding efficiently, rules containing more than two variables or source word sequences are binarized using the synchronous binarization method (Zhang et al., 2006; Xiao et al., 2009).

The system is evaluated in terms of the case-insensitive NIST version BLEU (using the shortest reference length), and statistical significant test is conducted using the re-sampling method proposed by Koehn (2004).

6.2 The Parsers

Four syntactic parsers are chosen for the experiments. They are Stanford Parser[4], Berkeley Parser[5], Collins Parser (Dan Bikel's reimplementation of Collins Model 2)[6] and Charniak Parser[7]. The former two are state-of-the-art non-lexicalized parsers, while the latter two are state-of-the-art lexicalized parsers. All the parsers are trained on sections 02-21 of the Wall Street Journal (WSJ) Treebank, and tuned on section 22. Table 2 summarizes the performance of the parsers.

Parser	Recall	Precision	F1
Stanford	86.29%	87.21%	86.75%
Berkeley	90.18%	90.45%	90.32%
Collins	89.14%	88.85%	88.99%
Charniak	89.99%	90.28%	90.13%

Table 2: Performance of the four parsers on section 23 of the WSJ Treebank.

We parse the target-side of the bilingual data using the four parsers individually. From the 1-best parses generated by these parsers, we obtain four baseline rule sets using the method described in Section 3, as well as the rule sets usi-

[3] Generally a higher baseline can be obtained by combining more (unit) rules. However, we find that using more composed rules does not affect the impact of using multiple parsers. Thus, we choose this setting in order to finish all experiments in time.

Table 5: Evaluation results. + or ++ = significantly better than all the baseline systems (using single parser) at the 95% or 99% confidence level.

	Stanford	Berkeley	Collins	Charniak
Stanford	100%	76.72%	73.32%	74.89%
Berkeley	76.72%	100%	75.69%	76.76%
Collins	73.32%	75.69%	100%	74.84%
Charniak	74.89%	76.76%	74.84%	100%

Table 3: Agreement between different parsers.

ng the multi-parser based rule extraction method. Before conducting primary experiments, we first investigate the differences between the 1-best outputs of the parsers. Table 3 shows the agreement between each pair of parsers. Here the degree of agreement shown in each cell is computed by using one parser's output as a good standard to evaluate the other parser's output in terms of F1 score, and a higher agreement score (i.e. F1 score) means that the 1-best outputs of the two parsers are more similar to each other. We see that the agreement scores between different parsers are always below 80%. This result reflects a large diversity in parse trees generated by different parsers, and thus confirms our observations in Section 4.

We also examine the "complementarity" between the baseline rule sets generated by using different parsers individually. Table 4 shows the results, where the degree of "complementarity" between two rule sets is defined as the percentage of the rules in one rule set that are not covered by the other rule set. It can be regarded as a measure of the disagreement between two rule sets, and a higher number indicates large "complementarity". For example, in Row 2, Column 3 (Table 4), "25.09%" means that 25.09% rules in the first rule set (using Stanford Parser) are not covered by the second rule set (using Berkeley Parser). Table 4 shows that there is always a disagreement of over 25% between different rule sets. These results indicate that using different parsers can lead to a relatively large "complementarity" between the rule sets.

	Stanford	Berkeley	Collins	Charniak
Stanford	0%	25.09%	29.91%	31.43%
Berkeley	27.98%	0%	27.90%	29.68%
Collins	32.84%	28.15%	0%	30.89%
Charniak	35.70%	31.43%	32.37%	0%

Table 4: Disagreement between the rule sets obtained using different parsers individually.

6.3 Evaluation of Translations

We then study the impact of multi-parser based rule extraction on translation accuracy. Table 5 shows the BLEU scores as well as the rule coverage for various rule extraction methods. We see, first of all, that the rule coverage is improved significantly by multi-parser based rule extraction. Compared to the baseline method (i.e. single-parser based rule extraction), the multi-parser based rule extraction achieves over 20% coverage improvements when only two parsers are used, even yields gains of over 50 percentage

points when all the four parsers are used together. Also, BLEU score is improved by multi-parser based rule extraction. When two parsers are employed in rule extraction, there is generally a gain of over 0.4 BLEU points on both MT04 and MT05 test sets. Further improvements are achieved when more parsers are involved. On both test sets, using three parsers in rule extraction generally yields a +0.7 BLEU improvement, and using all the parsers together yields a +0.9 BLEU improvement which is the biggest improvement achieved in this set of experiment. All these results show that multi-parser based rule extraction is an effective way to improve the rule coverage as well as the BLEU score of the syntax-based MT system.

An interesting finding is that there seems no significant differences in BLEU scores between the baseline systems (using single parsers), though the parsing performance of the corresponding parsers is very different from each other. For example, the MT performance corresponding to Berkeley Parser is very similar to that corresponding to Stanford Parser despite a 4-point difference in F1 score between the two parsers. Another example is that Charniak parser performs slightly worse than the other three on MT task, though it achieves the 2nd best parsing performance in all the parsers. This interesting finding shows that the performance of syntax-based MT systems is not very sensitive to the parsing performance of the parsers used in rule extraction.

6.4 Preferences for Parsers

We also investigate the preferences for different parsers in our system. Table 6 shows the weights of the parser indicator features learned by MERT, as well as the number of edges generated by applying the rules corresponding to different parsers during decoding. Both of the metrics are used to evaluate the contributions of the parsers to MT decoding. We see that though Stanford Parser and Berkeley Parser are shown to be relatively more preferred by the decoder, there are actually no significant differences in the degrees of the contributions of different parsers. This result also confirms the fact observed in Table 5 that the MT system does not have special preferences for different parsers.

Indicator	Weight	# of edges (Dev.)	# of edges (MT04)	# of edges (MT05)
Stanford	0.1990	7.7 M	169.2 M	101.7 M
Berkeley	0.1982	7.7 M	166.3 M	100.2 M
Collins	0.1690	6.9 M	149.9 M	93.1 M
Charniak	0.1729	7.1 M	156.5 M	97.2 M

Table 6: Preferences for different parsers.

Though Table 6 provides some information about the contributions of different parsers, it still does not answer how often these rules are really used to generate final (1-best) translation. Table 7 gives an answer to this question. We see that, following the similar trend in Table 5, different parsers have nearly equal contributions in generating final translation.

Indicator	# of rules used in 1-best (Dev.)	# of rules used in 1-best (MT04)	# of rules used in 1-best (MT05)
Stanford	2,410	23,513	14,357
Berkeley	2,455	23,878	14,670
Collins	2,309	22,654	13,815
Charniak	2,269	22,406	13,731

Table 7: Numbers of rules used in generating final (1-best) translation.

6.5 Rule Extraction with *k*-best Parses

We also conduct experiments to compare the effectiveness of multi-parser based rule extraction and rule extraction with *k*-best parses generated by a single parser. As Berkeley parser is one of the best-performing parsers in previous experiments, we employ it to generate *k*-best parses in this set of experiment. As shown in Figure 3, both of the methods improve the BLEU scores by enlarging the set of parse trees used in rule extraction. Compared to *k*-best extraction, multi-parser extraction shows consiste-

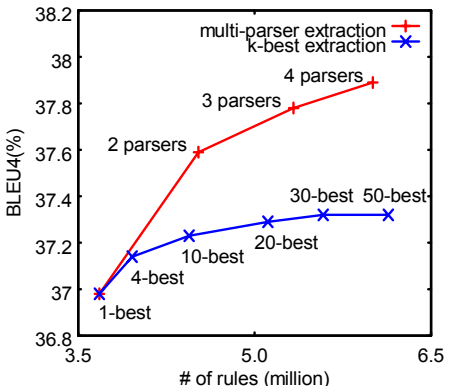

Figure 3: Multi-parser based rule extraction vs. rule extraction with *k*-best parses (MT05).

ntly better BLEU scores. Using 4 different parsers, it achieves an improvement of 0.6 BLEU points over *k*-best extraction where even 50-best parses are used.

Finally, we extend multi-parser based rule extraction to extracting rules from the *k*-best parses generated by multiple parsers. Figure 4 shows the results on "S + B + Co + Ch" system. We see that multi-parser based rule extraction can benefit from *k*-best parses, and yields a modest (+0.2 BLEU points) improvement when extracting from 10-best parses. However, since *k*-best extraction generally results in much slower extraction speed, it might not be a good choice to use *k*-best parses to improve our method in practice.

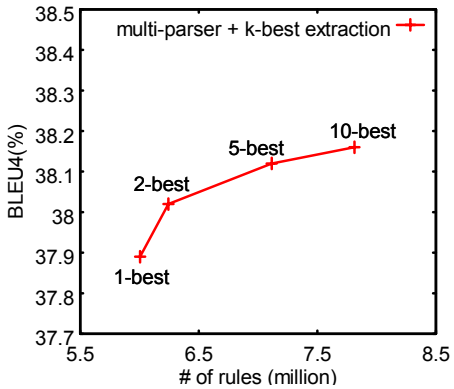

Figure 4: Multi-parser based rule extraction & rule extraction with *k*-best parses (MT05).

7 Discussion and Future Work

In this work, all the parsers are trained using the same treebank. To obtain diversified parse trees for multi-parser based rule extraction, an alternative way is to learn parsers on treebanks annotated by different organizations (e.g. Penn Treebank and ICE-GB corpus). Since different treebanks can provide us with more diversity in parsing, we believe that our system can benefit a lot from the parsers that are learned on multiple different treebanks individually. But here is a problem that due to the different annotation standards used, there is generally an incompatibility between treebanks annotated by different organizations. It will result in that we cannot straightforwardly mix the resulting rule sets (or *heterogeneous grammars* for short) for probability estimation as well as the use for decoding. To solve this problem, a simple solution might be that we transform the incompatible rules into a unified form. Alternatively, we can use *heterogeneous decoding* (or *parsing*) techniques (Zhu et al., 2010) to make use of heterogeneous grammars in the stage of decoding. Both topics are very interesting and worth studying in our future work.

Besides *k*-best extraction, our method can also be applied to other rule extraction schemes, such as forest-based rule extraction. As (Mi and Huang, 2008) has shown that forest-based extraction is more effective than *k*-best extraction in improving translation accuracy, it is expected to achieve further improvements by using multi-parser based rule extraction and forest-based rule extraction together.

8 Conclusions

In this paper, we present a simple and effective method to improve rule coverage by using multiple parsers in translation rule extraction. Experimental results show that

- Using multiple parsers in rule extraction achieves large improvements of rule coverage over the baseline method where only a single parser is used, as well as a +0.9 BLEU improvement on both NIST 2004 and 2005 test corpora.
- The MT system can be further improved by using multiple parsers and *k*-best parses together. However, with the consideration of extraction speed, it might not be a good choice to use *k*-best parses to improve multi-parser based rule extraction in practice.
- The MT performance is not influenced by the parsing performance of the parsers used in rule extraction very much. Actually, the MT system does not show different preferences for different parsers.

Boosting Relation Extraction with Limited Closed-World Knowledge

Abstract

This paper presents a new approach to improving relation extraction based on minimally supervised learning. By adding some limited closed-world knowledge for confidence estimation of learned rules to the usual seed data, the precision of relation extraction can be considerably improved. Starting from an existing baseline system we demonstrate that utilizing limited closed world knowledge can effectively eliminate "dangerous" or plainly wrong rules during the bootstrapping process. The new method improves the reliability of the confidence estimation and the precision value of the extracted instances. Although recall suffers to a certain degree depending on the domain and the selected settings, the overall performance measured by F-score considerably improves. Finally we validate the adaptability of the best ranking method to a new domain and obtain promising results.

1 Introduction

Minimally supervised machine-learning approaches to learning rules or patterns for relation extraction (RE) in a bootstrapping framework are regarded as very effective methods for building information extraction (IE) systems and for adapting them to new domains (e. g., (Riloff, 1996), (Brin, 1998), (Agichtein and Gravano, 2000), (Yangarber, 2001), (Sudo et al., 2003), (Jones, 2005), (Greenwood and Stevenson, 2006), (Agichtein, 2006), (Xu et al., 2007), (Xu, 2007)). On the one hand, these approaches show very promising results by utilizing minimal domain knowledge as seeds. On the other hand, they are all confronted with the same problem, i.e., the acquisition of wrong rules because of missing knowledge for their validation during bootstrapping. Various approaches to confidence estimation of learned rules have been proposed as well as methods for identifying "so-called" negative rules for increasing the precision value (e.g., (Brin, 1998), (Agichtein and Gravano, 2000), (Agichtein, 2006), (Yangarber, 2003), (Pantel and Pennacchiotti, 2006), (Etzioni et al., 2005), (Xu et al., 2007) and (Uszkoreit et al., 2009)).

In this paper, we present a new approach to estimating or ranking the confidence value of learned rules by utilizing limited closed-world knowledge. As many predecessors, our ranking method is built on the "Duality Principle" (e. g., (Brin, 1998), (Yangarber, 2001) and (Agichtein, 2006)). We extend the validation method by an evaluation of extracted instances against some limited closed-world knowledge, while also allowing cases in which knowledge for informed decisions is not available. In comparison to previous approaches to negative examples or negative rules such as (Yangarber, 2003), (Etzioni et al., 2005) and (Uszkoreit et al., 2009), we implicitly generate many negative examples by utilizing the positive examples in the closed-world portion of our knowledge. Rules extracting wrong instances are lowered in rank.

In (Xu et al., 2007) and (Xu, 2007), we develop a generic framework for learning rules for relations of varying complexity, called ***DARE*** (Domain Adaptive Relation Extraction). Furthermore, there is a systematic error analysis of the base-

Coling 2008: Poster Volume, pages 1354–1362,
Beijing, August 2010

line system conducted in (Xu, 2007). We employ our system both as a baseline reference and as a platform for implementing and evaluating our new method.

Our first experiments conducted on the same data used in (Xu et al., 2007) demonstrate: 1) limited closed-world knowledge is very useful and effective for improving rule confidence estimation and precision of relation extraction; 2) integration of soft constraints boosts the confidence value of the good and relevant rules, but without strongly decreasing the recall value. In addition, we validate our method on a new corpus of newspaper texts about celebrities and obtain promising results.

The remainder of the paper is organized as follows: Section 2 explains the relevant related work. Sections 3 and 4 describe ***DARE*** and our extensions. Section 5 reports the experiments with two ranking strategies and their results. Section 6 gives a summary and discusses future work.

2 Related Work

In the existing minimally supervised rule learning systems for relation extraction based on bootstrapping, they already employ various approaches to confidence estimation of learned rules and different methods for identification of so-called negative rules. For estimation of confidence/relevance values of rules, most of the approaches follow the so-called "Duality Principle" as mentioned by Brin (1998) and Yangarber (2001), namely, the confidence value of learned rules is dependent on the confidence value of their origins, which can be documents or relation instances. For example, Riloff (1996), Yangarber (2001), Sudo et al. (2003) and Greenwood and Stevenson (2006) use domain relevance of documents in which patterns are discovered as well as the distribution frequency of these patterns in those relevant documents as an indication of good patterns. Their methods are aimed at detecting all patterns for a specific domain, but those patterns cannot be applied directly to a specific relation. In contrast, systems presented by Brin (1998), Agichtein and Gravano (2000), Agichtein (2006), Pantel and Pennacchiotti (2006) as well as our baseline system (Xu et al., 2007) are designed to learn rules for a specific relation. They start with some relation instances as their so-called "semantic seeds" and detect rules from texts matching with these instances. The new rules are applied to new texts for extracting new instances. These new instances in turn are utilized as new seeds. All these systems calculate their rule confidence based on the confidence values of the instances from which they stem. In addition to the confidence value of the seed instances, most of them also consider frequency information and include some heuristics for extra validation. For example, Agichtein (2006) intellectually defines certain constraints for evaluating the truth value of extracted instances. But it is not clear whether this strategy can be adapted to new domains and other relations. In (Xu et al., 2007) we make use of domain relevance values of terms occurring in rules. This method is not applicable to general relations.

Parallel to confidence estimation strategies, the learning of negative rules is useful for identifying wrong rules straightforwardly. Yangarber (2003) and Etzioni et al. (2005) utilize the so-called *Counter-Training* for detecting negative rules for a specific domain or a specific class by learning from multiple domains or classes at the same time. Examples of one certain domain or class are regarded as negative examples for the other ones. Bunescu and Mooney (2007) follow a classification-based approach to RE. They use positive and negative sentences of a target relation for a SVM classifier. Uszkoreit et al. (2009) exploit negative examples as seeds for learning further negative instances and negative rules. The disadvantage of the above four approaches is that the selected negative domains or classes or negative instances cover only a subset of the negative domains/classes/relations of the target domain/class/relation.

3 *DARE* Baseline System

Our baseline system ***DARE*** is a minimally supervised learning system for relation extraction, initialized by so-called "semantic seeds", i.e., examples of the target relations, labelled with their semantic roles. The system supports domain adaptation through a compositional rule representation and a bottom-up rule discovery strategy. In this

way, ***DARE*** can handle target relations of varying arity. The following example is a relation instance of the target relation from (Xu, 2007) concerning Nobel Prize awards: *<Mohamed ElBaradei, Nobel, Peace, 2005>*. The target relation contains four arguments: WINNER, PRIZE_NAME, PRIZE_AREA and YEAR. This example refers to an event mentioned in the sentence in example (1).

(1) *Mohamed ElBaradei, won the 2005 Nobel Prize for Peace on Friday because of ....*

Figure 1 is a simplified dependency tree of example (1). ***DARE*** utilizes a bottom-up rule discovery strategy to extract rules from such dependency trees. All sentences are processed with named entity recognition and dependency parsing.

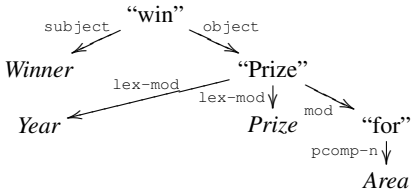

Figure 1: Dependency tree for example (1)

From the tree in Figure 1, ***DARE*** learns three rules. The first rule is dominated by the preposition "for", extracting the argument PRIZE_AREA (*Area*). The second rule is dominated by the noun "Prize", extracting the arguments YEAR (*Year*) and PRIZE_NAME (*Prize*), and calling the first rule for the argument PRIZE_AREA (*Area*). The rule "winner_prize_area_year_1" from Figure 2 extracts all four arguments from the verb phrase dominated by the verb "win" and calls the second rule to handle the arguments embedded in the linguistic argument "object".

Rule name :: winner_prize_area_year_1
Rule body ::

$$\begin{bmatrix} \text{head} & \begin{bmatrix} \text{pos} & \text{verb} \\ \text{mode} & \text{active} \\ \text{lex-form} & \text{"win"} \end{bmatrix} \\ \text{daughters} & < \left[\text{subject} \quad \left[\text{head} \quad \boxed{1}\textit{Winner}\right]\right], \\ & \left[\text{object} \quad \begin{bmatrix} \text{rule} & \text{year\_prize\_area\_1} :: \\ & < \boxed{4}\textit{Year}, \boxed{2}\textit{Prize}, \\ & \boxed{3}\textit{Area} > \end{bmatrix}\right] > \end{bmatrix}$$

Output :: $< \boxed{1}\textit{Winner}, \boxed{2}\textit{Prize}, \boxed{3}\textit{Area}, \boxed{4}\textit{Year} >$

Figure 2: ***DARE*** extraction rule.

We conduct a systematic error analysis based on our experiments with the Nobel Prize award data (Xu, 2007). The learned rules are divided into four groups: *good*, *useless*, *dangerous* and *bad*. The good rules are rules that only extract correct instances, while bad ones exclusively produce wrong instances. Useless rules are those that do not detect any new instances. Dangerous rules are dangerous because they extract both correct and wrong instances. Most good rules are rules with high specificity, namely, extracting all or most arguments of the target relation. The 14.7% extraction errors are from bad rules and dangerous rules. Other errors are caused by wrong reported content, negative modality, parsing and named entity recognition errors.

4 Our Approach: Boosting Relation Extraction

4.1 Closed-World Knowledge: Modeling and Construction

The error analysis of ***DARE*** confirms that the identification of bad rules or dangerous rules is important for the precision of an extraction system. Using closed-world knowledge with large numbers of implicit negative instances opens a possibility to detect such rules directly. In our work, closed-world knowledge for a target relation is the total set of positive relation instances for entire relations or for some selected subsets of individuals. For most real world applications, closed-world knowledge can only be obtained for relatively small subsets of individuals participating in the relevant relations. We store the closed-world knowledge in a relational database, which we dub "closed-world knowledge database" (abbr. ***cwDB***). Thus, a ***cwDB*** for a target relation should fill the following condition:

> A ***cwDB*** must contain all correct relation instances ($insts$) for an instantiation value (***argValue***) of a selected relation argument ***cwArg*** in the target relation.

Given $\mathbf{R}$ (the total set of relation instances of a target relation), a ***cwDB*** is defined as follows:

$$\textbf{\textit{cwDB}}=\{inst \in \mathbf{R} : \textbf{\textit{cwArg}}(inst) = \textbf{\textit{argValue}}\}.$$

An example of a ***cwDB*** is the set of all prize winners of a specific prize area such as *Peace*, where PRIZE_AREA is the selected ***cwArg*** and ***argValue*** is *Peace*. Note that the merger of two ***cwDB***s, for example with PRIZE_AREAS *Peace* and *Literature*, is again a ***cwDB*** (with two ***argValue***s in this case).

4.2 Modified Learning Algorithm

In Algorithm 1, we present the modification of the ***DARE*** algorithm (Xu, 2007). The basic idea of ***DARE*** is that it takes some initial seeds as input and learns relation extraction rules from sentences in the textual corpus matching the seeds. Given the learned rules, it extracts new instances from the texts. The modified algorithm adds the **validate** step to evaluate the new instances against the closed-world knowledge ***cwDB***. Based on the evaluation result, both new instances and learned rules are ranked with a confidence value.

INPUT: *initial seeds*
1 $i \leftarrow 0$ (iteration of bootstrapping)
2 $seeds \leftarrow initial\ seeds$
3 $all\ instances \leftarrow \{\}$
4 **while** $(seeds \neq \{\})$
5 $rules_i \leftarrow$ **getRules**$(seeds)$
6 $instances_i \leftarrow$ **getInstances**$(rules_i)$
7 $new\ instances_i \leftarrow instances_i - all\ instances$
8 **validate**$(new\ instances_i,$ ***cwDB***$)$
9 **rank**$(new\ instances_i)$
10 **rank**$(rules_i)$
11 $seeds \leftarrow new\ instances_i$
12 $all\ instances \leftarrow all\ instances + new\ instances_i$
13 $i \leftarrow i + 1$
OUTPUT: *all instances*

Algorithm 1: Extended ***DARE***

4.3 Validation against *cwDB*

Given a ***cwDB*** of a target relation and its ***argValue*** of its selected argument ***cwArg***, the validation of an extracted instance $(inst)$ against the ***cwDB*** is defined as follows.

$$\begin{aligned} inst\ correct &\Leftrightarrow inst \in \textbf{\textit{cwDB}} \\ inst\ wrong &\Leftrightarrow inst \notin \textbf{\textit{cwDB}} \wedge \\ &\quad \textbf{\textit{cwArg}}(inst) = \textbf{\textit{argValue}} \\ inst\ unknown &\Leftrightarrow (inst \notin \textbf{\textit{cwDB}} \wedge \\ &\quad \textbf{\textit{cwArg}}(inst) \neq \textbf{\textit{argValue}}) \\ &\vee (inst \notin \textbf{\textit{cwDB}} \wedge \\ &\quad \textbf{\textit{cwArg}}(inst) \text{ is } unspecified) \end{aligned} \quad (1)$$

4.4 Rule Confidence Ranking with *cwDB*

We develop two rule-ranking strategies for confidence estimation, in order to investigate the best way of integrating the closed-world knowledge: (a) **exclusive ranking**: This ranking strategy excludes every rule which extracts wrong instances after their validation against the closed-world knowledge; (b) **soft ranking**: This ranking strategy is built on top of the duality principle and takes specificity and the depth of learning into account.

Exclusive Ranking The exclusive ranking method is a very naive ranking method which estimates the confidence value of a learned rule (e.g., $rule$) depending on the truth value of its extracted instances (**getInstances**$(rule)$) against a ***cwDB***. Any rule with one *wrong* extraction is regarded as a bad rule in this method. This method works effectively in a special scenario where the total list of the instances of the target relation is available as the ***cwDB***.

$$\textbf{confidence}(rule) = \begin{cases} 1 & \text{if } \textbf{getInstances}(rule) \subseteq \textbf{\textit{cwDB}}, \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

Soft Ranking The soft ranking method works in the spirit of the "Duality Principle", the confidence value of rules is dependent on the truth value of their extracted instances and on the seed instances from which they stem. The confidence value of the extracted instances is estimated based on their validation against the ***cwDB*** or the confidence value of their ancestor seed instances from which their extraction rules stem. Furthermore, the *specificity* of the instances (percentage of the filled arguments) and the *learning depth* (iteration step of bootstrapping) are parameters too. The definition of instance scoring, namely, **score**$(inst)$, is given as follows:

$$\textbf{score}(inst) = \begin{cases} \gamma > 0 & \text{if } \textbf{validate}(inst, \textbf{\textit{cwDB}}) = correct, \\ 0 & \text{if } \textbf{validate}(inst, \textbf{\textit{cwDB}}) = wrong, \\ UN_{inst} & \text{if } \textbf{validate}(inst, \textbf{\textit{cwDB}}) = unknown. \end{cases} \quad (3)$$

As defined above, if a new instance is confirmed as correct by the ***cwDB***, it will obtain a positive value. In our experiment, we set γ=10 in order to boost the precision. In the case of *unknown* about its truth value, the confidence value of a new instance $(inst)$ is dependent on the confidence values of the seed instances (ancestor seeds) from which its mother rules (R_{inst}) stem. Below, the scoring of the *unknown* case, namely, UN_{inst}, is defined, where R_{inst} are rules that extract the new instance $inst$, while I_{rule} are instances from which a $rule$ in R_{inst} is learned and α is the specificity value of $inst$ while β is utilized to express the noisy potential of each further iteration during bootstrapping.

$$UN_{inst} = \frac{\sum_{rule \in R_{inst}} \left(\frac{\sum_{j \in I_{rule}} \textbf{score}(j)}{|I_{rule}|} \times \beta^{i_{rule}} \right)}{|R_{inst}|} \times \alpha$$

where
$R_{inst} = \textbf{getMotherRulesOf}(inst)$,
$I_{rule} = \textbf{getMotherInstancesOf}(rule)$,
$\alpha = specificity$,
$\beta = 0.8$,
$i_{rule} = i$-th iteration where $rule$ occurs (4)

Given the scoring of instance $inst$, the confidence estimation of a rule is the average score of all $inst$s extracted by this rule:

$$\textbf{confidence}(rule) = \frac{\sum_{inst \in \mathbb{I}} \textbf{score}(inst)}{|\mathbb{I}|}$$

where $\mathbb{I} = \textbf{getInstances}(rule)$ (5)

5 Experiments

5.1 Corpora and Closed-World Knowledge

We conduct our experiments with two different domains. We start with the Nobel Prize award domain reported in (Xu, 2007) and apply our method to the same corpus, a collection from various online newspapers. The target relation is the one with the four arguments as mentioned in Section 3. In this way, we can compare our results with those reported in (Xu, 2007). Furthermore, all Nobel Prize winners can be found from `http://nobelprize.org`, so it is easy to construct a ***cwDB*** for Nobel Prize winners. We take the PRIZE_AREA as our selected argument for closing sub-relations and construct various ***cwDB***s with the instantiation of this argument (e.g., all winners of Nobel *Peace* Prize). The second domain is about celebrities. Our text corpus is collected from tabloid newspaper texts, containing 6850 articles from the years 2001 and 2002. The target relation is the marriage relationship between two persons. We construct a ***cwDB*** of 289 persons in which we have listed all their (ex-)spouses as well as the time span of the marriage relation.

Table 1 summarizes the size of the corpus data of the two domains.

Domain	Space	#Doc.
Nobel Prize	18,4 MB	3328
Celebrity Marr.	16,6 MB	6850

Table 1: Corpus data.

5.2 Nobel Prize Domain

We apply the extended ***DARE*** system to the Nobel Prize corpus at first and conduct two rule ranking strategies with different sizes of the ***cwDB***. We conduct all our experiments with the seed *<Guenter Grass, Nobel, Literature, 1999>*. The ***DARE***-Baseline performance is shown in Table 2.

	Precision	Absolute Recall
Baseline	77.98%	89.01%

Table 2: ***DARE***-Baseline Performance

Exclusive Ranking

Given the complete list of Nobel Laureates, we can apply the exclusive ranking strategy to this domain. Our ***cwDB*** is the total list of Nobel Prize winners. The wrong instances will not be used as seed for the next iteration. Rules that extracted at least one wrong instance are marked as *bad*, the other rules as *good*. We utilize only the good rules for relation extraction.

Prec.	Rel. Recall	Rel. F-Measure
100.00%	82.88%	90.64%

Table 3: Performance of Exclusive Ranking in Nobel Prize award domain.

In comparison to the ***DARE*** baseline system, given the same seed setup, this experiment results in a precision boost from 77.98% to 100% (see Table 3). This is not surprising since the ***cwDB*** covers all relation instances for the target relation. Nevertheless, this experiment shows that the closed-world knowledge approach is effective to exclude bad rules. However, the recall decreases and is only 82.88% of the one of the baseline system. As we explain above, not all rules extracting wrong instances are bad rules because wrong extractions can also be caused by other error sources such as named entity recognition. Therefore, even good rules can be excluded because of other error sources. The exclusive ranking strategy is useful for application scenarios where people want to learn rules for achieving 100% precision performance and do not expect high recall. It is especially effective when a big ***cwDB*** is available.

Soft Ranking

This ranking strategy does not exclude any rules and assigns a score to each rule based on

the definition in Section 4.4. Rules which extract correct instances, more specific relation instances and stem from high-scored seed instances obtain a better value than others. In our approach, the *specificity* is dependent on the number of the arguments in the extracted instances. For this domain, the most specific instances contain all four arguments. In the following, we conduct two experiments with two different sizes of the ***cwDB***: 1) with the total list of winners (*complete* ***cwDB***) and 2) with only winners in one PRIZE_AREA (*limited* ***cwDB***).

1) Complete closed-world database Figure 3 displays the correlation between the score of rules and their extraction precision performance. Each point stands for a set of rules with the same score and extraction precision. In this setup, the higher the score, the higher the precision. Given the scored rules, Figure 4 depicts precision, recall and F-Measure for different score thresholds. For a given threshold j we take all $rule$s with **score**$(rule) \geq j$ and use the instances they extract. The recall value here is the relative recall w. r. t. to the ***DARE*** baseline performance: i. e. the number of correct extracted instances divided by the number of correct instances extracted by the ***DARE*** baseline system. The F-Measure value is calculated by using the relative recall values, we therefore refer to it as the *relative* F-Measure. If the system takes all rules with score ≥ 7, the system achieves the best relative F-Measure.

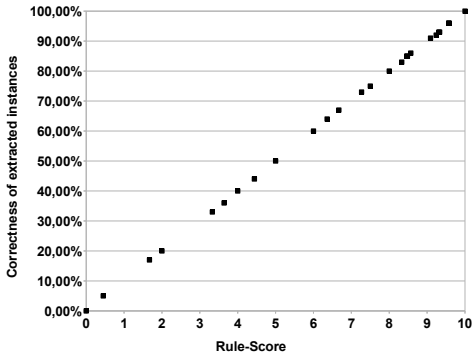

Figure 3: Rule scores vs. precisions with the complete closed-world database.

2) Limited closed-world database This experiment investigates the system performance in cases in which only a limited ***cwDB*** is available. This is the typical situation for most real world RE applications. Therefore, this experiment is much more important than the previous one. We construct a smaller database containing only *Peace* Nobel Prize winners, which is about 1/8 of the previous complete ***cwDB***.

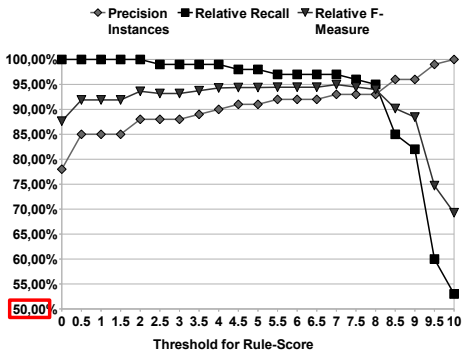

Figure 4: Performance with the complete closed-world database.

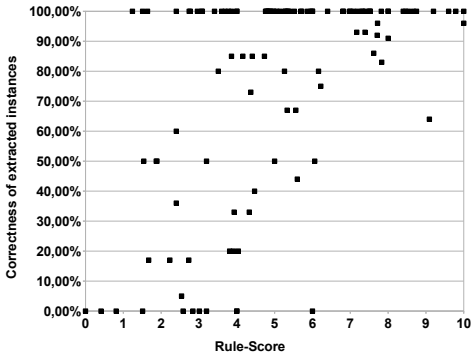

Figure 5: Rule score vs. precision with the limited closed-world database

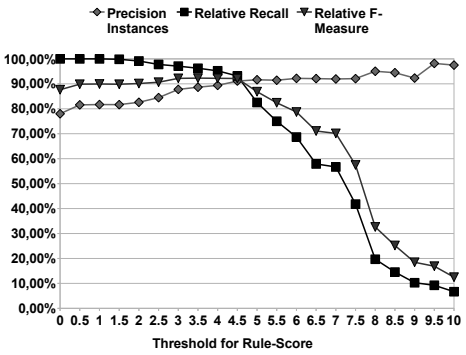

Figure 6: Performance with the limited closed-world database

Figure 5 shows the correlation between the score of the rules and their extraction precision. Although the development curve here is not as smooth as depicted in Figure 3, the higher scored rules have better precision values than most of the lower scored rules. However, we can observe that some very good rules are scored low, located in

Thresh.	Good	Dangerous	Bad
Baseline	58.94%	26.49%	14.57%
1	64.96%	29.20%	5.84%
2	66.67%	27.91%	5.43%
3	69.23%	26.50%	4.27%
4	**73.27%**	**23.76%**	**2.97%**
5	76.00%	22.67%	1.33%
6	77.59%	20.69%	1.72%
7	77.50%	22.50%	0.00%
8	87.50%	12.50%	0.00%
9	85.71%	14.29%	0.00%
10	90.00%	10.00%	0.00%

Table 4: Quality analysis of rules with the limited closed-world database

the left upper corner. The reason is that many of their extracted instances are *unknown*, even if their extracted instances are mostly correct.

As shown in Figure 6, even with the limited ***cwDB***, the precision values are comparable with the complete ***cwDB*** (see Figure 4). However, the recall value drops much earlier than with the complete ***cwDB***. With a threshold of score 4, the system achieves the best modified F-Measure 92,21% with an improvement of precision of about 11 percentage points compared to the ***DARE*** baseline system (89.39% vs. 77.98%). These results show that even with a limited ***cwDB*** this ranking system can help to improve the precision without loosing too much recall.

We take a closer look on the useful (actively extracting) rules and their extraction performance, using the same rule classification as (Xu, 2007). As shown in Table 4, more than one fourth of the extraction rules created by the baseline system are dangerous ones and almost 15% are plainly wrong. Applying the rule scoring with the limited ***cwDB*** increases the fraction of good rules to almost three quarters and nearly eliminates all bad rules at threshold 4. By choosing higher thresholds, surviving good rules raises to 90%. The total remaining set of rules then only consists of rules that at least partially extract correct instances.

5.3 Celebrity Domain

As presented above, the soft ranking method delivers very promising result. In order to validate this ranking method, we choose an additional domain and decide to learn marriage relations among celebrities, where the target relation consists of the following arguments: [NAME_OF_SPOUSE, NAME_OF_SPOUSE, YEAR].

The value of the marriage year is valid when the year is within the marriage time interval. The motivation of selecting this target relation is the large number of possible relations between two persons leading to dangerous or even bad rules. For example, the rule in Figure 7 is a very dangerous rule because "meeting" events of two married celebrities are often reported. A good confidence estimation method is very useful for boosting the good rules like the one in Figure 8. From our text corpus we extract 37.000 sentences that mention at least two persons. The ***cwDB*** consists of sample relation instances, in which one NAME_OF_SPOUSE is instantiated, i. e. we manually construct a database which contains all (ex-) spouses of 289 celebrities.

```
head([SPOUSE<ne_person>]),
mod({head(("meet", VB)),
    subj({head([SPOUSE<ne_person>])})})
```

Figure 7: A dangerous extraction rule example

```
head(("marry", VB)),
aux({head(("be", VB))}),
dep({head([SPOUSE<ne_person>]),
       dep({head([DATE<point>])})}),
nsubj({head([SPOUSE<ne_person>])})
```

Figure 8: Example of a positive rule

Since a gold standard of mentions for this corpus is not available, we manually validate 100 random samples from each threshold group. This evaluation gives us an opportunity to estimate the effect of a ***cwDB*** in this domain. Table 5 presents the performance of the rules with different thresholds. The precision value of the baseline system is very low. Threshold 3 slightly improves the precision of the ***DARE*** baseline without damaging recall too much. Step 4 excludes dangerous rules such as the one in Figure 7 which drastically boosts the precision. Unfortunately, the exclusion of such general rules leads to the loss of many correct relation instances too, therefore, the immense drop of recall from threshold 3 to 4 as well as from threshold 4 to 5. Positive extraction rules such as Figure 8 are quite highly scored. Because of the large number of rules and instances, we start the quality analysis of rules with score 3. As the table indicates, the use of the rule scoring in this domain clearly improves the quality of the created extraction rules. The error analysis shows that the major error resource for this domain is wrong coreference resolution or identity resolution. For ex-

Thresh.	# Instances	Prec.	Rel. Rec.	Rel. F-Meas.	# Rules	Good	Dangerous	Bad

Table 5: Soft ranking for the celebrity marriage domain with a limited ***cwDB***.

ample, the inability to distinguish *Prince Charles* (former husband of British princess Diana) from *Charles Spencer* (her brother) is the reason that ***DARE*** crosses the border between the marriage and the sibling relation. In comparison to the Nobel Prize award event, the marriage relation between persons is often used as additional information to a person which is involved in a reported event. Therefore, anaphoric references occur more often in their mentionings, as the example relation in (3).

(3) *"My kids, I really don't like them to watch that much television," said Cruise, 40, who adopted Isabella and Connor while he was married to second wife Nicole Kidman.*

6 Summary

We propose a new way in which prior knowledge about domains can be efficiently used as additional criteria for confidence estimation of learned new rules or new instances in a minimally supervised machine learning framework. By introducing rule scoring on the basis of available domain knowledge (the cwDB), rules can be evaluated during the bootstrapping process with respect to their extraction precision. The results are rather promising. The rule score threshold is an easy way for users of an extraction system to adjust the precision-recall-trade-off to their own needs. The rule estimation method is also general enough to extend to integration of common sense knowledge. Although the relation instances in the closed-world knowledge database can also be used as seed in the beginning, the core idea of our research work is to develop a general confidence estimation strategy for discovered new information. As discussed in (Xu, 2007) and (Uszkoreit et al., 2009), the size of seed is not always relevant for the learning and extraction performance, in particular if the data corpus exhibits the small world property. Using all instances in the cwDB as seed, our experiments with the baseline system yield worse precision performance than the modified ***DARE*** algorithm with only one seed instance.

This approach is quite general and easily adaptable to many domains; the only prerequisite is the existence of a database with relation instances from the target domain with a fulfilled closed-world property on some relational argument. A database of this kind should be easily obtainable for many domains, e. g. by exploiting structured and semi-structured information sources in the Internet, such as *YAGO* (Suchanek et al. (2007)) and *DBpedia* (Bizer et al. (2009)). Furthermore, in some areas, such as Business Intelligence, there is nearly complete knowledge already present for past years, while the task is to extract information only from recent news articles. Constructing closed-worlds out of the present knowledge to improve the learning of new information is therefore a straightforward approach. Even the manual collection of suitable data might be a reasonable choice since appropriate closed worlds could be rather small if ***cwDB***is chosen properly.

Applying Syntactic, Semantic and Discourse Constraints in Chinese Temporal Annotation

yzhou@brandeis.edu

Abstract

We describe a Chinese temporal annotation experiment that produced a sizable data set for the TempEval-2 evaluation campaign. We show that while we have achieved high inter-annotator agreement for simpler tasks such as identification of events and time expressions, temporal relation annotation proves to be much more challenging. We show that in order to improve the inter-annotator agreement it is important to strategically select the annotation targets, and the selection of annotation targets should be subject to syntactic, semantic and discourse constraints.

1 Introduction

Event-based temporal inference is a fundamental natural language technology that attempts to determine the temporal location of an event as well as the temporal ordering between events. It supports a wide range of natural language applications such as Information Extraction, Question Answering and Text Summarization. For some genres of text (such as news), a temporal ordering of events can be the most informative summarization of a document (Mani and Wilson, 2000; Filatova and Hovy, 2001). Temporal inference is especially important for multi-document summarization where events extracted from multiple documents need to be put in a chronological order (Lin and Hovy, 2001; Barzilay et al., 2002) to make logical sense. Event-based temporal inference is also necessary for Question Answering (Harabagiu and Bejan, 2005; Harabagiu and Bejan, 2006). For example, to answer "When was Beijing Olympics held?", events extracted from natural language text have to be associated with a temporal location, whereas to answer "how many terrorists have been caught since 9/11?", temporal ordering of multiple events is the prerequisite. Event-based temporal inference has also been studied extensively in the context of Information Extraction, which typically involves extracting unstructured information from natural language sources and putting them into a structured database for querying or other forms of information access. For event extraction, this means extracting the event participants as well as its temporal location. Generally, an event has to occur in a specific time and space, and the temporal location of an event provides the necessary context for accurately understanding that event.

Being able to infer the temporal location of an event in Chinese text has many additional applications. Besides Information Extraction, Question Answering and Text Summarization, knowing the temporal location of an event is also highly valuable to Machine Translation. To translate a language like Chinese into a language like English in which tense is grammatically marked with inflectional morphemes, an MT system will have to infer the necessary temporal information to determine the correct tense for verbs. Statistical MT systems, the currently dominant research paradigm, typically do not address this issue directly or even indirectly.

As machine learning approaches are gaining dominance in computational linguistics and producing state-of-the-art results in many areas, they have in turn fueled the demand for large quantities of human-annotated data of various types

Coling 2008: Poster Volume, pages 1363–1372,
Beijing, August 2010

that machine learning algorithms can be trained on and evaluated against. In the temporal inference domain, this has led to the creation of TimeBank (Pustejovsky et al., 2003), which is annotated based on the TimeML language (Pustejovsky et al., 2005). TimeML is becoming an ISO standard for annotating events and time expressions (ISO/TC 37/SC 4/WG 2, 2007). A version of the TimeBank has been provided as a shared public resource for TempEval-2007, the first temporal evaluation campaign aimed at automatically identifying temporal relations between events and time expressions as well the temporal ordering between events.

In this paper, we report work for a Chinese temporal annotation project as part of the 2010 multilingual temporal evaluation campaign (TempEval-2)[1]. Besides Chinese, TempEval-2 also includes English, French, Italian, Korean and Spanish. Our temporal annotation project is set up within the confines of BAT[2], a database-driven multilingual temporal annotation tool that is also used to support other TempEval-2 languages. The TempEval-2 evaluation framework takes a divide-and-conquer approach to temporal annotation. With the eventual goal being the annotation of temporal relations between events and between events and time expressions, the TempEval-2 annotation consists of a series of event and temporal annotation subtasks. The idea is that each of these subtasks will be easier to annotate than the larger task as a whole and is less demanding on the annotators. The hope is that this will lead to more consistent annotation that will be easier to learn for automatic systems as well.

The rest of the paper will be organized as follows. In Section 2, we briefly describe the seven layers of annotation. In Section 3, we describe our annotation procedure. In Section 4, we address a major issue that arises from our annotation effort, which is the question of how to select annotation targets. Our experience, some positive and some negative, shows that temporal annotation can be carried out much more smoothly and with higher quality when the right annotation targets are presented to the annotators. This is especially true during the annotation of temporal relations between events and between events and time expressions, which are more complex than simpler annotation tasks such as identifying the events and time expressions. Section 5 concludes our paper.

2 Layers of annotation

2.1 Events and time expressions

The ultimate goal for a temporal annotation project is to determine the temporal relationship between events, and between events and time expressions. In order to achieve that objective, events and time expressions must be first identified. Specifically, this means marking up text spans in a document that can be used to represent the events and time expressions. Events in particular are abstract objects and a full description of an event would include its participants and temporal and spatial location. The TempEval annotation framework simplifies this by just marking a verb or a noun that best represents an event. The verb or noun can be considered as an "event anchor" that represents the most important aspect of the event. This is illustrated in (1), where the verbs 参加 ("attend"), 举行 ("hold") and the noun 仪式 ("ceremony") are marked as event anchors.

参加 了 今天 举行 的 投产
attend ASP today hold DE commissioning
剪彩 仪式 。
ribbon-cutting ceremony .

"Vice Premier Zou Jiahua of the State Council attended today's commissioning ribbon-cutting ceremony".

Once the text spans of event anchors are annotated, these events are then annotated with a set of attributes. The TempEval annotation framework allows variations across languages in the number of attributes one can define as well as the values for these attributes. For example, in the English annotation, one of the event attributes is grammatical *tense* which can be read off the morphological inflections of a verb. Chinese verbs, on the other hand, are not inflected for tense. Instead, in the

Chinese annotation, we have a more fully developed *aspect* attribute that has eight possible values: *Actual*, *Experiential*, *Complementive*, *Delimitative*, *Progressive*, *Durative*, *Inceptive*, and *Continuative*, largely based on the theoretical work of Xiao and McEnery (2004).

The most important attribute for both English and Chinese, however, is the *Class* attribute. The values for this attribute include *Reporting*, *Aspectual*, *Perception*, *I-Action*, *I-State*, *State*, and *Occurrence*. The different values of the *Class* attribute effectively constitute a classification of events, and they are defined in the TimeML specification language (Pustejovsky et al., 2005).

The other building block in the TempEval annotation framework is time expressions. Like events, time expressions are marked with both text spans and a set of attributes. The annotation of time expressions is relatively straightforward, and we follow the TimeML standards in our annotation study. In TimeML, time expressions are formally called TIMEX3s, and they have two obligatory attributes: *Type* and *Value*. The value of *Type* is one of *time*, *date*, *duration* or *set*. The *Value* attribute is essentially a normalized time value based on the TIDES standard for annotating time expressions (Ferro et al., 2004). The normalization allows easy comparison of time expression. For example, there are three time expressions in (2), 一九九二年("1992"), 一九九六年 ("1996") and 今年 ("this year"). Note that even though 一九九二年 至 一九九六年 (" 1992 to 1996") forms one duration, it is annotated as two time expressions. All three time expressions in the sentence are dates, and their normalized values are *1992*, *1996*, and *1997* respectively. To determine the normalized value for 今年 ("this year"), we need to know the document creation time, and fortunately this information is available in the metadata for the Chinese Treebank documents.

以上 。
above

"From 1992 to 1996, Shanghai's GDP on average grows at14.2% per year. This year the (GDP) growth will also reach above 13%."

2.2 Temporal relations

Once the events and time expressions are in place, we are in a position to annotate various temporal relations that are defined over them. (Since events and time expressions are entities that temporal relation is defined upon, we will subsume them under the cover term "temporal entity" when convenient.) The ultimate goal of temporal annotation is to identify all temporal relations in text. This goal cannot be achieved by manually annotating temporal relation of all temporal entities for three reasons. First, it is infeasible, given the number of temporal entities in a typical document. Second, it is unnecessary due to the transitive property of certain types of temporal relation. For example, if *e1*, *e2* and *e3* are all events, and if *e1* is before *e2*, and *e2* is before *e3*, there is no need to also annotate the relation between *e1* and *e3*. Third, the result of annotating all temporal entity pairs does not reflect the natural temporal relations that exist in text. Verhagen et al. (2009) found that a major contributor to high inter-annotator disagreement was hard-to-classify cases that annotators were instructed not to avoid. If a temporal relation is not made clear in text, then it should not be present in annotation.

Since it is infeasible, unnecessary and even detrimental to manually annotate all possible relations between temporal entities, the question then becomes one of selecting which temporal relations to annotate. The TempEval-2 evaluation starts by annotating the following temporal relations, which it considers to be a priority:

1. between an event and a time expression
2. between an event and the document creation time
3. between a subordinating event and its corresponding subordinated event

4. between a main event and its immediately preceding main event

The TempEval-2 annotation uses six values for all temporal relations, and they are *Before*, *Before-or-Overlap*, *Overlap*, *Overlap-or-After*, *After* and *Vague*. The *Vague* value is only used as the last resort when the annotator really cannot determine the temporal relationship between a pair of temporal entities. In the meantime, the TempEval-2 also allows variations from language to language regarding specific annotation strategies for each subtask. For Chinese temporal annotation, most of the decisions we have to make revolve around one central question, and that is which temporal entity pair to annotate.

2.2.1 Relation between events and time expressions

The annotation of the relationship between events and time expressions involves i) determining which event is related to which time expression, and ii) what is the nature of this relationship. In (3), for example, there are three events and three time expressions that enter into the temporal relation annotation. If the annotator is required to annotate all possible event/time combinations, there will be nine possible pairs. There are at least three possible strategies to go about selecting event/time pairs to annotate. The first strategy is to annotate all possible pairs. This seems to add unnecessary burden to the annotator because if we know that *e1* overlaps *t1*, we can infer the temporal relationship between *e1* and *t3* by virtue of the fact that *t1* occurs before *t3*. The second strategy is to allow the annotator to freely choose which event/time pair to annotate based on whether there is a clear temporal relation between them. This eliminates the possibility that the annotator is forced to annotate hard-to-classify and inconsequential relations, but leaving this decision to the annotator entirely might lead to low inter-annotator agreement where annotators choose to annotate different event/time pairs.

global economic growth speed DE
预测] 。
forecast .

"The International Monetary Fund on 21 published a preliminary assessment report, again lowering its forecast of the global economic growth for this year and next year."

In our annotation, we adopt a third strategy. Instead of simply asking which event bears a temporal relation to which temporal expression in the same sentence, we ask annotators to judge *which event(s) a given temporal expression is **intended** to modify*. In essence, this amounts to asking the annotator to first make a syntactic decision about which events fall within the scope of a time expression. In (3), all three events *e1*, *e2* and *e3* fall within the scope of *t1*, and none of them are in the scope of *t2* and *t3*. This approach reduces the number of fuzzy temporal relations that annotators might disagree on due to preference for thoroughness vs. accuracy.

2.2.2 Temporal relation between subordinating event and subordinated event

The two tasks in the TempEval framework that deal with event pairs are to annotate temporal relation between the subordinating event and the subordinated event, as well as the relation in main event pairs. The division of labor between them is quite clear: the former deals with intra-sentential temporal relations whereas the latter handles inter-sentential relations. It is not immediately clear, however, how each of the two types of relations should be defined.

Unlike in the event/time annotation where syntactic notions are invoked in selecting event/time pairs to annotate, our definitions of subordinating and subordinated events are primarily based on semantic criteria. The subordinating event is roughly the predicate while the subordinated event is one of its arguments, provided that both the

predicate and the argument are anchors of events. For example, in (4), there are two subordinating and subordinated event pairs. *e2* is a subordinated event of *e1*, and *e4* is a subordinated event of *e3*.

(4) 广东 [**e1** 举行] [**e2** 研讨会] [**e3** 介绍] [**e4** 税改] 及 加工 贸易 台帐 制度
Guangdong hold symposium introduce tax reform and processing trade accounting regulation

"Guangdong held a symposium introducing the tax reform and the accounting regulations on processing trade."

An alternative to using the notion of predicate-argument structure in determining the subordinating/subordinated events is to resort to syntactic relations such as the verb and its object. The net result would be the same for Example (4). However, the same argument that motivates the annotation of the predicate-argument structures in the Propbank (Palmer et al., 2005) and the Chinese Propbank (Xue and Palmer, 2009) also applies to temporal annotation. That is, the predicate-argument structure and temporal relations tend to hold constant in spite of the syntactic alternations and variations. For example, the temporal relation between the noun 研讨会 ("symposium") event and the verb 举行 ("hold") event remains the same in (5) in spite of the change in the syntactic relation between them. If only event pairs in a verb-object relation are annotated, the temporal relation between *e2* and *e1* in (5) would be lost.

(5) [**e2** 研讨会] 在 广东 [**e1** 举行]
symposium PREP Guangdong hold

"The symposium was held in Guangdong."

2.2.3 Temporal relations between main events

The purpose of annotating the temporal relation between main events is to capture the temporal ordering of events scattered in different sentences that constitute the main chain of events covered in the article. Annotation of the temporal relation between main events is further divided into two steps. In the first step, main events are first identified among all events in a sentence, and then the temporal relation between the main events in adjacent pairs of sentences is annotated. As a first approximation, we define "main event" as follows: a main event is the event expressed by the main verb of the top-most level clause of a sentence. The underlying assumption is that good writing would place words representing important events in prominent positions of a sentence and the first choice of a prominent position in a sentence is probably the main verb. An additional stipulation is that in case of a co-ordinated construction involving two or more main verbs at the top-most level, the event represented by the first is the main event of the sentence. This is to ensure that each sentence has only one main event. As we shall see in Section 3, this seemingly simple turns out to be surprisingly difficult, as reflected in the low inter-annotator agreement.

2.2.4 Temporal relation between events and the document creation time

In this layer, all the events identified in a document are annotated according to their temporal relation to the document creation time. This task is particularly challenging and intellectually interesting for Chinese. As an isolating language (Li and Thompson, 1981), Chinese has a small word to morpheme ratio. That is, the majority of its words consist of single morphemes. As a result, it lacks the inflectional morphology that grammatically marks tense. Tense directly encodes the temporal location of an event in natural language text and the lack of observable grammatical tense makes it that much harder to determine the temporal location of an event in Chinese text. This is not to say, however, that Chinese speakers do not attempt to convey the temporal location of events when they speak or write, or that they cannot interpret the temporal location when they read Chinese text, or even that they have a different way of representing the temporal location of events. In fact, there is evidence that the temporal location is represented in Chinese in exactly the same way as it is represented in English and most world languages: in relation to the moment of speech. One piece of evidence to support this claim is that Chinese temporal expressions like 今天 ("today"), 明天 ("tomorrow") and 昨天 ("yesterday") all assume a

temporal deixis that is the moment of speech in relation to which all temporal locations are defined. Annotating the temporal relation between events and document creation time would then directly capture the temporal location of events.

3 Annotation procedure and annotation consistency

The data set consists of 60 files taken from the Chinese Treebank (Xue et al., 2005). The source of these files is Xinhua newswire. It goes through a two-phase double blind and adjudication process. The first phase involves three annotators, with each file annotated by two annotators; the second phase involves two judges, with each double annotated document assigned to a single judge for disagreement resolution. The inter-annotator agreement between the two annotators (A and B) as the agreement between each annotator and the judge (J) are presented in Table 1. The agreement is measured in terms of F1-score[3], which is a weighted average between precision and recall. The F1-score is calculated as follows:

$$F = 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}} \quad (1)$$

The agreement statistics in Table 1 clearly show that event and time expression annotations are easier but temporal relations are harder as reflected in the lower inter-annotator agreement scores. This is somewhat expected because relations involve two temporal entities while we are only dealing with one temporal entity with event and time expression annotations. The figures also show the seemingly simple task of main event annotation (which only involves picking one event per sentence as the main event) has a surprisingly low inter-annotator agreement score. One reason might be that in a less grammaticalized language like Chinese, it is not always clear which verb is the main verb when the syntactic tree information is not displayed in the annotation interface. Another reason is that annotators sometimes disregard the syntax-based rule when it runs too much afoul to their intuition, a point that we will come back to and discuss in greater detail in Section 4.

[3]For a subset of the tasks, the total number of annotated instances for the two annotators is the same. This subset includes identification of main events, the temporal relation between the main events in two adjacent sentences, and the temporal relation between an event and the document creation time.

Layer	f(A, B)	f(A, J)	f(B, J)
event-extent	0.90	0.93	0.94
timex-extent	0.86	0.88	0.93
main-events	0.74	0.90	0.82
tlinks-main-events	0.65	0.70	0.75
tlinks-dct-events	0.77	0.86	0.90
tlinks-e-t	0.75	0.88	0.83
tlinks-sub-e	0.53	0.74	0.70

Table 1: Inter-annotator agreement for the subtasks: *event-extent*, the textual extent of an event anchor; *timex-extent*, the textual span of a time expression; *tlinks-main-event*, the temporal relation between the main events; *tlinks-dct-events*, the temporal link between an event and the document creation time; *tlinks-e-t*, the temporal relation between an event and a time expression; *tlinks-sub-e*, the temporal relation between a subordinating event and a subordinated event.

It is worth noting that the annotation of the temporal relation between an event and a time expression, and between a subordinating event and a subordinated event involves two decisions. The annotator needs to first decide which pairs of temporal entities to annotate, and then decide what temporal relation should be assigned to each temporal entity pair. To take a closer look at which of these two decisions creates more of a problem for the annotator, we computed the agreement figures for these two steps respectively. In Table 2, Column 3 presents the figure for just identifying which pair to annotate, and Column 4 is the agreement for just assigning the temporal relation, assuming the same pair of temporal entities are found by both annotators.

Layer	all	identification f	relation
tlinks-e-t	0.75	0.86	0.89
tlinks-sub-e	0.53	0.60	0.87

Table 2: Detailed agreement for event-time and subordinating-subordinated events

From Table 2, it is clear that for both tasks,

there is lower agreement between the annotators in deciding which pair to annotate. Once the two annotators agree on which pair to annotate, determining the temporal relation is relatively easier, as reflected in higher agreement.

4 Detailed discussion

As described in Section 2, when annotating the temporal relation between an event and a time expression, the annotators are instructed to annotate an event-time pair if the event is falling within the syntactic scope of the time expression. When annotating the relation between subordinating and subordinated events, the annotators are instructed to select event pairs based on the semantic notion of predicate-argument structure. This assumes a certain level of linguistic sophistication on the part of the annotators. From the lower agreement score in identifying event-time pairs (Table 2), it is clear that our annotators, who are not trained linguists, lack in this type of specialized knowledge. They are better at making the more intuitive judgment regarding the temporal relation between two temporal entities. One solution is obviously to find better trained linguists to perform these tasks, but it may not always be feasible. Since our data is taking from the Chinese Treebank and has already been annotated with syntactic structures and predicate-argument structures (from the Chinese Propbank annotation (Xue and Palmer, 2009)), an alternative is to extract the event-time or event-event pairs using the syntactic and predicate-argument structures as constraints.[4]

The annotation of main events and their relations presents a different challenge. Our first approximation is to select main events based on syntactic considerations. A main event is equated with the matrix verb in a sentence. In many cases this turns out to be unintuitive. Two of the recurring counter-intuitive cases involve directly quoted speech and coordination structures.

Directly quoted speech In Chinese newswire text, it is often the case that the source of information is explicitly cited in the form of direct quotations. (6) is such an example:

(6) 宋健 说：“如今 ，中国
Song-Jian say , “ nowadays , China
已 能 生产 上万 门
already can produce tens-of-thousands CL
数字 电话 程控交换机。”
digital telephone PBX

“Song Jian said, ‘nowadays, China is capable of producing tens of thousands of digital telephone PBX.’ ”

While the event represented by the underlined verb 说 (“say”) may very well be important in some natural language processing applications (for example, sometimes the source of the target information is crucial), it is not normally part of the intended information being covered by a news article. And it does not make much sense to annotate its temporal relation to adjacent main events that are on a par with what was said, not the saying event itself. The point would be even clearer when such a case is contrasted with a case in which a similar semantic relation is formulated in a different syntactic structure, as shown in (7):

(7) **据** 官方 权威 人士
according to official authority source
透露 ，今年 中国 政府
divulge , this-year China government
确定 的 经济 增长率 为
determine DE economic growth rate be
百分之八。
8%

“According to some official sources in position of authority, the economic growth rate determined by the Chinese government is 8%.”

Because of the presence of the preposition 据 (“according to”), the underlined reporting verb 透露 (“divulge”), similar to 说 (“say”) in (6) with respect to its semantic relation to the following material, would not be annotated as representing the main event of the sentence. The difference in the annotation of the main event between (7) and (6) seems to be an undesirable artifact of the purely syntax-based annotation rule for identifying main events.

[4] See a similar approach in Bethard et al. (2007).

Co-ordination structure Co-ordination by no means is a rare occurrence in the data, and often times, all events within a co-ordination structure, taken together, represent the main event of the sentence. For example, in (8), both events represented by the underlined verbs seem to be equally significant and should be included in the same chain of events. Given the prevalence of co-ordination between verbs, the stipulation that only the first one counts significantly undermines the coverage of the task and goes against the annotator's intuitions.

“In September of this year, many foreign oil companies signed a series of ‘century contract’ with Kazakstan National Oil Company. These contracts will generate an enormous profit of 700-billion dollars.”

The issue in the annotation of the temporal relation between main events seem to be more in the selection of main event pairs than in the determination of the nature of their relationship. Our current rule states that any two main events in consecutive sentences form a pair for annotation. This task suffers a low level of inter-annotator agreement partly because many main events identified by syntactic criteria are not actually main events in our intended sense. Often times, two consecutive main events come from different levels of the discourse structure or different chains of events, which puts annotators in a hard-to-classify situation.

To achieve high inter-annotator consistency when annotating the temporal relation between events from different sentences, we believe the selection of event pairs has to be informed by the discourse structure of the document. This only makes sense given that the annotation of temporal relation between events and time expressions within one sentence is informed by the syntactic structure, and the temporal relation between subordination and subordinating events benefits from an understanding of the predicate-argument structure.

The specific type of discourse structure we have in mind is the kind represented in the Penn Discourse Treebank (Miltsakaki et al., 2004). The Penn Discourse Treebank-style of annotation can inform temporal relation annotation in at least two ways. First, the Penn Discourse Treebank annotates the discourse relation between two adjacent sentences. The discourse relation holds between two abstract objects such as events or propositions. If a discourse relation holds between two events, the temporal relation between those two events might also be what we are interested in for temporal annotation. The implicit assumption is that the discourse structure of a document represents the important temporal relations within that document as well. (9) is an example taken from the Penn Discourse Treebank. The discourse relation, characterized by the discourse connective “in particular”, holds between the events anchored by“dropped” and “fell”. The temporal relation between these events also happens to be what we would be interested in if we are to annotate the main events between two adjacent sentences. Notice that in (9), material that is irrelevant to the discourse relation is taken out of the two arguments of this discourse relation, which are marked in italics and bold face respectively.

(9) *Meanwhile, the average yield on taxable funds dropped nearly a tenth of a percentage point, the largest drop since midsummer.* implicit = in particular **The average seven-day compound yield**, which assumes that dividends are reinvested and that current rates continue for a year, **fell to 8.47%, its lowest since late last year, from 8.55% the week before, according to Donoghue’ s.**

The Penn Discourse Treebank also marks attributions when annotating discourse relations. In

(10), for example, "he says" will be marked as a case of attribution and the "say" verb would be marked as the main event of the sentence if syntactic criteria are followed. Having attributions identified would directly help with the temporal annotation of examples like (6), where the main event is embedded in direct quoted speech.

(10) When *Mr. Green won a $240,000 verdict in a land condemnation case against the State in June 1983*, [he says] **Judge O' Kicki unexpectedly awarded him an additional $100,000.**

As of now, the data we use for our temporal annotation experiment have not yet been annotated with discourse structures. In order to make our temporal annotation sensitive to the discourse structure, we either have to annotate the discourse structure in a separate pass, or to incorporate the key elements of the discourse structure when developing guidelines for temporal annotation.

5 Conclusion

We described a Chinese temporal annotation experiment that produced a sizable data set for the TempEval-2 annotation campaign. We show that while we have achieved high inter-annotator agreement for simpler tasks such as identification of events and time expressions, temporal relation annotation proves to be much more challenging. We show that in order to improve annotation consistency it is important to strategically select the annotation targets, and this selection process should be subject to syntactic, semantic and discourse constraints.

Syntax-Driven Machine Translation as a Model of ESL Revision

Huichao Xue and **Rebecca Hwa**
Department of Computer Science
University of Pittsburgh
{hux10,hwa}@cs.pitt.edu

Abstract

In this work, we model the writing revision process of English as a Second Language (ESL) students with syntax-driven machine translation methods. We compare two approaches: tree-to-string transformations (Yamada and Knight, 2001) and tree-to-tree transformations (Smith and Eisner, 2006). Results suggest that while the tree-to-tree model provides a greater coverage, the tree-to-string approach offers a more plausible model of ESL learners' revision writing process.

1 Introduction

When learning a second language, students make mistakes along the way. While some mistakes are idiosyncratic and individual, many are systematic and common to people who share the same primary language. There has been extensive research on grammar error detection. Most previous efforts focus on identifying specific types of problems commonly encountered by English as a Second Language (ESL) learners. Some examples include the proper usage of determiners (Yi et al., 2008; Gamon et al., 2008), prepositions (Chodorow et al., 2007; Gamon et al., 2008; Hermet et al., 2008), and mass versus count nouns (Nagata et al., 2006). However, previous work suggests that *grammar error correction* is considerably more challenging than detection (Han et al., 2010). Furthermore, an ESL learner's writing may contain multiple interacting errors that are difficult to detect and correct in isolation.

A promising research direction is to tackle automatic grammar error correction as a machine translation (MT) problem. The disfluent sentences produced by an ESL learner can be seen as the input source language, and the corrected revision is the result of the translation. Brockett et al. (2006) showed that phrase-based statistical MT can help to correct mistakes made on mass nouns. To our knowledge, phrase-based MT techniques have not been applied for rewriting entire sentences. One major challenge is the lack of appropriate training data such as a sizable parallel corpus. Another concern is that phrase-based MT may not be similar enough to the problem of correcting ESL learner mistakes. While MT rewrites an entire source sentence into the target language, not every word written by an ESL learner needs to be modified.

Another alternative that may afford a more general model of ESL error corrections is to consider syntax-driven MT approaches. We argue that syntax-based approaches can overcome the expected challenges in applying MT to this domain. First, it can be less data-intensive because the mapping is formed at a structural level rather than the surface word level. While it does require a robust parser, a syntax-driven MT model may not need to train on a very large parallel corpus. Second, syntactic transformations provide an intuitive description of how second language learners revise their writings: they are transforming structures in their primary language to those in the new language.

In this paper, we conduct a first inquiry into the applicability of syntax-driven MT methods to automatic grammar error correction. In particular, we investigate whether a syntax-driven model can capture ESL students' process of writing revisions. We compare two approaches: a tree-to-string mapping proposed by Yamada & Knight (2001) and a tree-to-tree mapping using the Quasi-Synchronous

Coling 2008: Poster Volume, pages 1373–1381,
Beijing, August 2010

Grammar (QG) formalism (Smith and Eisner, 2006). We train both models on a parallel corpus consisting of multiple drafts of essays by ESL students. The approaches are evaluated on how well they model the revision pairs in an unseen test corpus. Experimental results suggest that 1) the QG model has more flexibility and is able to describe more types of transformations; but 2) the YK model is better at capturing the incremental improvements in the ESL learners' revision writing process.

2 Problem Description

This paper explores the research question: can ESL learners' process of revising their writings be described by a computational model? A successful model of the revision process has several potential applications. In addition to automatic grammar error detection and correction, it may also be useful as an automatic metric in an intelligent tutoring system to evaluate how well the students are learning to make their own revisions.

Revising an ESL student's writing bears some resemblance to translating. The student's first draft is likely to contain disfluent expressions that arose from translation divergences between English and the student's primary language. In the revised draft, the divergences should be resolved so that the text becomes fluent English. We investigate to what extent are formalisms used for machine translation applicable to model writing revision. We hypothesize that ESL students typically modify sentences to make them sound more fluent rather than to drastically change the meanings of what they are trying to convey. Thus, our work focuses on syntax-driven MT models.

One challenge of applying MT methods to model grammar error correction is the lack of appropriate training data. The equivalence to the bilingual parallel corpus used for developing MT systems would be a corpus in which each student sentence is paired with a fluent version re-written by an instructor. Unlike bilingual text, however, there is not much data of this type in practice because there are typically too many students for the teachers to provide detailed manual inspection and correction at a large scale. More commonly, students are asked to revise their previously written essays as they learn more about the English language. Here is an example of a student sentence from a first-draft essay:

> The problem here is that they come to the US like illegal.

In a later draft, it has been revised into:

> The problem here is that they come to the US illegally.

Although the students are not able to create "gold standard revisions" due to their still imperfect understanding of English, a corpus that pairs the students' earlier and later drafts still offers us an opportunity to model how ESL speakers make mistakes.

More formally, the corpus $\mathcal{C}$ consists of a set of sentence pairs (O, R), where O represents the student's original draft and R represents the revised draft. Note that while R is assumed to be an improvement upon O, its quality may fall short of the gold standard revision, G. To train the syntax-driven MT models, we optimize the joint probability of observing the sentence pair, $\Pr(O, R)$, through some form of mapping between their parse trees, τ_O and τ_R.

An added wrinkle to our problem is that it might not always be possible to assign a sensible syntactic structure to an ungrammatical sentence. It is well-known that an English parser trained on the Penn Treebank is bad at handling disfluent sentences (Charniak et al., 2003; Foster et al., 2008). In our domain, since O (and perhaps also R) might be disfluent, an important question that a translation model must address is: how should the mapping between the trees τ_O and τ_R be handled?

3 Syntax-Driven Models for Essay Revisions

There is extensive literature on syntax-driven approaches to MT (cf. a recent survey by

Lopez (2008)); we focus on two particular formalisms that reflects different perspectives on the role of syntax. Our goal is to assess which formalism is a better fit with the domain of essay revision modeling, in which the data largely consist of imperfect sentences that may not support a plausible syntactic interpretation.

3.1 Tree-to-String Model

The Yamada & Knight (henceforth, YK) tree-to-string model is an instance of noisy channel translation systems, which assumes that the observed source sentence is the result of transformation performed on the parse tree of the intended target sentence due to a noisy communication channel. Given a parallel corpus, and a parser for the the target side, the parameters of this model can be estimated using EM(Expectation Maximization). The trained model's job is to recover the target sentence (and tree) through decoding.

While the noisy channel generation story may sound somewhat counter-intuitive for translation, it gives a plausible account of ESL learner's writing process. The student really wants to convey a fluent English sentence with a well-formed structure, but due to an imperfect understanding of the language, writes down an ungrammatical sentence, O, as a first draft. The student serves as the noisy channel. The YK model describes this as a stochastic process that performs three operations on τ_G, the parse of the intended sentence, G:

1. Each node in τ_G may have its children **reordered** with some probability.

2. Each node in τ_G may have a child node **inserted** to its left or right with some probability.

3. Each leaf node (i.e., surface word) in τ_G is **replaced** by some (possibly empty) string according to its lexical translation distribution.

The resulting sentence, O, is the concatenation of the leaf nodes of the transformed τ_G.

Common mistakes made by ESL learners, such as misuses of determiners and prepositions, word choice errors, and incorrect constituency orderings, can be modeled by a combination of the **insert**, **replace**, and **reorder** operators. The YK model allows us to perform transformations on a higher syntactic level. Another potential benefit is that the model does not attempt to assign syntactic interpretations over the source sentences (i.e., the less fluent original draft).

3.2 Tree-to-Tree Model

The Quasi-Synchronous Grammar formalism (Smith and Eisner, 2006) is a generative model that aims to produce the most likely target tree for a given source tree. It differs from the more strict synchronous grammar formalisms (Wu, 1995; Melamed et al., 2004) because it does not try to perform simultaneous parsing on parallel grammars; instead, the model learns an augmented target-language grammar whose rules make "soft alignments" with a given source tree.

QG has been applied to some NLP tasks other than MT, including answer selection for question-answering (Wang et al., 2007), paraphrase identification (Das and Smith, 2009), and parser adaptation and projection (Smith and Eisner, 2009). In this work we use an instantiation of QG that largely follows the model described by Smith and Eisner (2006). The model is trained on a parallel corpus in which both the first-draft and revised sentences have been parsed. Using EM to estimate its parameters, it learns an augmented target PCFG grammar[1] whose production rules form associations with the given source trees.

Consider the scenario in Figure 1. Given a source tree τ_O, the trained model generates a target tree by expanding the production rules in the augmented target PCFG. To apply a

[1]For expository purposes, we illustrate the model using a PCFG production rule. In the experiment, a statistical English *dependency* parser (Klein and Manning, 2004) was used.

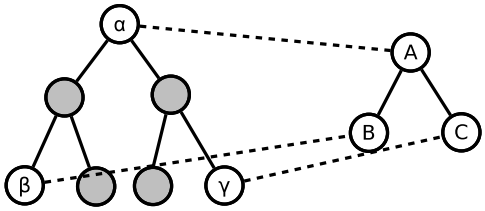

Figure 1: An example of QG's soft alignments between a given source tree and a possible target rule expansion.

target-side production rule such as

$$A \rightarrow BC,$$

the model considers which source tree nodes might be associated with each target-side nonterminals:

$$(\alpha, A) \rightarrow (\beta, B)(\gamma, C)$$

where α, β, γ are nodes in τ_O. Thus, assuming that the target symbol A has already been aligned to source node α from an earlier derivation step, the likelihood of expanding (α, A) with the above production rule depends on three factors:

1. the likelihood of the **monolingual target rule**, $\Pr(A \rightarrow BC)$
2. the likelihood of **alignments** between B and β as well as C and γ.
3. the likelihood that the source nodes form some expected **configuration** (i.e., between α and β as well as between α and γ). In this work, we distinguish between two configuration types: *parent-child* and *other*. This restriction doesn't reduce the explanatory power of the resulting QG model, though it may not be as fine-tuned as some models in (Smith and Eisner, 2006).

Under QG, the ESL students' first drafts are seen as text in a different language that has its own syntactic constructions. QG explains the grammar rules that govern the revised text in terms of how different components map to structures in the original draft. It makes explicit the representation of divergences between the students' original mental model and the expected structure.

3.3 Method of Model Comparison

Cross entropy can be used as a metric that measures the distance between the learned probabilistic model and the real data. It can be interpreted as measuring the amount of information that is needed in addition to the model to accurately recover the observed data. In language modeling, cross entropy is widely used in showing a given model's prediction power.

To determine how well the two syntax-driven MT models capture the ESL student revision generation process, we measure the cross entropy of each trained model on an unseen test corpus. This quantity measures how surprised a model is about relating an initial sentence, O, to its corresponding revision, R. Specifically, the cross entropy for some model M on a test corpus $\mathcal{C}$ of original and revised sentence pairs (O, R) is:

$$-\frac{1}{|\mathcal{C}|} \sum_{(O,R)\in\mathcal{C}} \log \Pr_M(O, R)$$

Because neither model computes the joint probability of the sentence pair, we need to make additional computations so that the models can be compared directly.

The YK model computes the likelihood of the first-draft sentence O given an assumed gold parse τ_R of the revised sentence: $\Pr_{YK}(O \mid \tau_R)$. To determine the joint probability, we would need to compute:

$$\begin{aligned} \Pr_{YK}(O, R) &= \sum_{\tau_R \in \Lambda_R} \Pr_{YK}(O, \tau_R) \\ &= \sum_{\tau_R \in \Lambda_R} \Pr_{YK}(O \mid \tau_R) \Pr(\tau_R) \end{aligned}$$

where Λ_R represents the set of possible parse trees for sentence R. Practically, performing tree-to-string mapping over the entire set of trees in Λ_R is computationally intractable. Moreover, the motivation behind the YK

	mean	stdev
percentage of $O = R$	54.11%	N/A
O's length	12.95	4.87
R's length	12.74	4.20
edit distance	1.88	3.58

Table 1: This table summarizes some statistics of the dataset.

model is to trust the given τ_R. Thus, we made a Viterbi approximation:

$$\begin{aligned}\Pr_{YK}(O, R) &= \sum_{\tau_R \in \Lambda_R} \Pr_{YK}(O \mid \tau_R) \Pr(\tau_R) \\ &\approx \Pr_{YK}(O \mid \hat{\tau_R}) \Pr(\hat{\tau_R})\end{aligned}$$

where $\Pr(\hat{\tau_R})$ is the probability of the single best parse tree according to a standard English parser.

Similarly, to compute the joint sentence pair probability under the QG model would require summing over both sets of trees because the model computes $\Pr_{QG}(\tau_R \mid \tau_O)$. Here, we make the Viterbi approximation on both trees.

$$\begin{aligned}\Pr_{QG}(O, R) &= \sum_{\tau_R \in \Lambda_R} \sum_{\tau_O \in \Lambda_O} \Pr_{QG}(\tau_O, \tau_R) \\ &= \sum_{\tau_R \in \Lambda_R} \sum_{\tau_O \in \Lambda_O} \Pr_{QG}(\tau_R \mid \tau_O) \Pr(\tau_O) \\ &\approx \Pr_{QG}(\hat{\tau_R} \mid \hat{\tau_O}) \Pr(\hat{\tau_O})\end{aligned}$$

where $\hat{\tau_O}$ and $\hat{\tau_R}$ are the best parses for sentences O and R according to the underlying English dependency parser, respectively.

4 Experiments

4.1 Data

Our experiments are conducted using a collection of ESL students' writing samples[2]. These are short essays of approximately 30 sentences on topics such as "a letter to your parents." The students are asked to revise their essays at least once. From the dataset, we extracted 358 article pairs.

[2]The dataset is made available by the Pittsburgh Science of Learning Center English as a Second Language Course Committee, supported by NSF Award SBE-0354420.

Typically, the changes between the drafts are incremental. Approximately half of the sentences are not changed at all. These sentences are considered useful because this phenomenon strongly implies that the original version is good enough to the best of the author's knowledge. In a few rare cases, students may write an entirely different essay. We applied TF-IDF to automatically align the sentences between essay drafts. Any sentence pair with a cosine similarity score of less than 0.3 is filtered. This resulted in a parallel corpus of 7580 sentence pairs.

Because both models are computational intensive, we further restricted our experiments to sentence pairs for which the revised sentence has no more than 20 words. This reduces our corpus to 4666 sentence pairs. Some statistics of the sentence pairs are shown in Table 1.

4.2 Experimental Setup

We randomly split the resulting dataset into a training corpus of 4566 sentence pairs and a test corpus of 100 pairs.

The training of both models involve an EM algorithm. We initialize the model parameters with some reasonable values. Then, in each iteration of training, the model parameters are re-estimated by collecting the expected counts across possible alignments between each sentence pair in the training corpus. In out experiments, both models had two iterations of training. Below, we highlight our initialization procedure for each model.

In the YK model, the initial **reordering** probability distribution is set to prefer no change 50% of the time. The remaining probability mass is distributed evenly over all of the other permutations. For the **insertion** operation, for each node, the YK model first chooses whether to insert a new string to its left, to its right, or not at all, conditioned on the node's label and its parent's label. These distributions are initialized uniformly ($\frac{1}{3}$). If a new string should be inserted, the model then makes that choice with some probability. The insertion probability of each string in the

dictionary is assigned evenly with $\frac{1}{N}$, where N is the number of words in the dictionary. Finally, the **replace** probability distribution is initialized uniformly with the same value ($\frac{1}{N+1}$) across all words in the dictionary, including the empty string.

For the QG model, the initial parameters are determined as follows: For the **monolingual target parsing model parameters**, we first parse the target side of the corpus (i.e., the revised sentences) with the Stanford parser; we then use the maximum likelihood estimates based on these parse trees to initialize the parameters of the target parser, Dependency Model with Valence (DMV). We uniformly initialized the **configuration parameters**; the *parent-child* configuration and *other* configuration each has 0.5 probability. For the **alignment parameters**, we ran the GIZA++ implementation of the IBM word alignment model (Och and Ney, 2003) on the sentence pairs, and used the resulting translation table as our initial estimation. There may be better initialization setups, but the difference between those setups will become small after a few rounds of EM.

Once trained, the two models compute the joint probability of every sentence pair in the test corpus as described in Section 3.3.

4.3 Experiment I

To evaluate how well the models describe the ESL revision domain, we want to see which model is less "surprised" by the test data. We expected that the better model should be able to transform more sentence pair in the test corpus; we also expect that the better model should have a lower cross entropy with respect to the test corpus.

Applying both YK and QG to the test corpus, we find that neither model is able to transform all the test sentence pairs. Of the two, QG had the better coverage; it successfully modeled 59 pairs out of 100 (we denote this subset as D_{QG}). In contrast, YK modeled 36 pairs (this subset is denoted as D_{YK}).

To determine whether there were some characteristics of the data that made one model better at performing transformations for certain sentence pairs, we compare corpus statistics for different test subsets. Based on the results summarized in Table 2, we make a few observations.

First, the sentence pairs that neither model could transform seem, as a whole, more difficult. Their average lengths are longer, and the average per word Levenshtein edit distance is bigger. The differences between *Neither* and the other subsets are statistically significant with 90% confidence. For the length difference, we applied standard two-sample t-test. For the edit distance difference, we applied hypothesis testing with the null-hypothesis that "longer sentence pairs are as likely to be covered by our model as shorter ones."

Second, both models sometimes have trouble with sentence pairs that require no change. This may be due to out-of-vocabulary words in the test corpus. A more aggressive smoothing strategy could improve the coverage for both models.

Third, comparing the subset of sentence pairs that only QG could transform ($D_{QG} - D_{YK}$) against the subset of sentences that both models could transform ($D_{QG} \cap D_{YK}$), the former has slightly higher average edit distance and length, but the difference is not statistically significant. Although QG could transform more sentence pairs, the cross entropy of $D_{QG} - D_{YK}$ is higher than QG's estimate for the $D_{QG} \cap D_{YK}$ subset. QG's soft alignment property allows it to model more complex transformations with greater flexibility.

Finally, while the YK model has a more limited coverage, it models those transformations with a greater certainty. For the common subset of sentence pairs that both models could transform, YK has a much lower cross entropy than QG. Table 3 further breaks down the common subset. It is not surprising that both models have low entropy for identical sentence pairs. For modeling sentence pairs that contain revisions, YK is more efficient than QG.

	Neither	$D_{QG} \cap D_{YK}$	$D_{QG} - D_{YK}$	$D_{YK} - D_{QG}$
number of instances	38	33	26	3
average edit distance	2.42	1.88	2.08	1
% of identical pairs	53%	48%	58%	67%
average O length	14.63	12.36	12.58	6.67
average R length	13.87	12.06	12.62	6.67
QG cross entropy	N/A	127.95	138.9	N/A
YK cross entropy	N/A	78.76	N/A	43.84

Table 2: A comparison of the two models based on their coverage of the test corpus. Some relevant statistics on the sentence subsets are also summarized in the table.

	YK	QG
overall entropy	78.76	127.95
on identical pairs	52.59	85.40
on non-identical pairs	103.99	168.00

Table 3: A further comparison of the two models on $D_{QG} \cap D_{YK}$, the sentence pairs in the test corpus that both could transform.

4.4 Experiment II

The results of the previous experiment raises the possibility that QG might have a greater coverage because it is too flexible. However, an appropriate model should not only assign large probability mass to positive examples, but it should also have a low chance of choosing negative examples. In this next experiment, we construct a "negative" test corpus to see how it affects the models.

To construct a negative scenario, we still use the same test corpus as before, but we *reverse* the sentence pairs. That is, we use the revised sentences as "originals" and the original sentences as "revisions." We would expect a good model to have a raised cross entropy values along with a drop in coverage on the new dataset because the "revisions" should be more disfluent than the "original" sentences.

Table 4 summarizes the results. We observe that the number of instances that can be transformed has dropped for both models: from 59 to 49 pairs for QG, and from 36 to 20 pairs for YK; also, the proportion of identical instances in each set has raised. This means that both models are more surprised by the reverse test corpus, suggesting that both models have, to some extent, succeeded in modeling the ESL revision domain. However, QG still allows for many more transformations. Moreover, 16 out of the 49 instances are non-identical pairs. In contrast, YK modeled only 1 non-identical sentence pair. The results from these two experiments suggest that YK is more suited for modeling the ESL revision domain than QG. One possible explanation is that QG allows more flexibility and would require more training. Another possible explanation is that because YK assumes well-formed syntax structure for only the target side, the philosophy behind its design is a better fit with the ESL revision problem.

5 Related Work

There are many research directions in the field of ESL error correction. A great deal of the work focuses on the lexical or shallow syntactic level. Typically, local features such as word identity and POS tagging information are combined to deal with some specific kind of error. Among them, (Burstein et al., 2004) developed a tool called Critique that detects collocation errors and word choice errors. Nagata et al. (2006) uses a rule-based approach in distinguishing mass and count nouns. Knight and Chander (1994) and Han et al. (2006) both addressed the misuse of articles. Chodorow et al. (2007), Gamon et al. (2008), Hermet et al. (2008) proposed several techniques in detecting and correcting proposition errors. In detecting errors and giving suggestions, Liu et al. (2000), Gamon et al. (2008) and Hermet et al. (2008) make use of

	Neither	$D_{QG} \cap D_{YK}$	$D_{QG} - D_{YK}$	$D_{YK} - D_{QG}$
number of instances	50	19	30	1
average edit distance	2.88	0.05	2.17	1

average O length	14.18	9.00	12.53	17
average R length	14.98	9.05	12.47	16
QG cross entropy	N/A	81.85	139.36	N/A
YK cross entropy	N/A	51.2	N/A	103.75

Table 4: This table compares the two models on a "trick" test corpus in which the earlier and later drafts are reversed. If a model is trained to prefer more fluent English sentences are the revision, it should be perplexed on this corpus.

information retrieval techniques. Chodorow et al. (2007) instead treat it as a classification problem and employed a maximum entropy classifier. Similar to our approach, Brockett et al. (2006) view error correction as a Machine Translation problem. But their translation system is built on phrase level, with the purpose of correcting local errors such as mass noun errors.

The problem of error correction at a syntactic level is less explored. Lee and Seneff (2008) examined the task of correcting verb form misuse by applying tree template matching rules. The parse tree transformation rules are learned from synthesized training data.

6 Conclusion

This paper investigates the suitability of syntax-driven MT approaches for modeling the revision writing process of ESL learners. We have considered both the Yamada & Knight tree-to-string model, which only considers syntactic information from the typically more fluent revised text, as well as Quasi-Synchronous Grammar, a tree-to-tree model that attempts to learn syntactic transformation patterns between the students' original and revised texts. Our results suggests that while QG offers a greater degree of freedom, thus allowing for a better coverage of the transformations, YK has a lower entropy on the test corpus. Moreover, when presented with an alternative "trick" corpus in which the "revision" is in fact the earlier draft, YK was more perplexed than QG. These results suggest that the YK model may be a promising approach for automatic grammar error correction.

Abstract

Empty categories represent an important source of information in syntactic parses annotated in the generative linguistic tradition, but empty category recovery has only started to receive serious attention until very recently, after substantial progress in statistical parsing. This paper describes a unified framework in recovering empty categories in the Chinese Treebank. Our results show that given skeletal gold standard parses, the empty categories can be detected with very high accuracy. We report very promising results for empty category recovery for automatic parses as well.

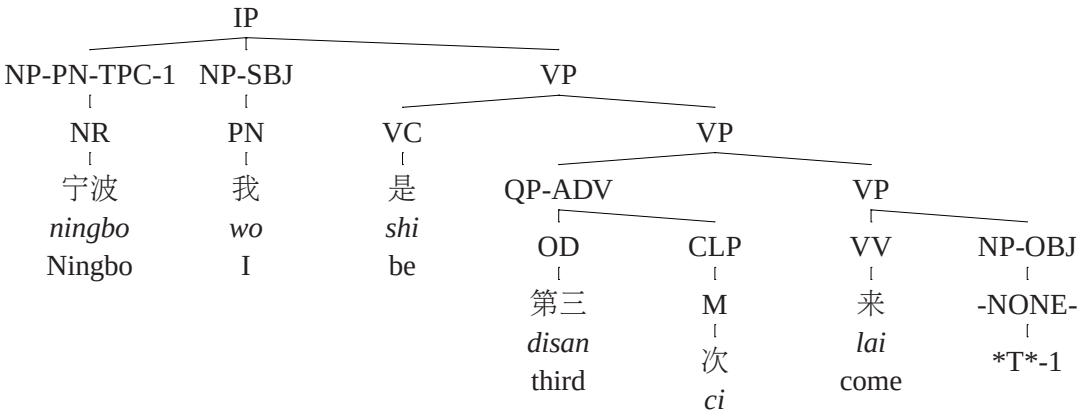
1 Introduction

The use of empty categories to represent the syntactic structure of a sentence is the hallmark of the generative linguistics and they represent an important source of information in treebanks annotated in this linguistic tradition. The use of empty categories in the annotation of treebanks started with the Penn Treebank (Marcus et al., 1993), and this practice is continued in the Chinese Treebank (CTB) (Xue et al., 2005) and the Arabic Treebank, the Penn series of treebanks. Empty categories come in a few different varieties, serving different purposes. One use of empty categories is to mark the extraction site of an dislocated phrase, thus effectively reconstructing the canonical structure of a sentence, allowing easy extraction of its predicate-argument structure. For example, in Figure 1, the empty category ***T*-1** is coindexed with the dislocated topic NP 宁波 ("Ningbo"), indicating that the canonical position of this NP is next to the verb 来 ("come"). The empty category effectively localizes the syntactic dependency between the verb and this NP, making it easier to detect and extract this relation.

Marking the extraction site of a dislocated item is not the only use of empty categories. For languages like Chinese, empty categories are also used to represent dropped pronouns. Chinese is a pro-drop language (Huang, 1989) and subject pronouns are routinely dropped. Recovering these elliptical elements is important to many natural language applications. When translated into another language, for example, these dropped pronouns may have to be made explicit and replaced with overt pronouns or noun phrases if the target language does not allow dropped pronouns.

Although empty categories have been an integral part of the syntactic representation of a sentence ever since the Penn Treebank was first constructed, it is only recently that they are starting to receive the attention they deserve. Works on automatic detection of empty categories started to emerge (Johnson, 2002; Dienes and Dubey, 2003; Campbell, 2004; Gabbard et al., 2006) after substantial progress has been made in statistical syntactic parsing. This progress has been achieved after over a decade of intensive research on syntactic parsing that has essentially left the empty categories behind (Collins, 1999; Charniak, 2000). Empty categories were and still are routinely pruned out in parser evaluations (Black et al., 1991). They have been excluded from the parser development and evaluation cycle not so much because their importance was not understood, but because researchers haven't figured out

Coling 2008: Poster Volume, pages 1382–1390,
Beijing, August 2010



"Ningbo, this is the third time I came here."

Figure 1: A CTB tree with empty categories

a way to incorporate the empty category detection in the parsing process. In fact, the detection of empty categories relies heavily on the other components of the syntactic representation, and as a result, empty category recovery is often formulated as postprocessing problem after the skeletal structure of a syntactic parse has been determined. As work on English has demonstrated, empty category detection can be performed with high accuracy given high-quality skeletal syntactic parses as input.

Because Chinese allows dropped pronouns and thus has more varieties of empty categories than languages like English, it can be argued that there is added importance in Chinese empty category detection. However, to our knowledge, there has been little work in this area, and the work we report here represents the first effort in Chinese empty category detection. Our results are promising, but they also show that Chinese empty category detection is a very challenging problem mostly because Chinese syntactic parsing is difficult and still lags significantly behind the state of the art in English parsing. We show that given skeletal gold-standard parses (with empty categories pruned out), the empty detection can be performed with a fairly high accuracy of almost 89%. The performance drops significantly, to 63%, when the output of an automatic parser is used.

The rest of the paper is organized as follows. In Section 2, we formulate the empty category detection as a binary classification problem where each word is labeled as either having a empty category before it or not. This makes it possible to use any standard machine learning technique to solve this problem. The key is to find the appropriate set of features. Section 3 describes the features we use in our experiments. We present our experimental results in Section 4. There are two experimental conditions, one with gold standard treebank parses (stripped of empty categories) as input and the other with automatic parses. Section 5 describes related work and Section 6 conclude our paper.

2 Formulating the empty category detection as a tagging problem

In the CTB, empty categories are marked in a parse tree which represents the hierarchical structure of a sentence, as illustrated in Figure 1. There are eight types of empty categories annotated in the CTB, and they are listed in Table 1. Among them, *pro* and *PRO* are used to represent nominal empty categories, *T* and *NP* are used to represent traces of dislocated items, *OP* is used to represent empty relative pronouns in relative clauses, and *RNR* is used to represent pseudo attachment. The reader is referred to the CTB bracketing manual (Xue and Xia, 2000) for detailed descriptions and examples. As can be seen from Table 1, the distribution of these empty categories is very uneven, and many of these empty categories do not occur very often.

EC Type	count	Description
pro	2024	small pro
PRO	2856	big pro
T	4486	trace for extraction
RNR	217	right node raising
OP	879	operator
*	132	trace for raising

Table 1: Empty categories in CTB.

As a first step of learning an empty category model, we treat all the empty categories as a unified type, and for each word in the sentence, we only try to decide if there is an empty category before it. This amounts to an empty category detection task, and the objective is to first locate the empty categories without attempting to determine the specific empty category type. Instead of predicting the locations of the empty categories in a parse tree and having a separate classifier for each syntactic construction where an empty category is likely to occur, we adopt a linear view of the parse tree and treat empty categories, along with overt word tokens, as leaves in the tree. This allows us to identify the location of the empty categories in relation to overt word tokens in the same sentence, as illustrated in Example (1):

(1) 宁波 我 是 第三 次 来 *T* 。

In this representation, the position of the empty category can be defined either in relation to the previous or the next word, or both. To make this even more amenable to machine learning approaches, we further reformulate the problem as a tagging problem so that each overt word is labeled either with EC, indicating there is an empty category *before* this word, or NEC, indicating there is no empty category. This reformulated representation is illustrated in Example (2):

(2) 宁/NEC 波/NEC 我/NEC 是/NEC 第/NEC 三/NEC 次/NEC 来/NEC 。/EC

In (2), the EC label attached to the final period indicates that there is an empty category before this punctuation mark. There is a small price to pay with this representation: when there is more than one empty category before a word, it is indistinguishable from cases where there is only one empty category. What we have gained is a simple unified representation for all empty categories that lend itself naturally to machine learning approaches. Another advantage is that for natural language applications that do not need the full parse trees but only need the empty categories, this representation provides an easy-to-use representation for those applications. Since this linearlized representation is still aligned with its parse tree, we still have easy access to the full hierarchical structure of this tree from which useful features can be extracted.

3 Features

Having modeled empty category detection as a machine learning task, feature selection is crucial to successfully finding a solution to this problem. The machine learning algorithm scans the words in a sentence from left to right one by one and determine if there is an empty category before it. When the sentence is paired with its parse tree, the feature space is all the surrounding words of the target word as well as the syntactic parse for the sentence. The machine learning algorithm also has access to the empty category labels (EC or NEC) of all the words before the current word. Figure 2 illustrates the feature space for the last word (a period) in the sentence.

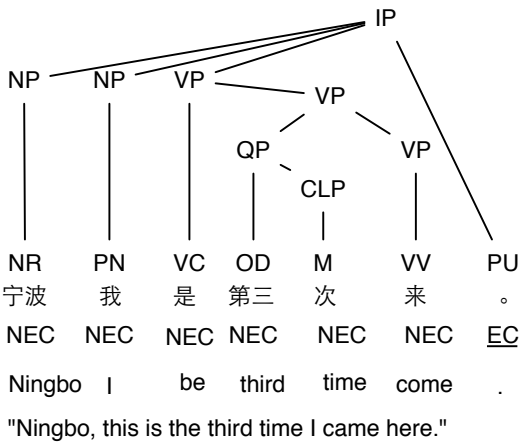


Figure 2: Feature space of empty category detection

For purposes of presentation, we divide our features into lexical and syntactic features. The

lexical features are different combinations of the words and their parts of speech (POS), while syntactic features are the structural information gathered from the nonterminal phrasal labels and their syntactic relations.

3.1 Lexical features

The lexical features are collected from a narrow window of five words and their POS tags. If the target word is a verb, the lexical features also include transitivity information of this verb, which is gathered from the CTB. A transitivity lexicon is induced from the CTB by checking whether a verb has a right NP or IP sibling. Each time a verb is used as a transitive verb (having a right NP or IP sibling), its transitive count is incremented by one. Conversely, each time a verb is used as an intransitive verb (not having a right NP or IP sibling), its intransitive use is incremented by one. The resulting transitivity lexicon after running through the entire Chinese Treebank consists of a list of verbs with frequencies of their transitive and intransitive uses. A verb is considered to be transitive if its intransitive count in this lexicon is zero or if its transitive use is more than three times as frequent as its intransitive use. Similarly, a verb is considered to be intransitive if its transitive count is zero or if its intransitive use is at least three times as frequent as its transitive use. The full list of lexical features is presented in Table 2.

Feature Names	Description
word(0)	Current word
word(-1)	Previous word
pos(0)	POS of current word
pos(-1,0)	POS of previous and current word
pos(0, 1)	POS of current and next word
pos(0, 1, 2)	POS of current & next word, & word 2 after
pos(-2, -1)	POS of previous word & word 2 before
word(-1), pos(0)	Previous word & POS of current word
pos(-1),word(0)	POS of previous word& current word
trans(0)	current word is transitive or intransitive verb
prep(0)	true if POS of current word is a preposition

Table 2: Feature set.

3.2 Syntactic features

Syntactic features are gathered from the CTB parses stripped of function tags and empty categories when the gold standard trees are used as input. The automatic parses used as input to our system are produced by the Berkeley parser. Like most parsers, the Berkeley parser does not reproduce the function tags and empty categories in the original trees in the CTB. Syntactic features capture the syntactic context of the target word, and as we shall show in Section 4, the syntactic features are crucial to the success of empty category detection. The list of syntactic features we use in our system include:

1. **1st-IP-child**: True if the current word is the first word in the lowest IP dominating this word.
2. **1st-word-in-subjectless-IP**: True if the current word starts an IP with no subject. Subject is detected heuristically by looking at left sisters of a VP node. Figure 3 illustrates this feature for the first word in a sentence where the subject is a dropped pronoun.
3. **1st-word-in-subjectless-IP+POS**: POS of the current word if it starts an IP with no subject.
4. **1st-VP-child-after-PU**: True if the current word is the first terminal child of a VP following a punctuation mark.
5. **NT-in-IP**: True if POS of current word is NT, and it heads an NP that does not have a subject NP as its right sister.
6. **verb-in-NP/VP**: True if the current word is a verb in an NP/VP.
7. **parent-label**: Phrasal label of the parent of the current node, with the current node always corresponding to a terminal node in the parse tree.
8. **has-no-object**: True If the previous word is a transitive verb and this verb does not take an object.

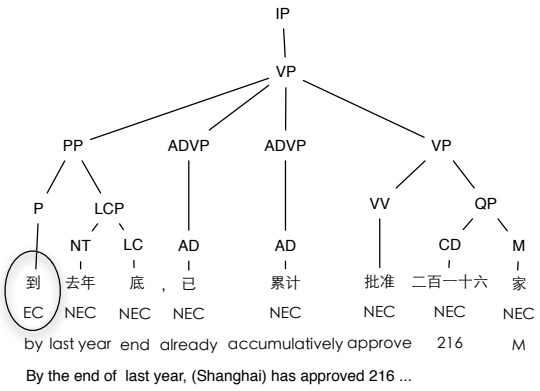

Figure 3: First word in a subject-less IP

Empty categories generally occur in clausal or phrasal boundaries, and most of the features are designed to capture such information. For example, the five feature types, *1st-IP-child*, *1st-word-in-subjectless-IP*, *1st-word-in-subjectless-IP*, *1st-VP-child-after-PU* and *NT-in-IP* all represent the left edge of a clause (IP) with some level of granularity. *parent label* and *verb-in-NP/VP* represent phrases within which empty categories typically occur do not occur. The *has-no-object* feature is intended to capture transitive uses of a verb when the object is missing.

4 Experiments

Given that our approach is independent of specific machine learning techniques, many standard machine learning algorithms can be applied to this task. For our experiment we built a Maximum Entropy classifier with the Mallet toolkit[1].

4.1 Data

In our experiments, we use a subset of the CTB 6.0. This subset is further divided into training (files chtb_0081 thorough chtb_0900), development (files chtb_0041 through chtb_0080) and test sets (files chtb_0001 through chtb_0040, files chtb_0901 through chtb_0931). The reason for not using the entire Chinese Treebank is that the data in the CTB is from a variety of different sources and the automatic parsing accuracy is very uneven across these different sources.

[1]http://mallet.cs.umass.edu

4.2 Experimental conditions

Two different kinds of data sets were used in the evaluation of our method: 1) gold standard parse trees from the CTB; and 2) automatic parses produced by the Berkeley parser[2] .

4.2.1 Gold standard parses

There are two experimental conditions. In our first experiment, we use the gold standard parse trees from the CTB as input to our classifier. The version of the parse tree that we use as input to our classifier is stripped of the empty category information. What our system effectively does is to restore the empty categories given a skeletal syntactic parse. The purpose of this experiment is to establish a topline and see how accurately the empty categories can be restored given a "correct" parse.

4.2.2 Automatic parses

To be used in realistic scenarios, the parse trees need to be produced automatically from raw text using an automatic parser. In our experiments we use the Berkeley Parser as a representative of the state-of-the-art automatic parsers. The input to the Berkeley parser is words that have already been segmented in the CTB. Obviously, to achieve fully automatic parsing, the raw text should be automatically segmented as well. The Berkeley parser comes with a fully trained model, and to make sure that none of our test and development data is included in the training data in the original model, we retrained the parser with our training set and used the resulting model to parse the documents in the development and test sets.

When training our empty category model using automatic parses, it is important that the quality of the parses match between the training and test sets. So the automatic parses in the training set are acquired by first training the parser with 4/5 of the data and using the resulting model to parse the remaining 1/5 of the data that has been held out. Measured by the ParsEval metric (Black et al., 1991), the parser accuracy stands at 80.3% (F-score), with a precision of 81.8% and a recall of 78.8% (recall).

[2]http://code.google.com/p/berkeleyparser

4.3 Evaluation metrics

We use precision, recall and F-measure as our evaluation metrics for empty category detection. Precision is defined as the number of correctly identified Empty Categories (ECs) divided by the total number of ECs that our system produced. Recall is defined as the number of correctly identified ECs divided by the total number of EC labels in the CTB gold standard data. F-measure is defined as the geometric mean of precision and recall.

$$R = \frac{\text{\# of correctly detected EC}}{\text{\# of EC tagged in corpus}} \quad (1)$$

$$P = \frac{\text{\# of correctly detected EC}}{\text{\# of EC reported by the system}} \quad (2)$$

$$F = \frac{2}{1/R + 1/P} \quad (3)$$

4.4 Overall EC detection performance

We report our best result for the gold standard trees and the automatic parses produced by the Berkeley parser in Table 3. These results are achieved by using all lexical and syntactic features presented in Section 3.

Data	Prec.(%)	Rec.(%)	F(%)
Gold	95.9 (75.3)	83.0 (70.5)	89.0 (72.8)
Auto	80.3 (57.9)	52.1 (50.2)	63.2 (53.8)

Table 3: Best results on the gold tree.

As shown in Table 3, our feature set works well for the gold standard trees. Not surprisingly, the accuracy when using the automatic parses is lower, with the performance gap between using the gold standard trees and the Berkeley parser at 25.8% (F-score). When the automatic parser is used, although the precision is 80.3%, the recall is only 52.1%. As there is no similar work in Chinese empty category detection using the same data set, for comparison purposes we established a baseline using a rule-based approach. The rule-based algorithm captures two most frequent locations of empty categories: the subject and the object positions. Our algorithm labels the first word within a VP with EC if the VP does not have a subject NP. Similarly, it assigns the EC label to the word immediately following a transitive verb if it does not have an NP or IP object. Since the missing subjects and objects account for most of the empty categories in Chinese, this baseline covers most of the empty categories. The baseline results are also presented in Table 3 (in brackets). The baseline results using the gold standard trees are 75.3% (precision), 70.5% (recall), and 72.8% (F-score). Using the automatic parses, the results are 57.9% (precision), 50.2% (recall), and 53.8% (F-score) respectively. It is clear from our results that our machine learning model beats the rule-based baseline by a comfortable margin in both experimental conditions. Table 4 breaks down our results by empty category types. Notice that we did not attempt to predict the specific empty category type. This only shows the percentage of empty categories our model is able to recover (recall) for each type. As our model does not predict the specific empty category type, only whether there is an empty category before a particular word, we cannot compute the precision for each empty category type. Nevertheless, this breakdown gives us a sense of which empty category is easier to recover. For both experimental conditions, the empty category that can be recovered with the highest accuracy is ***PRO***, an empty category often used in subject/object control constructions. ***pro*** seems to be the category that is most affected by parsing accuracy. It has the widest gap between the two experimental conditions, at more than 50%.

EC Type	Total	Correct	Recall(%)
pro	290	274/125	94.5/43.1
PRO	299	298/196	99.7/65.6
T	578	466/338	80.6/58.5
RNR	32	22/20	68.8/62.5
OP	134	53/20	40.0/14.9
*	19	9/5	47.4/26.3

Table 4: Results of different types of empty categories.

4.5 Comparison of feature types

To investigate the relative importance of lexical and syntactic features, we experimented with using just the lexical or syntactic features under both experimental conditions. The results are pre-

sented in Table 5. Our results show that when using only the lexical features, the drop in accuracy is small when automatic parses are used in place of gold standard trees. However, when using only the syntactic features, the drop in accuracy is much more dramatic. In both experimental conditions, however, syntactic features are more effective than the lexical features, indicating the crucial importance of high-quality parses to successful empty category detection. This makes intuitive sense, given that all empty categories occupy clausal and phrasal boundaries that can only defined in syntactic terms.

Data	Prec.(%)	Rec.(%)	F(%)
Lexical	79.7/77.3	47.6/39.9	59.6/52.7
Syntactic	95.9/78.0	70.0/44.5	81.0/56.7

Table 5: Comparison of lexical and syntactic features.

4.6 Comparison of individual features

Given the importance of syntactic features, we conducted an experiment trying to evaluate the impact of each individual syntactic feature on the overall empty category detection performance. In this experiment, we kept the lexical feature set constant, and switched off the syntactic features one at a time. The performance of the different syntactic features is shown in Table 6. The results here assume that automatic parses are used. The first row is the result of using all features (both syntactic and lexical) while the last row is the result of using only the lexical features. It can be seen that syntactic features contribute more than 10% to the overall accuracy. The results also show that features (e.g., *1st-IP-child*) that capture clause boundary information tend to be more discriminative and they occupy the first few rows of a table that sorted based on feature performance.

5 Related work

The problem of empty category detection has been studied both in the context of reference resolution and syntactic parsing. In the reference resolution literature, empty category detection manifests itself in the form of zero anaphora (or zero pronoun)

Feature Name	Prec.(%)	Rec.(%)	F(%)
all	80.3	52.1	63.2
1st-IP-child	79.8	49.2	60.8
1st-VP-child-after-PU	79.7	50.5	61.8
NT-in-IP	79.4	50.8	61.9
1st-word-in-subjectless-IP+Pos	79.5	51.1	62.2
has-no-object	80.0	51.1	62.4
1st-word-in-subjectless-IP	79.4	51.5	62.5
verb-in-NP/VP	79.9	52.0	63.0
parent-label	79.4	52.4	63.1
only lexical	77.3	39.9	52.7

Table 6: Performance for individual syntactic features with automatic parses.

detection and resolution. Zero anaphora resolution has been studied as a computational problem for many different languages. For example, (Ferrández and Peral, 2000) describes an algorithm for detecting and resolving zero pronouns in Spanish texts. (Seki et al., 2002) and (Lida et al., 2007) reported work on zero pronoun detection and resolution in Japanese.

Zero anaphora detection and resolution for Chinese has been studied as well. Converse (2006) studied Chinese pronominal anaphora resolution, including zero anaphora resolution, although there is no attempt to automatically detect the zero anaphors in text. Her work only deals with anaphora resolution, assuming the zero anaphors have already been detected. Chinese zero anaphora identification and resolution have been studied in a machine learning frameworking in (Zhao and Ng, 2007) and (Peng and Araki, 2007).

The present work studies empty category recovery as part of the effort to fully parse natural language text and as such our work is not limited to just recovering zero anaphors. We are also interested in other types of empty categories such as traces. Our work is thus more closely related to the work of (Johnson, 2002), (Dienes and Dubey, 2003), (Campbell, 2004) and (Gabbard et

al., 2006).

Johnson (2002) describes a pattern-matching algorithm for recovering empty nodes from phrase structure trees. The idea was to extract minimal connected tree fragments that contain an empty node and its antecedent(s), and to match the extracted fragments against an input tree. He evaluated his approach both on Penn Treebank gold standard trees stripped of the empty categories and on the output of the Charniak parser (Charniak, 2000).

(Dienes and Dubey, 2003) describes an empty detection method that is similar to ours in that it treats empty detection as a tagging problem. The difference is that the tagging is done without access to any syntactic information so that the identified empty categories along with word tokens in the sentence can then be fed into a parser. The success of this approach depends on strong local cues such as infinitive markers and participles, which are non-existent in Chinese. Not surprisingly, our model yields low accuracy if only lexical features are used.

Cambell (2004) proposes an algorithm that uses linguistic principles in empty category recovery. He argues that a rule-based approach might perform well for this problem because the locations of the empty categories, at least in English, are inserted by annotators who follow explicit linguistic principles.

Yuqing(2007) extends (Cahill et al., 2004) 's approach for recovering English non-local dependencies and applies it to Chinese. This paper proposes a method based on the Lexical-Functional Grammar f-structures, which differs from our approach. Based on parser output trees including 610 files from the CTB, the authors of this paper claimed they have achieved 64.71% f-score for trace insertion and 54.71% for antecedent recovery.

(Gabbard et al., 2006) describes a more recent effort to fully parse the Penn Treebank, recovering both the function tags and the empty categories. Their approach is similar to ours in that they treat empty category recovery as a post-processing process and use a machine learning algorithm that has access to the skeletal information in the parse tree. Their approach is different from ours in that they have different classifiers for different types of empty categories.

Although generally higher accuracies are reported in works on English empty category recovery, cross-linguistic comparison is difficult because both the types of empty categories and the linguistic cues that are accessible to machine learning algorithms are different. For example, there are no empty complementizers annotated in the CTB while English does not allow dropped pronouns.

6 Conclusion and future work

We describe a unified framework to recover empty categories for Chinese given skeletal parse trees as input. In this framework, empty detection is formulated as a tagging problem where each word in the sentence receives a tag indicating whether there is an empty category before it. This advantage of this approach is that it is amenable to learning-based approaches and can be addressed with a variety of machine learning algorithms. Our results based on a Maximum Entropy model show that given skeletal gold standard parses, empty categories can be recovered with very high accuracy (close to 90%). We also report promising results (over 63%). when automatic parses produced by an off-the-shelf parser is used as input.

Detecting empty categories is only the first step towards fully reproducing the syntactic representation in the CTB, and the obvious next step is to also classify these empty categories into different types and wherever applicable, link the empty categories to their antecedent. This is the line of research we intend to pursue in our future work.

Abstract

We show that unsupervised part of speech tagging performance can be significantly improved using likely substitutes for target words given by a statistical language model. We choose unambiguous substitutes for each occurrence of an ambiguous target word based on its context. The part of speech tags for the unambiguous substitutes are then used to filter the entry for the target word in the word–tag dictionary. A standard HMM model trained using the filtered dictionary achieves 92.25% accuracy on a standard 24,000 word corpus.

1 Introduction

We define the unsupervised part-of-speech (POS) tagging problem as predicting the correct part-of-speech tag of a word in a given context using an unlabeled corpus and a dictionary with possible word–tag pairs[0] The performance of an unsupervised POS tagging system depends highly on the quality of the word–tag dictionary (Banko and Moore, 2004). We propose a dictionary filtering procedure based on likely substitutes suggested by a statistical language model. The procedure reduces the word–tag dictionary size and leads to significant improvement in the accuracy of the POS models.

Probabilistic models such as the hidden Markov model (HMM) trained by expectation maximization (EM), maximum a posteriori (MAP) estimation, and Bayesian methods have been used to solve the unsupervised POS tagging problem (Merialdo, 1994; Goldwater and Griffiths, 2007). All of these approaches first learn the parameters connecting the hidden structure to the observed sequence of variables and then identify the most probable values of the hidden structure for a given observed sequence. They differ in the way they estimate the model parameters. HMM-EM estimates model parameters by using the maximum likelihood estimation (MLE), MAP defines a prior distribution over parameters and finds the parameter values that maximize the posterior distribution given data, and Bayesian methods integrate over the posterior of the parameters to incorporate all possible parameter settings into the estimation process. Some baseline results and performance reports from the literature are presented in Table 1.

(Johnson, 2007) criticizes the standard EM based HMM approaches because of their poor performance on the unsupervised POS tagging and their tendency to assign equal number of words to each hidden state. (Mitzenmacher, 2004) further claims that words have skewed POS tag distributions, and a Bayesian method with sparse priors over the POS tags may perform better than HMM estimated with EM. (Goldwater and Griffiths, 2007) uses a fully Bayesian HMM model that averages over all possible parameter values. Their model achieves 86.8% tagging accuracy with sparse POS priors and outperforms 74.50% accuracy of the standard second order HMM-EM (3-gram tag model) on a 24K word subset of the Penn Treebank corpus. (Smith and Eisner, 2005) take a different approach and use the conditional random fields estimated using contrastive estimation which outperforms the HMM-EM and

[0]In the POS literature the term "unsupervised" is typically used to describe systems that do not directly use the tagged data. However, many of the unsupervised systems, including ours, uses the tag–word dictionary.

Beijing, August 2010

Accuracy	System
64.2	Random baseline
74.4	Second order HMM
82.0	First order HMM
86.8	Fully Bayesian approach with sparse priors (Goldwater and Griffiths, 2007)
88.6	CRF/CE (Smith and Eisner, 2005)
91.4	EM-HMM with language specific information, good initialization and manual adjustments to standard dictionary (Goldberg et al., 2008)
91.8	Minimized models for EM-HMM with 100 random restarts (Ravi and Knight, 2009).
94.0	Most frequent tag baseline

Table 1: Tagging accuracy on a 24K-word corpus. All the systems – except (Goldwater and Griffiths, 2007) – use the same 45 tag dictionary that is constructed from the Penn Treebank.

Bayesian methods by achieving 88.6% accuracy on the same 24K corpus.

Despite the fact that HMM-EM has a poor reputation in POS literature (Goldberg et al., 2008) has shown that with good initialization together with some language specific features and language dependent constraints HMM-EM achieves 91.4% accuracy. Aside from the language specific information and the good initialization, they also manually reduce the noise in the word–tag dictionary.

(Ravi and Knight, 2009) focus on the POS tag collection to find the smallest POS model that explain the data. They apply integer programming to construct a minimal bi-gram POS tag set and use this set to constrain the training phase of the EM algorithm. The model trained by EM is used to reduce the dictionary and these steps are iteratively repeated until no further improvement is observed. Their model achieves 91.6% accuracy on the 24K word corpus (with 100 random starts this goes up to 91.8%). The main advantage of this model is the restriction of the tag set so that rare POS tags or the noise in the corpus do not get incorporated into the estimation process.

Language models for disambiguation: Recent work has shown that statistical language models trained on large amounts of unlabeled text can be used to improve the performance on various disambiguation problems. The language model is used to generate likely substitutes for the target word in the given context and these benefit the disambiguation process to the extent that the likely substitutes are unambiguous or have different ambiguities compared to the target word. Using statistical language models based on large corpora for unsupervised word sense disambiguation and lexical substitution has been explored in (Yuret, 2007; Hawker, 2007; Yuret and Yatbaz, 2010). Unsupervised morphological disambiguation in agglutinative languages using likely substitutes has been shown to improve on standard methods in (Yatbaz and Yuret, 2009).

In this paper we use the statistical language model to reduce the possible number of tags per word to help the disambiguation process. Specifically we assume that the same hidden tag sequence that has generated a particular test sentence can also generate artificial sentences where one of the words has been replaced with a likely substitute. POS tags of the likely substitutes can then be used to reduce the tag set of the target word. Thus, the substitutes are implicitly incorporated into the disambiguation process for reducing the noise and the rare tags in the dictionary.

Currency gyrations can **whipsaw(VB/NN)** the funds .

Table 2: Sample artificial sentences generated for a test sentence from the Penn Treebank.

Table 2 presents an example where the likely unambiguous replacements of the target word "whipsaw" for a given sentence taken from the Penn Treebank (Marcus et al., 1994) are listed. In this example each substitute is an unambiguous verb (VB), confirming our assumption that each artificial sentence comes from the same hidden sequence. For all occurrences of the word "whipsaw", our reduction algorithm will count the POS tags of the likely substitutes and remove the tags

that have not been observed from the dictionary. Assuming that the first sentence in Table 2 is the only sentence in which we observe "whipsaw", the "NN" tag of "whipsaw" will be removed.

The next section describes the details of our dictionary reduction method. Section 3 explains the details of statistical language model. We experimentally demonstrate that the word–tag dictionary reduced by the substitutes improve the performance by constraining the unsupervised model in Section 4. Finally, Section 5 comments on the results and discusses the possible extensions of our method.

2 Dictionary Reduction

Our main assumption is that likely replacements of a target word should have the same POS tag as the target word in a given context. Motivated by this idea we propose a new procedure that automatically reduces the dictionary size by using the unambiguous replacements of the target word. For all occurrences of the target word the procedure counts the POS tags of the replacement words and removes the unobserved POS tags of the target word from the dictionary.

Our approach is based on the idea that similar words in a given context should have the same tag sequence. To reduce the dictionary with the help of the replacement words similar to a target word w, we follow three rules:

1. Choose the replacement word from unambiguous substitutes that are likely to appear in the target word context.

2. Substitutes must be observed in the training corpus.

3. Count the tags of the replacement for all occurrences of the target word.

4. Remove the tags that are not observed as the tag of replacements in any occurrences of the target word.

The first rule is used to increase the likelihood of getting a replacement word with the same POS tag. The second rule makes sure that the size of the vocabulary does not change. The third rule determines the unused POS tags in all occurrences of w and finally, last rule removes the unobserved tags of w from the dictionary.

We use the standard first order HMM to test the performance of our method. In a standard n^{th} order HMM each hidden state is conditioned by its n preceding hidden states and each observation is conditioned by its corresponding hidden state. In POS tagging, the observed variable sequence is a sentence s and the hidden variables t_i are the POS tags of the words w_i in s. The HMM parameters θ can be estimated by using Baum-Welch EM algorithm on an unlabeled training corpus D (Baum, 1972). The tag sequence that maximizes $\Pr(t|s,\hat{\theta})$ can be identified by the Viterbi search algorithm.

3 Statistical Language Modeling

In order to estimate highly probable replacement words for a given word w in the context c_w, we use an n-gram language model. The context is defined as the $2n-1$ word window $w_{-n+1}\dots w_0\dots w_{n-1}$ and it is centered at the target word position. The probability of a word in a given context can be estimated as:

$$\begin{aligned} P(w_0 = w|c_w) &\propto P(w_{-n+1}\dots w_0\dots w_{n-1}) && (1)\\ &= P(w_{-n+1})P(w_{-n+2}|w_{-n+1}) \\ &\quad \dots P(w_{n-1}|w_{-n+1}^{n-2}) && (2)\\ &\propto P(w_0|w_{-n+1}^{-1})P(w_1|w_{-n+2}^{0}) \\ &\quad \dots P(w_{n-1}|w_0^{n-2}) && (3)\end{aligned}$$

where w_i^j represents the sequence of words $w_i w_{i+1}\dots w_j$. In Equation 1, $\Pr(w|c_w)$ is proportional to $\Pr(w_{-n+1}\dots w_0\dots w_{n+1})$ since the context of the target word replacements is fixed. Terms without w_0 are common for every replacement in Equation 2 therefore they have been dropped in Equation 3. Finally, because of the Markov property of n-gram language model, only $n-1$ words are used as a conditional context.

The probabilities in Equation 3 are estimated using a 4 gram language model for all the words in the vocabulary of D that are unambiguous and have a common tag with the target word w. The words with the highest $\Pr(r|c_w)$ where $r \in D$ are selected as the replacement words of w in c_w.

To get accurate domain independent probability estimates we used the Web 1T data-set (Brants and Franz, 2006), which contains the counts of word sequences up to length five in a 10^{12} word corpus derived from publicly accessible Web pages. The SRILM toolkit is used to train 5-gram language model (Stolcke, 2002). The language model parameters are optimized by using a randomly selected 24K words corpus from Penn Treebank. In order to efficiently apply the language model to a given test corpus, the vocabulary size is limited to the words seen in the test corpus.

4 Experiments

In this section we present a number of experiments measuring the performance of several variants of our algorithm. The models in this section are trained[1] and tested on the same unlabeled data therefore there aren't any out-of-vocabulary words. The experiments in this section focus on: (1) the analysis of the dictionary reduction (2) the number of the substitutes used for each ambiguous word and (3) the size of the word–tag dictionary.

4.1 Dataset

We trained HMM-EM models on a corpus that consists of the first 24K words of the Penn Treebank corpus. To be consistent with the POS tagging literature, the tag dictionary is constructed by listing all observed tags for each word in the entire Penn Treebank. Nearly 55% of the words in Penn Treebank corpus are ambiguous and the average number of tags is 2.3.

Groups	Member POS tags	Count	%
Noun	NN/NNP/NNS/NNPS	7511	31.30
Verb	VBD/VB/VBZ/VBN/VBG/VBP	3285	13.69
Adj	JJ/JJR/JJS	1718	7.16
Adv	RB/RBR	742	3.09
Pronoun	CD/PRP/PRP$	1397	5.82
Content	Noun/Verb/Adj/Adv/Pronoun	14653	61.05
Function	Other	9347	38.95
Total	All 45 POS tags	24K	100.00

Table 3: Group names, members, number and percentage of the words according to their gold POS tags.

[1]The GMTK tool is used to train HMM-EM model on an unlabeled corpus (Bilmes and Zweig, 2002).

Table 3 shows the POS speech groups and their distributions in the 24K word corpus. We report the model accuracy on several POS groups. Our motivation is to determine HMM-EM model accuracies on the subgroups before and after implementing the dictionary reduction procedure.

4.2 Baseline

Table 4 presents some standard baselines for comparison. We define a random and a most frequent tag (MFT) baseline on the 24K corpus. The random baseline is calculated by randomly picking one of the tags of each word and it also represents the amount of ambiguity in the corpus. The MFT baseline simply selects the most frequent POS tag of each word from the 1M word Penn Treebank corpus (counts of the first 24K words is not included in the 1M word corpus). If the target word does not exist in the training set, the MFT baseline randomly picks one of the possible tags of the missing word.

The first and second order HMMs can be treated as the unsupervised baselines. These unsupervised baselines are calculated by training uniformly initialized first and second order HMMs on the target corpus without any smoothing. All the initial parameters of HMM-EM are uniformly initialized to observe only the effects of the artificial sentences on the performance of HMM-EM.

The success of the MFT baseline on the $Noun$, Adj, $Pronoun$ and function word groups shows that tag distributions of the words in these groups are more skewed towards to one of the available tags. The MFT baseline performs poorly, compared to the above groups, on $Verb$, and Adv which is due to the less skewed POS tag behavior of these tags.

The POS tagging literature widely uses the second order HMM as the baseline model; however, the performance of this model can be outperformed by an unsupervised first order HMM model or a simple MFT baseline as presented in Table 4. A point worth noting is that although the first order HMM and the MFT baseline have similar content word accuracies, the MFT baseline is significantly better on the function words. This is expected since EM tends to assign words uniformly to the available POS tags. Thus EM can

	Noun	Verb	Adj	Adv	Pronoun	Content	Function	Total(%)
Random Baseline	76.98	53.87	68.46	72.98	87.64	71.59	52.64	64.21
3-gram HMM	77.43	68.16	78.06	73.32	94.85	76.88	70.45	74.38
2-gram HMM	92.22	83.84	85.22	83.96	95.56	89.42	70.49	82.05
MFT Baseline	96.11	80.30	88.56	83.15	98.75	91.28	98.25	93.99

Table 4: Percentages of words tagged correctly by different models using standard dictionary.

not capture the highly skewed behavior of function words. Moreover the amount of skewness affects the accuracy of the EM such that the performance gain of the MFT baseline over the first order HMM on function words is around 28%-30% while the performance gain on $Noun$, Adj and $Pronoun$ is around 3%-4%.

4.3 Reduced Dictionary

EM can not capture the sparse structure of the word distributions therefore it tends to assign equal number of words to each POS tag. Together with the noisy word–tag dictionary great portion of the function words are tagged with very rare POS tags. The abuse of the rare tags is presented in Table 5 in a similar fashion with (Ravi and Knight, 2009). The count of replacement word POS tags and the removed rare POS tags of 2 erroneous function words are also shown in Table 5.

Word	Tag dictionary	Gold tagging	EM tagging	Replacement POS counts
of	{RB,RP,IN}	IN(632)	IN(0)	IN(2377)
		RP(0)	RP(632)	**RP(0)**
		RB(0)	RB(0)	RB(850)
a	{LS,SYM,NNP,	DT(458)	DT(0)	DT(513)
	FW,JJ,IN,DT}	IN(1)	IN(0)	IN(317)
		JJ(2)	JJ(0)	JJ(1329)
		SYM(1)	SYM(258)	**SYM(0)**
		LS(0)	LS(230)	**LS(0)**

Table 5: Removed POS tags of the given words are shown in bold.

The results obtained with the dictionary that is reduced by using 5 replacements are presented in Table 6. Note that with reduced dictionary the uniformly initialized first order HMM-EM achieves 91.85% accuracy. Dictionary reduction also removes some of the useful tags therefore the upper–bound (oracle score) of the 24K dataset becomes 98.15% after the dictionary reduction. We execute 100 random restarts of the EM algorithm and select the model with the highest corpus likelihood, our model achieves 92.25% accuracy which is the highest accuracy reported for the 24K corpus so far.

As Table 6 shows, the effect of the dictionary reduction on the function words is higher than the effect on the content words. The main reason for this situation is, function words are frequently tagged with one of its tags which is also the reason for the high accuracy of the majority voting based baseline on the function words.

The reduced dictionary (RD) removes the rare problematic POS tags of the words as a result the accuracy on the content and function words shows a drastic improvement compared to HMM models trained with the original dictionary.

Pos groups	2-gram HMM accuracy(%)	2-gram HMM RD accuracy(%)
Noun	92.22	94.01
Verb	83.84	84.90
Adj	85.22	89.52
Adv	83.96	85.18
Pronoun	95.56	95.92
Content	89.42	91.18
Function	70.49	92.92
All	82.05	91.85

Table 6: Percentages of the correctly tagged words by different models with modified dictionary. The dictionary size is reduced by using the top 5 replacements of each target word.

4.4 More Data

In this set of experiments we doubled the size of the data and trained HMM-EM models on a corpus that consists of the first 48K words of the Penn Treebank corpus. Our aim is to observe the effect of more data on our dictionary reduction proce-

dure. Using the 5 replacements of each ambiguous word we reduce the dictionary and train a new HMM-EM model using this dictionary. The additional data together with 100 random starts increases the model accuracy to 92.47% on the 48K corpus.

Pos groups	3-gram HMM RD accuracy(%)	2-gram HMM RD accuracy(%)
Noun	89.45	93.47
Verb	85.56	88.99
Adj	86.02	87.53
Adv	94.44	95.92
Pronoun	94.08	94.04
Content	88.91	91.97
Function	92.44	92.26
All	90.31	92.09

Table 7: Percentages of the correctly tagged words by the first and second order HMM-EM model trained on the 48K corpus with reduced dictionary. The dictionary size is reduced by using the top 5 replacements of each target word.

As we mentioned before, when the model is trained using the original dictionary, the performance gap between the first order HMM the second order HMM is around 8% as presented in Table 4. On the other hand, when we use the reduced dictionary together with more data the accuracy gap between the second order and the first order HMM-EM becomes less than 2% as shown in Table 7. This confirms the hypothesis that the low performance of the second order HMM is due to data sparsity in the 24K-word dataset, and better results may be achieved with the second order HMM in larger datasets.

4.5 Number of Replacements

In this set of experiments we vary the number of artificial replacement words per each ambiguous word in s. We run our method on the 24K corpus with 1, 5, 10, 25 and 50 replacement words per ambiguous word and we present the results in Table 8. The performance of our method affected by the the number of replacements and highest score is achieved when 5 replacements are used. Incorporating the probability of the substitutes into the model rather than using a hard cutoff may be a better solution.

Number of replacements	2-gram HMM RD accuracy(%)
none	82.05
1	89.65
5	**91.85**
10	90.09
25	89.97
50	89.83

Table 8: Percentages of the correctly tagged words by the models trained on the 24K corpus with different reduced dictionaries. The dictionary size is reduced by using different number replacements.

4.6 17-Tagset

To observe the effect our method on a model with coarse grained dictionary, we collapsed the 45–tagset treebank dictionary to a 17–tagset coarse dictionary (Smith and Eisner, 2005). The POS literature after the work of Smith and Eisner follows this tradition and also tests the models on this 17–tagset. Table 9 summarizes the previously reported results on coarse grained POS tagging. Our system achieves 92.9% accuracy where the oracle accuracy of 24K dataset with the reduced 17–tagset dictionary is 98.3% and the state-of-the-art system IP+EM scores 96.8%.

Model	Accuracy	Data Size
BHMM	87.3	24K
CE+spl	88.7	24K
RD	**92.9**	24K
LDA+AC	93.4	1M
InitEM-HMM	93.8	1M
IP+EM	96.8	24K

Table 9: Performance of different systems using the coarse grained dictionary.

The IP+EM system constructs a model that describes the data by using minimum number of bigram POS tags then uses this model to reduce the dictionary size (Ravi and Knight, 2009). InitEM-HMM uses the language specific information together with good initialization and it achieves 93.8% accuracy on the 1M word treebank corpus. LDA+AC semi-supervised Bayesian model with strong ambiguity class component given the morphological features of words and scores 93.4% on the 1M word treebank corpus. (Toutanova and Johnson, 2007). CE+spl is HMM model estimated

by contrastive estimation method and achieves 88.7% accuracy (Smith and Eisner, 2005). Finally, BHMM is a fully Bayesian approach that uses sparse POS priors and scores 87.3% (Goldwater and Griffiths, 2007).

5 Contributions

In this paper we proposed a dictionary reduction method that can be applied to unsupervised tagging problems. With the help of a statistical language model, our system creates artificial replacements that are assumed to have the same POS tag as the target word and use them to reduce the size of the word–tag dictionary. To test our method we used HMM-EM as the unsupervised model. Our method significantly improves the prediction accuracy of the unsupervised first order HMM-EM system in all of the POS groups and achieves 92.25% and 92.47% word tagging accuracy on the 24K and 48K word corpora respectively. We also tested our model on a coarse grained dictionary with 17 tags and achieved an accuracy of 92.8%.

In this work, we show that unambiguous replacements of an ambiguous word can reduce the amount of the ambiguity thus replacement words might also be incorporated into the other unsupervised disambiguation problems.

Abstract

In this paper, we investigate the problem of entity identification and relation extraction from encyclopedia articles, and we propose a joint discriminative probabilistic model with arbitrary graphical structure to optimize all relevant subtasks simultaneously. This modeling offers a natural formalism for exploiting rich dependencies and interactions between relevant subtasks to capture mutual benefits, as well as a great flexibility to incorporate a large collection of arbitrary, overlapping and non-independent features. We show the parameter estimation algorithm of this model. Moreover, we propose a new inference method, namely collective iterative classification (CIC), to find the most likely assignments for both entities and relations. We evaluate our model on real-world data from Wikipedia for this task, and compare with current state-of-the-art pipeline and joint models, demonstrating the effectiveness and feasibility of our approach.

1 Introduction

We investigate a compound information extraction (IE) problem from encyclopedia articles, which consists of two subtasks — recognizing structured information about entities and extracting the relationships between entities. The most common approach to this problem is a pipeline architecture: attempting to perform different subtasks, namely, named entity recognition and relation extraction between recognized entities in several separate, and independent stages. Such kind of design is widely adopted in NLP.

The work described in this paper is substantially supported by grants from the Research Grant Council of the Hong Kong Special Administrative Region, China (Project No: CUHK4128/07) and the Direct Grant of the Faculty of Engineering, CUHK (Project Codes: 2050442 and 2050476). This work is also affiliated with the Microsoft-CUHK Joint Laboratory for Human-centric Computing and Interface Technologies.

The most common and simplest approach to performing compound NLP tasks is the 1-best pipeline architecture, which only takes the 1-best hypothesis of each stage and pass it to the next one. Although it is comparatively easy to build and efficient to run, this pipeline approach is highly ineffective and suffers from serious problems such as error propagation (Finkel *et al.*, 2006; Yu, 2007; Yu *et al.*, 2008). It is not surprising that, the end-to-end performance will be restricted and upper-bounded.

Usually, one can pass N-best lists between different stages in pipeline architectures, and this often gives useful improvements (Hollingshead and Roark, 2007). However, effectively making use of N-best lists often requires lots of engineering and human effort (Toutanova, 2005). On the other hand, one can record the complete distribution at each stage in a pipeline, to compute or approximate the complete distribution at the next stage. Doing this is generally infeasible, and this solution is rarely adopted in practice.

One promising way to tackle the problem of error propagation is to explore joint learning which integrates evidences from multiple sources and captures mutual benefits across multiple components of a pipeline for all relevant subtasks simultaneously (e.g., (Toutanova *et al.*, 2005), (Poon and Domingos, 2007), (Singh *et al.*, 2009)). Joint learning aims to handle multiple hypotheses and uncertainty information and predict many variables at once such that subtasks can aid each other to boost the performance, and thus usually leads to complex model structure. However, it is typically intractable to run a joint model and they sometimes can hurt the performance, since they

Coling 2008: Poster Volume, pages 1399–1407,
Beijing, August 2010

increase the number of paths to propagate errors. Due to these difficulties, research on building joint approaches is still in the beginning stage.

A significant amount of recent work has shown the power of discriminatively-trained probabilistic graphical models for NLP tasks (Lafferty *et al.*, 2001; Sutton and McCallum, 2007; Wainwright and Jordan, 2008). The superiority of graphical model is its ability to represent a large number of random variables as a family of probability distributions that factorize according to an underlying graph, and capture complex dependencies between variables. And this progress has begun to make the joint learning approach possible.

In this paper we study and formally define the joint problem of entity identification and relation extraction from encyclopedia text, and we propose a joint paradigm in a single coherent framework to perform both subtasks simultaneously. This framework is based on undirected probabilistic graphical models with arbitrary graphical structure. We show how the parameters in this model can be estimated efficiently. More importantly, we propose a new inference method — collective iterative classification (CIC), to find the maximum a posteriori (MAP) assignments for both entities and relations. We perform extensive experiments on real-world data from Wikipedia for this task, and substantial gains are obtained over state-of-the-art probabilistic pipeline and joint models, illustrating the promise of our approach.

2 Problem Formulation

2.1 Problem Description

This problem involves identifying entities and discovering semantic relationships between entity pairs from English encyclopedic articles. The basic document is an article, which mainly defines and describes an entity (known as *principal entity*). This document mentions some other entities as *secondary entities* related to the principal entity. Clearly, our task consists of two subtasks — first, for entity identification, we need to recognize the secondary entities (both the boundaries and types of them) in the document [1]. Second, after all the secondary entities are identified, our goal for relation extraction is to predict what relation, if any, each secondary entity has to the principal entity. We assume that there is no relationship between any two secondary entities in one document.

As an illustrative example, Figure 1 shows the task of entity identification and relationship extraction from encyclopedic documents. Here, *Abraham Lincoln* is the principal entity. Our task consists of assigning a set of pre-defined entity types (e.g., PER, DATE, YEAR, and ORG) to segmentations in encyclopedic documents and assigning a set of pre-defined relations (e.g., birth_day, birth_year, and member_of) for each identified secondary entity to the principal entity.

2.2 Problem Formulation

Let $\mathbf{x}$ be an observation sequence of tokens in encyclopedic text and $\mathbf{x} = \{x_1, \cdots, x_N\}$. Let s_p be the principal entity (we assume that it is known or can be easily recognized), and let $\mathbf{s} = \{s_1, \cdots, s_L\}$ be a segmentation assignment of observation sequence $\mathbf{x}$. Each segment s_i is a triple $s_i = \{\alpha_i, \beta_i, y_i\}$, where α_i is a start position, β_i is an end position, and y_i is the label assigned to all tokens of this segment. The segment s_i satisfies $0 \leq \alpha_i < \beta_i \leq |\mathbf{x}|$ and $\alpha_{i+1} = \beta_i + 1$. Let r_{pn} be the relation assignment between principal entity s_p and secondary entity candidate s_n from the segmentation $\mathbf{s}$, and $\mathbf{r}$ be the set of relation assignments for sequence $\mathbf{x}$.

Let $\mathbf{y} = \{\mathbf{r}, \mathbf{s}\}$ be the pair of segmentation $\mathbf{s}$ and segment relations $\mathbf{r}$ for an observation sequence $\mathbf{x}$. A valid assignment $\mathbf{y}$ must satisfy the condition that the assignments of the segments and the assignments of the relations of segments are maximized simultaneously. We now formally define this joint optimization problem as follows:

Definition 1 ***(Joint Optimization of Entity Identification and Relation Extraction)****: Given an observation sequence* $\boldsymbol{x}$*, the goal of joint optimization of entity identification and relation extraction is to find the assignment* $\boldsymbol{y}^* = \{\boldsymbol{r}^*, \boldsymbol{s}^*\}$ *that has the maximum a posteriori (MAP) probability*

$$\boldsymbol{y}^* = \arg\max_{\boldsymbol{y}} P(\boldsymbol{y}|\boldsymbol{x}), \quad (1)$$

[1] Since the topic/title of an article usually defines a principal entity (e.g., a famous person) and it is easy to identify, in this paper we only focus on secondary entity identification.

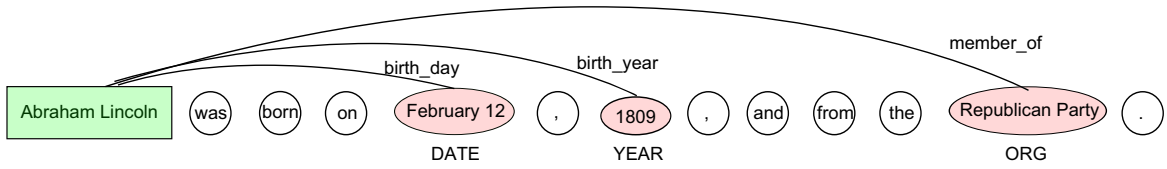

Figure 1: An example of entity identification and relation extraction excerpted from our dataset. The secondary entities are in pink color and labeled. The semantic relation of each secondary entity to the principal entity *Abraham Lincoln* (in green color and we assume that it is known or can be easily recognized) is also shown.

where $\mathbf{r}^*$ *and* $\mathbf{s}^*$ *denote the most likely relation assignment and segmentation assignment, respectively.*

Note that this problem is usually very challenging and offers new opportunities for information extraction, since complex dependencies between segmentations and relations should be exploited.

3 Our Proposed Model

3.1 Preliminaries

Conditional random fields (CRFs) (Lafferty *et al.*, 2001) are undirected graphical models trained to maximize the conditional probability of the desired outputs given the corresponding inputs. Let $\mathcal{G}$ be a factor graph (Kschischang *et al.*, 2001) defining a probability distribution over a set of output variables $\mathbf{o}$ conditioned on observation sequences $\mathbf{x}$. $C = \{\Phi_c(\mathbf{o}_c, \mathbf{x}_c)\}$ is a set of factors in $\mathcal{G}$, then the probability distribution over $\mathcal{G}$ can be written as

$$P(\mathbf{o}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{c \in C} \Phi_c(\mathbf{o}_c, \mathbf{x}_c) \qquad (2)$$

where Φ_c is a potential function and $Z(\mathbf{x}) = \sum_{\mathbf{o}} \prod_{c \in C} \Phi_c(\mathbf{o}_c, \mathbf{x}_c)$ is a normalization factor. We assume the potentials factorize according to a set of features $\{f_k(\mathbf{o}_c, \mathbf{x}_c)\}$ as $\Phi_c(\mathbf{o}_c, \mathbf{x}_c) = \exp(\sum_k \theta_k f_k(\mathbf{o}_c, \mathbf{x}_c))$ so that the family of distributions is an exponential family. The model parameters are a set of real-valued weights $\Theta = \{\theta_k\}$, one weight for each feature. Practical models rely extensively on parameter tying to use the same parameters for several factors.

However, the traditional fashion of CRFs can only deal with single task, they lack the capability to represent more complex interaction between multiple subtasks. In the following we will describe our joint model in detail for this problem.

3.2 A Joint Model for Entity Identification and Relation Extraction

Following the notations in Section 2.2, let L and M be the number of segments and number of relations for sequence $\mathbf{x}$, respectively. We define a joint conditional distribution for segmentation $\mathbf{s}$ in observation sequence $\mathbf{x}$ and segment relation $\mathbf{r}$ in undirected, probabilistic graphical models. The nature of our modeling enables us to partition the factors C of $\mathcal{G}$ into three groups $\{C_S, C_R, C_\nabla\}$=$\{\{\phi^S\}, \{\phi^R\}, \{\phi^\nabla\}\}$, namely the segmentation potential ϕ^S, the relation potential ϕ^R, and the segmentation-relation joint potential ϕ^∇, and each potential is a clique template whose parameters are tied. The potential function $\phi^S(i, \mathbf{s}, \mathbf{x})$ models segmentation $\mathbf{s}$ in $\mathbf{x}$, the potential function $\phi^R(r_{pm}, r_{pn}, \mathbf{r})$ $(m \neq n)$ represent dependencies (e.g., long-distance dependencies, relation transitivity, etc) between any two relations in the relation set $\mathbf{r}$, where r_{pm} is the relation assignment between the principal entity s_p and the secondary entity candidate s_m from $\mathbf{s}$, and similarly for r_{pn}. And the joint potential $\phi^\nabla(s_p, s_j, \mathbf{r})$ captures rich and complex interactions between segmentation $\mathbf{s}$ for secondary entity identification and relation $\mathbf{r}$ between each secondary entity candidate s_j to the principal entity s_p. According to the celebrated Hammersley-Clifford theorem (Besag, 1974), the joint conditional distribution $P(\mathbf{y}|\mathbf{x}) = P(\{\mathbf{r}, \mathbf{s}\}|\mathbf{x})$ is factorized as a product of potential functions over cliques in the graph $\mathcal{G}$ as the form of an exponential family:

$$P(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \Big(\prod_{C_S} \phi^S(i, \mathbf{s}, \mathbf{x}) \Big) \Big(\prod_{C_R} \phi^R(r_{pm}, r_{pn}, \mathbf{r}) \Big) \Big(\prod_{C_\nabla} \phi^\nabla(s_p, s_j, \mathbf{r}) \Big) \qquad (3)$$

where $Z(\mathbf{x}) = \sum_{\mathbf{y}} \prod_{C_S} \phi^S(i, \mathbf{s}, \mathbf{x}) \prod_{C_R} \phi^R(r_{pm}, r_{pn}, \mathbf{r}) \prod_{C_\nabla} \phi^\nabla(s_p, s_j, \mathbf{r})$ is the normalization factor of the joint model.

We assume the potential functions ϕ^S, ϕ^R and ϕ^∇ factorize according to a set of features and a corresponding set of real-valued weights. More specifically, $\phi^S(i, \mathbf{s}, \mathbf{x}) = \exp(\sum_{i=1}^{|\mathbf{s}|} \sum_{k=1}^{K} \lambda_k g_k(i, \mathbf{s}, \mathbf{x}))$. To effectively capture properties of segmentation, we relax the first-order Markov assumption to semi-Markov such that each segment feature function $g_k(\cdot)$ depends on the current segment s_i, the previous segment s_{i-1}, and the whole observation sequence $\mathbf{x}$, that is, $g_k(i, \mathbf{s}, \mathbf{x}) = g_k(s_{i-1}, s_i, \mathbf{x}) = g_k(y_{i-1}, y_i, \alpha_i, \beta_i, \mathbf{x})$. And transitions within a segment can be non-Markovian.

Similarly, the potential $\phi^R(r_{pm}, r_{pn}, \mathbf{r}) = \exp(\sum_{m,n}^{M} \sum_{w=1}^{W} \mu_w q_w(r_{pm}, r_{pn}, \mathbf{r}))$ and $\phi^\nabla(s_p, s_j, \mathbf{r}) = \exp(\sum_{j=1}^{L} \sum_{t=1}^{T} \nu_t h_t(s_p, s_j, \mathbf{r}))$, where W and T are number of feature functions, $q_w(\cdot)$ and $h_t(\cdot)$ are feature functions, μ_w and ν_t are corresponding weights for them. The potential $\phi^R(r_{pm}, r_{pn}, \mathbf{r})$ allows long-range dependency representation between different relations r_{pm} and r_{pn}. For example, if the same secondary entity is mentioned more than once in an observation sequence, all mentions probably have the same relation to the principal entity. Using potential $\phi^R(r_{pm}, r_{pn}, \mathbf{r})$, evidences for the same entity segments to the principal entity are shared among all their occurrences within the document. The joint factor $\phi^\nabla(s_p, s_j, \mathbf{r})$ exploits tight dependencies between segmentations and relations. For example, if a segment is labeled as a *location* and the principal entity is *person*, the semantic relation between them can be *birth_place* or *visited*, but cannot be *employment*. Such dependencies are essential and modeling them often leads to improved performance. In summary, the probability distribution of the joint model can be rewritten as:

$$P(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left\{ \sum_{i=1}^{|\mathbf{s}|} \sum_{k=1}^{K} \lambda_k g_k(i, \mathbf{s}, \mathbf{x}) + \sum_{m,n}^{M} \sum_{w=1}^{W} \mu_w q_w(r_{pm}, r_{pn}, \mathbf{r}) + \sum_{j=1}^{L} \sum_{t=1}^{T} \nu_t h_t(s_p, s_j, \mathbf{r}) \right\} \quad (4)$$

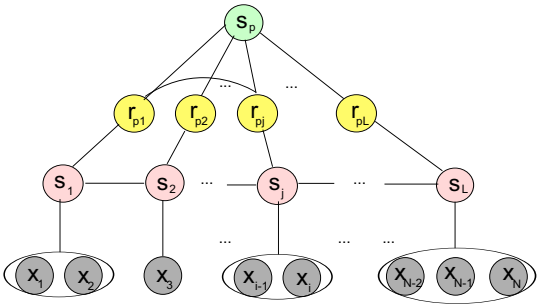

Figure 2: Graphical representation of the probabilistic joint model. The gray nodes represent sequence tokens $\{x_1, \cdots, x_N\}$. Each ellipse represents a segment consisting of several consecutive sequence tokens. The pink nodes represent segmentation assignment $\{s_1, \cdots, s_L\}$ of sequence. The yellow nodes represent relation assignment $\{r_{p1}, \cdots, r_{pL}\}$ between the principal entity s_p (in green color) and secondary entity segments.

As illustrated in Figure 2, our model consists of three sub-structures: a semi-Markov chain on the segmentations $\mathbf{s}$ conditioned on the observation sequences $\mathbf{x}$, represented by ϕ^S; potential ϕ^R measuring dependencies between different relations r_{pm} and r_{pn}; and a fully-connected graph on the principal entity s_p and each segment s_j for their relations, represented by ϕ^∇.

While several special cases of CRFs are of particular interest, and we emphasize on the differences and advantages of our model against others. Linear-chain CRFs (Lafferty *et al.*, 2001) can only perform single sequence labeling, they lack the ability to capture long-distance dependency and represent complex interactions between multiple subtasks. Skip-chain CRFs (Sutton and Mccallum, 2004) introduce skip edges to model long-distance dependencies to handle the label consistency problem in single sequence labeling and extraction. 2D CRFs (Zhu *et al.*, 2005) are two-dimensional conditional random fields incorporating the two-dimensional neighborhood dependencies in Web pages, and the graphical representation of this model is a 2D grid. Hierarchical CRFs (Liao *et al.*, 2007) are a class of CRFs with hierarchical tree structure. Our probabilistic model for joint entity identification and relation extraction has distinct graphical structure from 2D and hierarchical CRFs. And this modeling has sev-

eral advantages over previous probabilistic graphical models by using semi-Markov chains for efficient segmentation and labeling, by representing long-range dependencies between relations, and by capturing rich and complex interactions between relevant subtasks to exploit mutual benefits.

4 Learning the Parameters

Given independent and identically distributed (IID) training data $\mathcal{D} = \{\mathbf{x}^i, \mathbf{y}^i\}_{i=1}^{\mathbb{N}}$, where $\mathbf{x}^i$ is the i-th sequence instance, $\mathbf{y}^i = \{\mathbf{r}^i, \mathbf{s}^i\}$ is the corresponding segmentation and relation assignments. The objective of learning is to estimate $\Lambda = \{\lambda_k, \mu_w, \nu_t\}$ which is the vector of model's parameters. Under the IID assumption, we ignore the summation operator $\sum_{i=1}^{\mathbb{N}}$ in the log-likelihood during the following derivations. To reduce over-fitting, we use regularization and a common choice is a spherical Gaussian prior with zero mean and covariance $\sigma^2 I$. Then the regularized log-likelihood function $\mathcal{L}$ for the data is

$$\mathcal{L} = \log\big[\Phi(\mathbf{r}, \mathbf{s}, \mathbf{x})\big] - \log\big[Z(\mathbf{x})\big] - \sum_{k=1}^{K} \frac{\lambda_k^2}{2\sigma_\lambda^2} - \sum_{w=1}^{W} \frac{\mu_w^2}{2\sigma_\mu^2} - \sum_{t=1}^{T} \frac{\nu_t^2}{2\sigma_\nu^2} \quad (5)$$

where $\Phi(\mathbf{r}, \mathbf{s}, \mathbf{x}) = \exp\{\sum_{i=1}^{|\mathbf{s}|} \sum_{k=1}^{K} \lambda_k g_k(i, \mathbf{s}, \mathbf{x}) + \sum_{m,n}^{M} \sum_{w=1}^{W} \mu_w q_w(r_{pm}, r_{pn}, \mathbf{r}) + \sum_{j=1}^{L} \sum_{t=1}^{T} \nu_t h_t(s_p, s_j, \mathbf{r})\}$, $Z(\mathbf{x}) = \sum_{\mathbf{y}} \prod \Phi(\mathbf{r}, \mathbf{s}, \mathbf{x})$, and $1/2\sigma_\lambda^2$, $1/2\sigma_\mu^2$, $1/2\sigma_\nu^2$ are regularization parameters.

Taking derivatives of the function $\mathcal{L}$ over the parameter λ_k yields:

$$\frac{\partial \mathcal{L}}{\partial \lambda_k} = \sum_{i=1}^{|\mathbf{s}|} g_k(i, \mathbf{s}, \mathbf{x}) - \sum_{i=1}^{|\mathbf{s}|} g_k(i, \mathbf{s}, \mathbf{x}) P(\mathbf{y}|\mathbf{x}) - \sum_{k=1}^{K} \frac{\lambda_k}{\sigma_\lambda^2} \quad (6)$$

Similarly, the partial derivatives of the log-likelihood with respect to parameters μ_w and nu_t are as follows:

$$\frac{\partial \mathcal{L}}{\partial \mu_w} = \sum_{m,n}^{M} q_w(r_{pm}, r_{pn}, \mathbf{r}) - \sum_{m,n}^{M} q_w(r_{pm}, r_{pn}, \mathbf{r}) \times P(\mathbf{y}|\mathbf{x}) - \sum_{w=1}^{W} \frac{\mu_w}{\sigma_\mu^2} \quad (7)$$

$$\frac{\partial \mathcal{L}}{\partial \nu_t} = \sum_{j=1}^{L} h_t(s_p, s_j, \mathbf{r}) - \sum_{j=1}^{L} h_t(s_p, s_j, \mathbf{r}) P(\mathbf{y}|\mathbf{x}) - \sum_{t=1}^{T} \frac{\nu_t}{\sigma_\nu^2} \quad (8)$$

The function $\mathcal{L}$ is concave, and can be efficiently maximized by standard techniques such as stochastic gradient and limited memory quasi-Newton (L-BFGS) algorithms. The parameters λ_k μ_w and ν_t are optimized iteratively until converge.

5 Finding the Most Likely Assignments

The objective of inference is to find $\mathbf{y}^* = \{\mathbf{r}^*, \mathbf{s}^*\} = \arg\max_{\{\mathbf{r},\mathbf{s}\}} P(\mathbf{r}, \mathbf{s}|\mathbf{x})$ such that both $\mathbf{s}^*$ and $\mathbf{r}^*$ are optimized simultaneously. Unfortunately, exact inference to this problem is generally prohibitive, since it requires enumerating all possible segmentation and corresponding relation assignments. Consequently, approximate inference becomes an alternative.

We propose a new algorithm: collective iterative classification (CIC) to perform approximate inference to find the maximum a posteriori (MAP) segmentation and relation assignments of our model in an iterative fashion. The basic idea of CIC is to decode every target hidden variable based on the assigning labels of its sampled variables, where the labels might be dynamically updated throughout the iterative process. Collective classification refers to the classification of relational objects described as nodes in a graphical structure, as in our model.

The CIC algorithm performs inference in two steps, as shown in Algorithm 1. The first step, `bootstrapping`, predicts an initial labeling assignment for a unlabeled sequence $\mathbf{x}_i$, given the trained model $P(\mathbf{y}|\mathbf{x})$. The second step is the `iterative classification` process which re-estimates the labeling assignment of $\mathbf{x}_i$ several times, picking them in a sample set $\mathcal{S}$ based on initial assignment for $\mathbf{x}_i$. Here we exploit the sampling technique (Andrieu *et al.*, 2003). The advantages of sampling are summarized as follows. Sampling stochastically enables us to generate a wide range of inference situations, and the samples are likely to be in high probability areas, increasing our chances of finding the max-

imum, thus leading to more robust and accurate performance. The CIC algorithm may converge if none of the labeling assignments change during an iteration or a given number of iterations is reached.

Noticeably, this inference algorithm is also used to efficiently compute the marginal probability $P(\mathbf{y}|\mathbf{x})$ during parameter estimation (the normalization constant $Z(\mathbf{x})$ can also be calculated via approximation techniques). As can be seen, this algorithm is simple to design, efficient and scales well *w.r.t.* the size of data.

Algorithm 1: Collective Iterative Classification Inference

Input: A unlabeled sequence $\mathbf{x}_i$ and a trained model $P(\mathbf{y}|\mathbf{x})$
Output: The set of predicted assignment $y_i = \{r_i, s_i\}$
`// Bootstrapping`
foreach $y_i \in \mathcal{Y}$ **do**
  $\overline{y_i} \leftarrow \arg\max_{y_i} P(y_i|x_i)$;
end
`// Iterative Classification`
repeat
  Generate a sample set $\mathcal{S}$ based on initial label assignment $\overline{y_i}$ for sequence $\mathbf{x}_i$;
  foreach $\mathbb{s}_i \in \mathcal{S}$ **do**
    Assign new label assignment to sample $\mathbb{s}_i$;
  end
until *all labels have stabilized or a threshold number of iterations have elapsed* ;
return $y_i = \{r_i, s_i\}$

6 Experiments

6.1 Data

Our data comes from Wikipedia[2], the world's largest free online encyclopedia. This dataset consists of 1127 paragraphs from 441 pages from the online encyclopedia Wikipedia. We labeled 7740 entities into 8 categories, yielding 1243 *person*, 1085 *location*, 875 *organization*, 641 *date*, 1495 *year*, 38 *time*, 59 *number*, and 2304 *miscellaneous* names. This dataset also contains 4701 relation instances and 53 labeled relation types. The 10 most frequent relation types are *job_title*, *visited*, *birth_place*, *associate*, *birth_year*, *member_of*, *birth_day*, *opus*, *death_year*, and *death_day*. Note that this compound IE task involving entity identification and relation extraction is very challenging, and modeling tight interactions between entities and their relations is highly attractive.

6.2 Feature Set

Accurate entities enable features that are naturally expected to be useful to boost relation extraction. And a wide range of rich, overlapping features can be exploited in our model. These features include contextual features, part-of-speech (POS) tags, morphological features, entity-level dictionary features, clue word features. Feature conjunctions are also used. In leveraging relation extraction to improve entity identification, we use a combination of syntactic, entity, keyword, semantic, and Wikipedia characteristic features. More importantly, our model can incorporate multiple mention features $q_w(\cdot)$, which are used to collect evidences from other occurrences of the same secondary entities for consistent segmentation and relation labeling to the principal entity. The features $h_t(\cdot)$ capture deep dependencies between segmentations and relations, and they are natural and useful to enhance the performance.

[2]http://www.wikipedia.org/

6.3 Methodology

We perform four-fold cross-validation on this dataset, and take the average performance. For performance evaluation, we use the standard measures of Precision (P), Recall (R), and F-measure (the harmonic mean of P and R: $\frac{2PR}{P+R}$) for both entity identification and relation extraction. We conduct holdout methodology for parameter tuning and optimization of our model. We compare our approach with a series of linear-chain CRFs: **CRF+CRF** and a joint model **DCRF** (Sutton *et al.*, 2007): dynamic probabilistic models combined with factored approach to multiple sequence labeling. **CRF+CRF** perform entity identification and relation extraction separately. Relation extraction is viewed as a sequence labeling problem in the second CRF. All these models exploit standard parameter learning and inference algorithms

Table 1: Comparative performance of our model, CRF+CRF, and DCRF models for entity identification.

Entities	CRF+CRF			DCRF			Our model

in our experiments. To avoid over-fitting, penalization techniques on likelihood are performed. We also use the same set of features for all these models.

6.4 Experimental Results

Table 1 shows the performance of entity identification and Table 2 shows the overall performance of relation extraction [3], respectively. Our model substantially outperforms all baseline models on the overall F-measure for entity identification, resulting in an relative error reduction of up to 38.97% and 28.83% compared to **CRF+CRF** and **DCRF**, respectively. For relation extraction, the improvements on the F-measure over **CRF+CRF** and **DCRF** are 4.68% and 3.75%. McNemar's paired tests show that all improvements of our model over baseline models are statistically significant. These results demonstrate the merits of our approach by capturing tight interactions between entities and relations to explore mutual benefits. The pipeline model **CRF+CRF** performs entity identification and relation extraction independently, and suffers from problems such as error accumulation. For example, **CRF+CRF** cannot extract the *member_of* relation between the secondary entity *Republican* and the principal entity *George W. Bush*, since the organization name *Republican* is incorrectly labeled as a *miscellaneous*. By modeling interactions between two subtasks, enhanced performance is achieved, as illustrated by **DCRF**. Unfortunately, training a **DCRF** model with unobserved nodes (hidden variables) makes this approach difficult to optimize, as we will show below.

[3]Due to space limitation, we only present the overall performance and omit the performance for 53 relation types.

Table 2: Comparative performance of our model, CRF+CRF, and DCRF models for relation extraction.

Model	Precision	Recall	F-measure
CRF+CRF	70.40	57.85	63.51
DCRF	69.30	60.22	64.44
Our model	72.57	64.30	**68.19**

The efficiency of different models is summarized in Table 3. Compared to the pipeline model **CRF+CRF**, the learning time of our model is only a small constant factor slower. Notably, our model is over orders of magnitude (approximately 15.7 times) faster than the joint model **DCRF**. The **DCRF** model uses loopy belief propagation (LBP) for approximate learning and inference. When the graph has large tree-width as in our case, the LBP algorithm in **DCRF** is inefficient, and is slow to converge. Using L-BFGS and the CIC approximate inference algorithms, both learning and decoding can be carried out efficiently.

Table 3: Efficiency comparison of different models on learning time (sec.) and inference time (sec.).

Model	Learning time	Inference time
CRF+CRF	2822.55	6.20
DCRF	105993.00	127.50
Our model	6733.69	62.75

Table 4 compares our CIC inference with two state-of-the-art inference approaches: Gibbs sampling (GS) (Geman and Geman, 1984) and the iterative classification algorithm (ICA) (Neville and Jensen, 2000) for our model. The CIC inference is shown empirically to help improve classi-

Table 4: Comparative performance of different inference algorithms for our model on entity identification and relation extraction.

Entity	Precision	Recall	F-measure
GS	92.45	92.15	92.30
ICA	92.19	91.98	92.08
CIC	93.35	93.37	**93.36**
Relation	Precision	Recall	F-measure
GS	71.22	63.29	67.02
ICA	71.58	63.68	67.40
CIC	72.57	64.30	**68.19**

fication accuracy and robustness over these two algorithms. When probability distributions are very complex or even unknown, the GS algorithm cannot be applied. ICA iteratively infers the states of variables given the current predicted labeling assignments of neighboring variables as observed information. Prediction errors on labels may then propagate during the iterations and the algorithm will then have difficulties to generalize correctly.

We mention some recently published results related to Wikipedia datasets (Note that it is difficult to compare with them strictly, since these results can be based on different experimental settings). Culotta *et al.* (2006) used a data set with a 70/30 split for training/testing and Nguyen *et al.* (2007) used 5930 articles for training and 45 for testing, to perform relatione extraction from Wikipedia. And the obtained F-measures were 67.91 and 37.76, respectively. Yu *et al.* (2009) proposed an integrated approach incorporating probabilistic graphical models with first-order logic to perform relation extraction from encyclopedia articles, with a F-measure of 65.66. All these systems assume that the golden-standard entities are already known and they only perform relation extraction. However, such assumption is not valid in practice. Notably, our approach deals with a fairly more challenging problem involving both entity identification and relation extraction, and it is more applicable to real-world IE tasks.

7 Related Work

A number of previous researchers have taken steps toward joint models in NLP and information extraction, and we mention some recently proposed, closely related approaches here. Roth and Yih (2007) considered multiple constraints between variables from tasks such as named entities and relations, and developed a integer linear programming formulation to seek an optimal global assignment to these variables. Zhang and Clark (2008) employed the generalized perceptron algorithm to train a statistical model for joint segmentation and POS tagging, and applied multiple-beam search algorithm for fast decoding. Toutanova *et al.* (2008) presented a model capturing the linguistic intuition that a semantic argument frame is a joint structure, with strong dependencies among the arguments. Finkel and Manning (2009) proposed a discriminative feature-based constituency parser for joint named entity recognition and parsing. And Dahlmeier *et al.* (2009) proposed a joint model for word sense disambiguation of prepositions and semantic role labeling of prepositional phrases. However, most of the mentioned approaches are task-specific (e.g., (Toutanova *et al.*, 2008) for semantic role labeling, and (Finkel and Manning, 2009) for parsing and NER), and they can hardly be applicable to other NLP tasks. Since we capture rich and complex dependencies between subtasks via potential functions in probabilistic graphical models, our approach is general and can be easily applied to a variety of NLP and IE tasks.

8 Conclusion and Future Work

In this paper, we investigate the compound IE task of identifying entities and extracting relations between entities in encyclopedia text. And we propose a unified framework based on undirected, conditionally-trained probabilistic graphical models to perform all relevant subtasks jointly. More importantly, we propose a new algorithm: CIC, to enable approximate inference to find the MAP assignments for both segmentations and relations. As we shown, our modeling offers several advantages over previous models and provides a natural formalism for this compound task. Experimental study exhibits that our model significantly outperforms state-of-the-art models while also running much faster than the joint models. In addition, the superiority of the CIC algorithm is also discussed and compared. We plan to improve the scalability of our approach and apply it to other real-world problems in the future.

Abstract

We present the first known empirical results on sequence labeling based on maximum margin Markov networks (M^3N), which incorporate both kernel methods to efficiently deal with high-dimensional feature spaces, and probabilistic graphical models to capture correlations in structured data. We provide an efficient algorithm, the stochastic gradient descent (SGD), to speedup the training procedure of M^3N. Using official dataset for noun phrase (NP) chunking as a case study, the resulting optimizer converges to the same quality of solution over an order of magnitude faster than the structured sequential minimal optimization (structured SMO). Our model compares favorably with current state-of-the-art sequence labeling approaches. More importantly, our model can be easily applied to other sequence labeling tasks.

1 Introduction

The problem of annotating or labeling observation sequences arises in many applications across a variety of scientific disciplines, most prominently in natural language processing, speech recognition, information extraction, and bioinformatics. Recently, the predominant formalism for modeling and predicting label sequences has been based on discriminative graphical models and variants.

Among such models, maximum margin Markov networks (M^3N) and variants (Taskar *et al.* (2003); Taskar (2004); Taskar *et al.* (2005)) have recently gained popularity in the machine learning community. While the M^3N framework makes extensive use of many theoretical results available for Markov networks, it largely dispenses with the probabilistic interpretation. M^3N thus combines the advantages of both worlds, the possibility to have a concise model of the relationships present in the data via log-linear Markov networks over a set of label variables and the highly accurate predictions based on maximum margin estimation of the model parameters.

Traditionally, M^3N can be trained using the structured sequential minimal optimization (structured SMO), a coordinate descent method for solving quadratic programming (QP) problems (Taskar *et al.*, 2003). Clearly, however, the polynomial number of constraints in the QP problem associated with the M^3N can still be very large, making the structured SMO algorithm slow to converge over the training data. This currently limits the scalability and applicability of M^3N to large-scale real world problems.

Stochastic gradient methods (e.g., Lecun *et al.* (1998); Bottou (2004)), on the other hand, are online and scale sub-linearly with the amount of training data, making them very attractive for large-scale datasets. In stochastic (or online) gradient descent (SGD), the true gradient is approximated by the gradient of the cost function only evaluated on a single training example. The parameters are then adjusted by an amount proportional to this approximate gradient. Therefore, the parameters of the model are updated after each training example. For large-scale datasets, online gradient descent can be much faster than standard (or batch) gradient descent.

In this paper, we marry the above two techniques and show how SGD can be used to significantly accelerate the training of M^3N. And we

The work described in this paper is substantially supported by grants from the Research Grant Council of the Hong Kong Special Administrative Region, China (Project No: CUHK4128/07) and the Direct Grant of the Faculty of Engineering, CUHK (Project Codes: 2050442 and 2050476). Beijing, August 2010

then apply our model to the well-established sequence labeling task: noun phrase (NP) chunking. Experimental results show the validity and effectiveness of our approach. We now summarize the primary contributions of this paper as follows:

- We exploit M^3N to NP chunking on the standard evaluation dataset, achieving favorable performance against recent top-performing systems. The M^3N framework allows arbitrary features of observation sequence, as well as the important benefits of kernels. To the best of our knowledge, this is the first known empirical study on NP chunking using M^3N in the NLP community.

- We provide the efficient SGD algorithm to accelerate the training procedure of M^3N, and experimental results show that it converges over an order of magnitude faster than the structured SMO without sacrificing performance.

- Our model is easily extendable to other sequence labeling tasks, such as part-of-speech tagging and named entity recognition. Based on the promising results on NP chunking, we believe that our model will significantly further the applicability of margin-based approaches to large-scale sequence labeling tasks.

2 Maximum Margin Markov Networks for Sequence Labeling

In sequence labeling, the output is a sequence of labels $\mathbf{y} = (y_1, \ldots, y_T)$ which corresponds to an observation sequence $\mathbf{x} = (x_1, \ldots, x_T)$. Suppose each individual label can take values from set Σ, then the problem can be considered as a multiclass classification problem with $|\Sigma|^T$ different classes.

In M^3N, a pairwise Markov network is defined as a graph $\mathcal{G} = (Y, E)$. Each edge $(i, j) \in E$ is associated with a potential function

$$\begin{aligned}\psi_{ij}(\mathbf{x}, y_i, y_j) &= \exp(\sum_{k=1}^{l} w_k \phi_k(\mathbf{x}, y_i, y_j)) \\ &= \exp(\mathbf{w}^\top \phi(\mathbf{x}, y_i, y_j)) \end{aligned} \quad (1)$$

where $\phi(\mathbf{x}, y_i, y_j)$ is a pairwise basis function. All edges in the graph denote the same type of interaction, so that we can define a feature map $\phi_k(\mathbf{x}, \mathbf{y}) = \sum_{(i,j)\in E} \phi_k(\mathbf{x}, y_i, y_j)$. The network encodes the following conditional probability distribution (Taskar *et al.*, 2003):

$$P(\mathbf{y}|\mathbf{x}) \propto \prod_{(i,j)\in E} \psi_{ij}(\mathbf{x}, y_i, y_j) = \exp(\mathbf{w}^\top \phi(\mathbf{x}, \mathbf{y})) \quad (2)$$

where $\phi(\mathbf{x}, \mathbf{y}) = [\phi_1 \phi_2 \ldots \phi_{|\Sigma|} \phi_{trans}]^\top$ is used to learn a weight vector $\mathbf{w}$. $\phi_k = \sum_{i=1}^{n} \phi_i(x) \mathcal{I}(y_i = k), \forall k \in \{1, 2, \ldots, |\Sigma|\}$ and $\phi_{trans} = [c_{11} c_{12} \ldots c_{TT}]^\top$ where c_{ij} is the number of observed transitions from the i^{th} alphabet to the j^{th} alphabet in Σ.

Similar to SVMs (Vapnik, 1995), M^3N tries to find a projection to maximize the margin γ. On the other hand, M^3N also attempts to minimize $\|\mathbf{w}\|$ to minimize the generalization error. Suppose $\Delta \mathbf{t}_{\mathbf{x}}(\mathbf{y}) = \sum_{i=1}^{n} \Delta \mathbf{t}_{\mathbf{x}}(y_i) = \sum_{i=1}^{n} I(y_i \neq (\mathbf{t}(\mathbf{x}))_i)$ where $\mathbf{t}((\mathbf{x}))_i$ is the true label of the i^{th} sequence x_i, and $\Delta \phi_{\mathbf{x}}(\mathbf{y}) = \phi(\mathbf{x}, \mathbf{t}(\mathbf{x})) - \phi(\mathbf{x}, \mathbf{y})$ where $\mathbf{t}(\mathbf{x})$ is the true label of the observation sequence $\mathbf{x}$. We can get a quadratic program (QP) using a standard transformation to eliminate γ as follows:

$$\begin{aligned} \min \quad & \frac{1}{2}\|\mathbf{w}\|^2; \\ \text{s.t.} \quad & \mathbf{w}^\top \Delta \phi_{\mathbf{x}}(\mathbf{y}) \geq \Delta \mathbf{t}_{\mathbf{x}}(\mathbf{y}), \forall \mathbf{x} \in S, \forall \mathbf{y} \in \Sigma. \end{aligned} \quad (3)$$

However, the sequence data is often not separable by the defined hyperplane. In such cases, we can introduce slack variables $\xi_{\mathbf{x}}$ which are guaranteed to be non-negative to allow some constraints. Thus the complete primal form of the optimization problem can be formulated by:

$$\begin{aligned} \min \quad & \frac{1}{2}\|\mathbf{w}\|^2 + \mathcal{C} \sum_{\mathbf{x}} \xi_{\mathbf{x}}; \\ \text{s.t.} \quad & \mathbf{w}^\top \Delta \phi_{\mathbf{x}}(\mathbf{y}) \geq \Delta \mathbf{t}_{\mathbf{x}}(\mathbf{y}) - \xi_{\mathbf{x}}, \forall \mathbf{x} \in S, \forall \mathbf{y} \in \Sigma. \end{aligned} \quad (4)$$

where $\mathcal{C}$ is called the capacity in the support vector literature and presents a way to trade-off the training error and margin size. One should note that the number of constraints is $\sum_{i=1}^{T} |\Sigma^i|$, an extremely large number. And the corresponding dual formu-

lation can be defined as:

$$\max \sum_{\mathbf{x},\mathbf{y}} \alpha_{\mathbf{x}}(\mathbf{y})\Delta\mathbf{t}_{\mathbf{x}}(\mathbf{y}) - \frac{1}{2}\|\sum_{\mathbf{x},\mathbf{y}} \alpha_{\mathbf{x}}(\mathbf{y})\Delta\phi_{\mathbf{x}}(\mathbf{y})\|^2;$$
$$\text{s.t.} \sum_{\mathbf{y}} \alpha_{\mathbf{x}}(\mathbf{y}) = \mathcal{C}, \forall\mathbf{x}; \alpha_{\mathbf{x}}(\mathbf{y}) \geq 0, \forall\mathbf{x},\mathbf{y}. \quad (5)$$

where $\alpha_{\mathbf{x}}(\mathbf{y})$ is a dual variable.

As well as loss functions, kernels might have substantial influence on the performance of a classification system. M^3N is capable of incorporating many different kinds of kernel functions to reduce computations in the high-dimensional feature space $\mathcal{H}$. This is sometimes referred to as the "kernel trick" (Schölkopf and Smola, 2002; Shawe-Taylor and Cristianini, 2004). A linear kernel can be defined as

$$\kappa((\mathbf{x},\mathbf{y}),(\mathbf{x}',\mathbf{y}')) = \langle\phi(\mathbf{x},\mathbf{y}),\phi(\mathbf{x}',\mathbf{y}')\rangle_{\mathcal{H}} \quad (6)$$

For a polynomial kernel,

$$\kappa((\mathbf{x},\mathbf{y}),(\mathbf{x}',\mathbf{y}')) = (s\cdot\langle\phi(\mathbf{x},\mathbf{y}),\phi(\mathbf{x}',\mathbf{y}')\rangle_{\mathcal{H}} + r)^d, \quad (7)$$

and for a neural kernel,

$$\kappa((\mathbf{x},\mathbf{y}),(\mathbf{x}',\mathbf{y}')) = \tanh(s\cdot\langle\phi(\mathbf{x},\mathbf{y}),\phi(\mathbf{x}',\mathbf{y}')\rangle_{\mathcal{H}} + r), \quad (8)$$

where s, d, and r are coefficients in kernel functions.

3 Stochastic Gradient Descent

For M^3N optimization, Taskar *et al.* (2003) has proposed a reparametrization of the dual variables to take advantage of the network structure of the labeling sequence problem. The dual QP is then solved using the structured sequential minimal optimization (structured SMO) analogous to the SMO used for SVMs (Platt, 1998). However, the resulting number of constraints in the QP make the structured SMO algorithm slow to converge, or even prohibitively expensive for large-scale real world problems. In this section we will present stochastic gradient descent (SGD) method, and show SGD can significantly speedup the training of M^3N.

3.1 Regularized Loss Minimization

Recall that for M^3N, the goal is to find a linear hypothesis $h_{\mathbf{w}}$ such that $h_{\mathbf{w}}(\mathbf{x}) = \arg\max_{\mathbf{y}\in\Sigma} \mathbf{w}^\top\phi(\mathbf{x},\mathbf{y})$. The parameters $\mathbf{w}$ are learned by minimizing a regularized loss

$$\mathcal{L}(\mathbf{w};\{(x_i,y_i)\}_{i=1}^T, C) = \sum_{i=1}^m \ell(\mathbf{w},x_i,y_i) + \frac{C}{2}\|\mathbf{w}\|^2. \quad (9)$$

The function ℓ measures the loss incurred in using $\mathbf{w}$ to predict the label of x_i. Following (Taskar *et al.*, 2003), $\ell(\mathbf{w},x_i,y_i)$ is a variant of the hinge loss, and can be defined as follows:

$$\ell(\mathbf{w},x_i,y_i) = \max_{\mathbf{y}\in\Sigma}[e(x_i,y_i,\mathbf{y}) - \mathbf{w}\cdot(\phi(x_i,y_i) - \phi(x_i,\mathbf{y}))], \quad (10)$$

where $e(x_i,y_i,\mathbf{y})$ is some non-negative measure of the error incurred in predicting y instead of y_i as the label of x_i. We assume that $e(x_i,y_i,\mathbf{y}) = 0$ for all i, so that no loss is incurred for correct prediction, and therefore $\ell(\mathbf{w},x_i,y_i)$ is always non-negative. This loss function corresponds to the M^3N approach, which explicitly penalizes training examples for which, for some $y \neq y_i$, $\mathbf{w}\cdot(\phi(x_i,y_i) - \phi(x_i,\mathbf{y})) < e(x_i,y_i,\mathbf{y})$. And the function $\mathcal{L}$ is convex in $\mathbf{w}$ for $\ell(\mathbf{w},x_i,y_i)$. Therefore, minimization of $\mathcal{L}$ can be re-cast as optimization of the following dual convex problem:

$$\mathbf{w}^* = \arg\min_{\mathbf{w}} \sum_i \max_{\mathbf{y}\in\Sigma}[e(x_i,y_i,\mathbf{y}) - \mathbf{w}\cdot(\phi(x_i,y_i) - \phi(x_i,\mathbf{y}))] + \frac{C}{2}\|\mathbf{w}\|^2. \quad (11)$$

3.2 The SGD Algorithm

To perform parameter estimation, we need to minimize $\mathcal{L}(\mathbf{w};\{(x_i,y_i)\}_{i=1}^T, C)$. For this purpose we compute its gradient $\mathbf{G}(\mathbf{w})$:

$$\mathbf{G}(\mathbf{w}) = \frac{\partial}{\partial\mathbf{w}}(\mathcal{L}(\mathbf{w};\{(x_i,y_i)\}_{i=1}^T, C)) = \frac{\partial}{\partial\mathbf{w}}(\sum_{i=1}^m \ell(\mathbf{w},x_i,y_i) + \frac{C}{2}\|\mathbf{w}\|^2) \quad (12)$$

In addition to the gradient, second-order methods based on Newton steps also require computation and inversion of the Hessian $\mathbf{H}(\mathbf{w})$. Taking

the gradient of Equation 12 *wrt.* $\mathbf{w}$ yields:

$$\mathbf{H}(\mathbf{w}) = \frac{\partial}{\partial \mathbf{w}}\mathbf{G}(\mathbf{w}) = \frac{\partial^2}{\partial \mathbf{w}^2}\mathcal{L} \tag{13}$$

Explicitly computing the full Hessian is time consuming. Instead we can make use of the differential

$$\mathrm{d}\mathbf{G}(\mathbf{w}) = \mathbf{H}(\mathbf{w})\mathrm{d}\mathbf{w} \tag{14}$$

to efficiently compute the product of the Hessian with a chosen vector $\mathbf{v} =: \mathrm{d}\mathbf{w}$ by forward-mode algorithmic differentiation (Pearlmutter, 1994). These Hessian-vector products can be computed along with the gradient at only 2-3 times the cost of the gradient computation alone. We denote $\mathbf{G}(\mathbf{w}) = \nabla_{\mathbf{w}}\mathcal{L}$, and each iteration of the SGD algorithm consists in drawing an example (x_i, y_i) at random and applying the parameter update rule (Robbins and Monroe, 1951):

$$\mathbf{w}_{t+1} \leftarrow \mathbf{w}_t - \eta \cdot \nabla_{\mathbf{w}}\mathcal{L} \tag{15}$$

where η is the learning rate in the algorithm.

The SGD algorithm has been shown to be fast, reliable, and less prone to reach bad local minima. In this algorithm, the weights are updated after the presentation of each example, according to the gradient of the loss function (Lecun *et al.*, 1998). The convergence is very fast when the training examples are redundant since only a few examples are needed to perform. This algorithm can get a good estimation after considerably few iterations.

3.3 Choosing Learning Rate η

The learning rate η is crucial to the speed of SGD algorithm. Ideally, each parameter weight w_i should have its own learning rate η_i. Because of possible correlations between input variables, the learning rate of a unit should be inversely proportional to the square root of the number of inputs to the unit. If shared weights are used, the learning rate of a weight should be inversely proportional to the square root of the number of connection sharing that weight.

For one-dimensional sequence labeling task, the optimal learning rate yields the fastest convergence in the direction of highest curvature is (Bottou, 2004):

$$\eta_{\text{opt}} = (\frac{\partial^2 \mathcal{L}}{\partial \mathbf{w}^2})^{-1} = (\mathbf{H}(\mathbf{w}))^{-1}, \tag{16}$$

and the maximum learning rate is $\eta_{\text{max}} = 2\eta_{\text{opt}}$.

The simple SGD update offers lots of engineering opportunities. In practice, however, at any moment during the training procedure, we can select a small subset of training examples and try various learning rates on the subset, then pick the one that most reduces the cost and use it on the full dataset.

3.4 The SGD Convergence

The convergence of stochastic algorithms actually has been studied for a long time in adaptive signal processing. Given a suitable choice of the learning rate η_t, the standard (batch) gradient descent algorithm is known to converge to a local minimum of the cost function. However, the random noise introduced by SGD disrupts this deterministic picture and the specific study of SGD convergence usually is fairly complex (Benveniste *et al.*, 1987).

It is reported that for the convex case, if several assumptions and conditions are valid, then the SGD algorithm converges almost surely to the optimum $\mathbf{w}^*$ [1]. For the general case where the cost function is non-convex and has both local and global minima, if four assumptions and two learning rate assumptions hold, it is guaranteed that the gradient $\nabla_{\mathbf{w}}\mathcal{L}$ converges almost surely to zero (Bottou, 2004). We omit the details of the convergence theorem and corresponding proofs due to space limitation.

3.5 SGD Speedup

Unfortunately, many of sophisticated gradient methods are not robust to noise, and scale badly with the number of parameters. The plain SGD algorithm can be very slow to converge. Inspired by stochastic meta-descent (SMD) (Schraudolph, 1999), the convergence speed of SGD can be further improved with gradient step size adaptation by using second-order information. SMD is a highly scalable local optimizer. It shines when gradients are stochastically approximated.

In SMD, the learning rate η is simultaneously

[1] One may argue that SGD on many architectures does not result in a global optima. However, our goal is to obtain good performance on future examples in learning rather than achieving a global optima on the training set.

INPUT: training set $S\,\{(x_1, y_1), \ldots, (x_{\mathbb{T}}, y_{\mathbb{T}})\}$;
factor λ; number of iterations N.
INITIALIZE: $\mathbf{w}_0$, $\mathbf{v}_0 = 0$, η_0.
FOR $t = 1, 2, \ldots, N$
Choose a random example $(x_i, y_i) \in S$
Compute the gradient $\nabla_t = \mathbf{G}_t$ and $\mathbf{H}_t\mathbf{v}_t$
Set $\mathbf{v}_{t+1} = \lambda\mathbf{v}_t - \eta_t \cdot (\mathbf{G}_t + \lambda\mathbf{H}_t\mathbf{v}_t)$
Update the parameter vector:
$\mathbf{w}_{t+1} \leftarrow \mathbf{w}_t - \eta_t \cdot \nabla_t$
Adapt the gradient step size:
$\eta_{t+1} = \eta_t \cdot \max(\frac{1}{2}, 1 - \mu\mathbf{G}_{t+1} \cdot \mathbf{v}_{t+1})$
OUTPUT: $\mathbf{w}_{N+1}$

Figure 1: Pseudo-code for the SGD algorithm.

adapted via a multiplicative update with μ:

$$\eta_{t+1} = \eta_t \cdot \max(\frac{1}{2}, 1 - \mu\mathbf{G}_{t+1} \cdot \mathbf{v}_{t+1}), \quad (17)$$

where the vector $\mathbf{v}$ ($\mathbf{v} =: \mathrm{d}\mathbf{w}$) captures the long-term dependencies of parameters. $\mathbf{v}$ can be computed by the simple iterative update:

$$\mathbf{v}_{t+1} = \lambda\mathbf{v}_t - \eta_t \cdot (\mathbf{G}_t + \lambda\mathbf{H}_t\mathbf{v}_t), \quad (18)$$

where the factor $0 \leq \lambda \leq 1$ governs the time scale over which long-term dependencies are taken into account, and $\mathbf{H}_t\mathbf{v}_t$ can be calculated efficiently alongside the gradient by forward-mode algorithmic differentiation via Equation 14. This Hessian-vector product is computed implicitly and it is the key to SMD's efficiency. The pseudo-code for the SGD algorithm is shown in Figure 1.

4 Experiments: A Case Study of NP Chunking

4.1 Data

Our data comes from the CoNLL 2000 shared task (Sang and Buchholz, 2000). The dataset is divided into a standard training set of 8,936 sentences and a testing set of 2,012 sentences. This data consists of the same partitions of the Wall Street Journal corpus (WSJ) as the widely used data for NP chunking: sections 15-18 as training data (211,727 tokens) and section 20 as test data (47,377 tokens). And the annotation of the data has been derived from the WSJ corpus.

$w_{t-\delta} = w$
w_t matches `[A-Z]`
w_t matches `[A-Z]+`
w_t matches `[A-Z][a-z]+`
w_t matches `[A-Z]+[a-z]+[A-Z]+[a-z]`
w_t matches `.*[0-9].*`
w_t contains dash "-" or dash-based "-based"
w_t is capitalized, all-caps, single capital letter, or mixed capitalization
w_t contains years, year-spans or fractions
w_t is contained in a lexicon of words with POS p (from the Brill tagger)
$p_t = p$
$q_k(x, t + \delta)$ for all k and $\delta \in [-3, 3]$

Table 1: Input feature template $q_k(x, t)$ for NP chunking. In this table w_t is the token (word) at position t, p_t is the POS tag at position t, w ranges over all words in the training data, and p ranges over all POS tags.

4.2 Features

We follow some top-performing NP chunking systems and perform holdout methodology to design features for our model, resulting in a rich feature set including POS features provided in the official CoNLL 2000 dataset (generated by the Brill tagger (Brill, 1995), with labeling accuracy of around 95-97%), some contextual and morphological features. Table 1 lists our feature set for NP chunking.

4.3 Experimental Results

We trained linear-chain conditional random fields (CRFs) (Lafferty *et al.*, 2001) as the baseline. The well known limited memory quasi-Newton BFGS algorithm (L-BFGS) (Liu and Nocedal, 1989) was applied to learn the parameters for CRFs. To avoid over-fitting, we penalized the log-likelihood by the commonly used zero-mean Gaussian prior over the parameters. This gives us a competitive baseline CRF model for NP chunking. To make fair and accurate comparison, we used the same set of features listed in Table 1 for both M^3N and CRFs. All experiments were performed on the Linux platform, with a 3.2GHz Pentium 4 CPU and 4 GB of memory.

Model	Training Method	Kernel Function	Iteration	Training Time(s)	P(%)	R(%)	$F_{\beta=1}$
M^3N	structured SMO	linear kernel: $\langle a, b\rangle_{\mathcal{H}}$	100	1176	94.59	94.22	94.40

Our approach	94.69

Table 4: NP chunking: Comparison with some existing state-of-the-art systems.

Similar to other discriminative graphical models such as CRFs, the modeling flexibility of M^3N permits the feature functions to be complex, arbitrary, nonindependent, and overlapping features, allowing the multiple features described in Table 1 to be directly exploited. Moreover, M^3N is capable of incorporating multiple kernel functions (see Section 2) which allow the efficient use of high-dimensional feature spaces during the experiments.

The resulting number of features is 7,835,439, and both M^3N and CRFs were trained to predict 47,366 tokens with 12,422 noun phrases in the testing set. For simplicity, we denote $a = \phi(\mathbf{x}, \mathbf{y})$, and $b = \phi(\mathbf{x}', \mathbf{y}')$, and the linear kernel can be rewritten as $\kappa(a, b) = \langle a, b\rangle_{\mathcal{H}}$. We performed holdout methodology to find optimal values for coefficients s, d, and r in M^3N kernel functions. For polynomial kernels, we varied d from 2 to 4, resulting in quadratic, cubic, and biquadratic kernels, respectively. Finally, we chose optimized values: $s = 1, r = 1$ for polynomial kernels, and $s = 0.1, r = 0$ for neural kernels. The capacity $\mathcal{C}$ for M^3N was set to 1 in our experiments.

Table 2 shows comparative performance and training time for M^3N (trained with structured SMO) and CRFs, while Table 3 shows comparative performance and training time for M^3N (trained with SGD) and CRFs [2]. For M^3N, when trained with quadratic kernel and structured SMO, the best F-measure of 94.68 was achieved, leading to an improvement of 0.36 compared to the CRF baseline. What follows is the linear kernel that obtained 94.40 F-measure. The cubic and neural kernels obtained close performance, while the biquadratic kernel led to the worst performance. However, the structured SMO is very computationally intensive, especially for polynomial kernels. For example, CRFs converged in 352 sec-

[2]We used Taku Kudo's CRF++ toolkit (available at http://crfpp.sourceforge.net/) in our experiments. The M^3N model, and the structured SMO and SGD training algorithms were also implemented using C++.

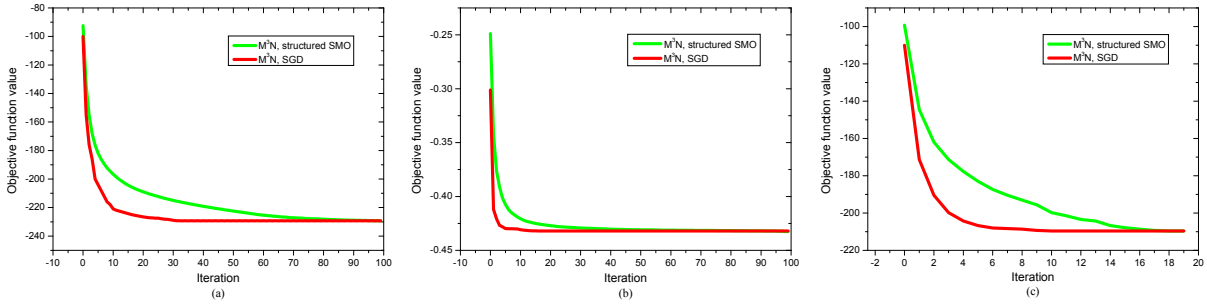

Figure 2: Convergence speed comparison for structured SMO and SGD algorithms. The X axis shows number of training iterations, and the Y axis shows objective function value. (a) The M^3N model was trained using linear kernel. (b) The M^3N model was trained using polynomial(quadratic) kernel. (c) The M^3N model was trained using neural kernel.

onds, while M^3N (polynomial kernels) took more than 8.5 hours to finish training.

As can be seen in Table 3, the SGD algorithm significantly accelerated the training procedure of M^3N without sacrificing performance. When the linear kernel was used, M^3N finished training in 89 seconds, more than 13 times faster than the model trained with structured SMO. And it is even much faster than the CRF model trained with L-BFGS. More importantly, SGD obtained almost the same performance as structured SMO with all M^3N kernel functions.

Table 4 gives some representative NP chunking results for previous work and for our best model on the same dataset. These results showed that our model compares favorably with existing state-of-the-art systems [3].

Figure 2 compares the convergence speed of structured SMO and SGD algorithms for the M^3N model. Linear (Figure 2 (a)), polynomial(quadratic) (Figure 2 (b)) and neural kernels (Figure 2 (c)) were used [4]. We calculated objective function values during effective training iterations. It can be seen that both structured SMO and SGD algorithms converge to the same objective function value for different kernels, but SGD converges considerably faster than the structured SMO.

Figure 3 (a) demonstrates the effect of training set size on performance for NP chunking. We increased the training set size from 1,000 sentences to 8,000 sentences, with an incremental step of 1,000. And the testing set was fixed to be 2,012 sentences. The M^3N models (with different kernels) were trained using the SGD algorithm. It is particularly interesting to know that the performance boosted for all the models when increasing the training set size. Using linear and quadratic kernels, M^3N model significantly and consistently outperforms the CRF model for different training set sizes. The cubic and neural kernels lead to almost the same performance for M^3N, which is slightly lower than the CRF baseline. As illustrated by the curves, M^3N (trained with quadratic kernel) achieved the best performance and larger training set size leads to better improvement for this model when compared to the CRF model, while M^3N (trained with biquadratic kernel) obtained the worst performance among all the models.

Accordingly, Figure 3 (b) shows the impact of increasing the training set size on training time for NP chunking. Increasing training set size leads to an increase in the computational complexity of training procedure for all models. For the M^3N model, it is faster when trained with linear kernel than the CRF model. And the three polynomial kernels (quadratic, cubic and biquadratic) have roughly the same training time. For CRFs and (M^3N, neural kernel), the training time is close to each other. For example, when the training set contains 1,000 sentences, the training time for CRFs, (M^3N, linear kernel), (M^3N, quadratic kernel), (M^3N, cubic kernel), (M^3N, biquadratic kernel), and (M^3N, neural kernel) is 24s, 7s, 72s,

[3] Note that it is difficult to compare strictly, since reported results sometimes leave out details (e.g., feature sets, significance tests, etc) needed for accurate comparison.

[4] For cubic and biquadratic kernels, the curves are very similar to that of quadratic kernel, and we omitted them for space.

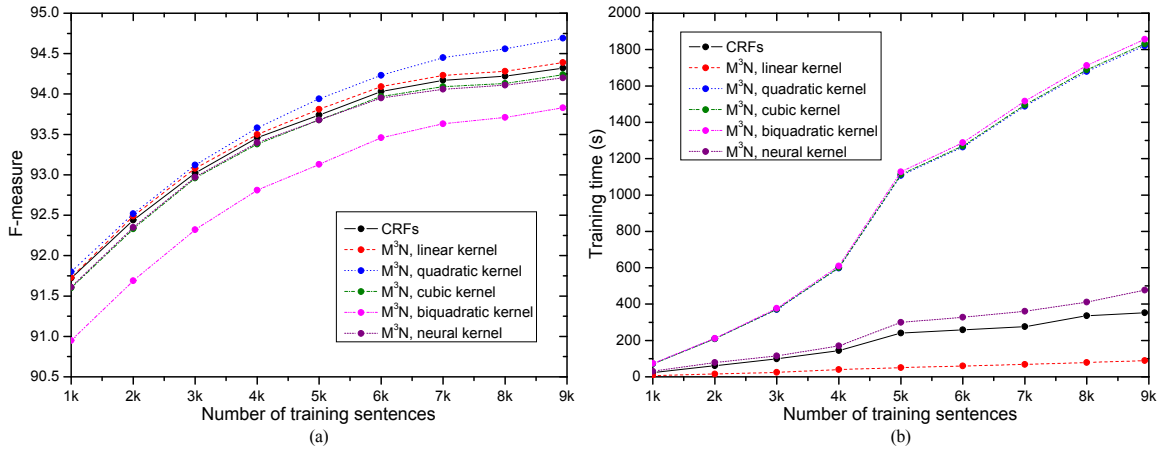

Figure 3: (a) Effect of training set size on performance for NP chunking. The training set size was increased from 1,000 sentences to 8,000 sentences, with an incremental step of 1,000. The testing set contains 2,012 sentences. All the M^3N models (with different kernels) were trained using the SGD algorithm. (b) Effect of training set size on training time for NP chunking.

72s, 74s, and 30s. When trained on 8,000 sentences, the numbers become 336s, 79s, 1679s, 1689s, 1712s, and 411s, respectively.

5 Related Work

The M^3N framework and its variants have generated much interest and great progress has been made, as evidenced by their promising results evaluated in handwritten character recognition, collective hypertext classification (Taskar *et al.*, 2003), parsing (Taskar *et al.*, 2004), and XML tag relabeling (Spengler, 2005). However, all the above mentioned research work used structured SMO algorithm for parameter learning, which can be computationally intensive, especially for very large datasets.

Recently, similar stochastic gradient methods have been applied to train log-linear models such as CRFs (Vishwanathan *et al.*, 2006). However, the maximum margin loss has a discontinuity in its derivative, making optimization of such models somewhat more involved than log-linear ones. We first exploit SGD method for fast parameter learning of M^3N and achieve state-of-the-art performance on the NP chunking task in the NLP community.

Several algorithms have been proposed to train max-margin models, including cutting plane SMO (Tsochantaridis *et al.*, 2005), exponentiated gradient (Bartlett *et al.*, 2004; Collins *et al.*, 2008), extragradient (Taskar *et al.*, 2006), and subgradient (Shalev-Shwartz *et al.*, 2007). Some methods are similar to SGD in that they all process a single training example at a time. The SGD methods directly optimize the primal problem, and at each update use a single example to approximate the gradient of the primal objective function. Some of the proposed algorithms, such as exponentiated gradient corresponds to block-coordinate descent in the dual, and uses the exact gradient with respect to the block being updated. We plan to implement and compare some of these algorithms with SGD for M^3N.

6 Conclusion and Future Work

We have presented the first known empirical study on sequence labeling based on M^3N. We have also provided the efficient SGD algorithm and shown how it can be applied to significantly speedup the training procedure of M^3N. As a case study, we performed extensive experiments on standard dataset for NP chunking, showing the promising and competitiveness of our approach. Several interesting issues, such as the convergence speed of the SGD algorithm, the effect of training set size on performance for NP chunking, and the effect of training set size on training time, were also investigated in our experiments. For the future work, we plan to further the scalability and applicability of our approach and evaluate it on other large-scale real world sequence labeling tasks, such as POS tagging and NER.

Abstract

In this paper, we introduce our recent work on Chinese HPSG grammar development through treebank conversion. By manually defining grammatical constraints and annotation rules, we convert the bracketing trees in the Penn Chinese Treebank (CTB) to be an HPSG treebank. Then, a large-scale lexicon is automatically extracted from the HPSG treebank. Experimental results on the CTB 6.0 show that a HPSG lexicon was successfully extracted with 97.24% accuracy; furthermore, the obtained lexicon achieved 98.51% lexical coverage and 76.51% sentential coverage for unseen text, which are comparable to the state-of-the-art works for English.

1 Introduction

Precise, in-depth syntactic and semantic analysis has become important in many NLP applications. Deep parsing provides a way of simultaneously obtaining both the semantic relation and syntactic structure. Thus, the method has become more popular among researchers recently (Miyao and Tsujii, 2006; Matsuzaki et al., 2007; Clark and Curran, 2004; Kaplan et al., 2004).

This paper introduces our recent work on deep parsing for Chinese, specifically focusing on the development of a large-scale grammar, based on the HPSG theory (Pollard and Sag, 1994). Because it takes a decade to manually develop an HPSG grammar that achieves sufficient coverage for real-world text, we use a semi-automatic approach, which has successfully been pursued for English (Miyao, 2006; Miyao et al., 2005; Xia, 1999; Hockenmaier and Steedman, 2002; Chen and Shanker, 2000; Chiang, 2000) and other languages (Guo et al., 2007; Cramer and Zhang, 2009; Hockenmaier, 2006; Rehbei and Genabith, 2009; Schluter and Genabith, 2009).

The following lists our method of approach: *(1) define a skeleton of the grammar (in this work, the structure of sign, grammatical principles and schemas)*, *(2) convert the CTB (Xue et al., 2002) into an HPSG-style treebank*, *(3) automatically extract a large-scale lexicon from the obtained treebank*.

Experiments were performed to evaluate the quality of the grammar developed from the CTB 6.0. More than 95% of the sentences in the CTB could be successfully converted, and the extracted lexicon was 97.24% accurate. The extracted lexicon achieved 98.51% lexical coverage and 76.51% sentential coverage for unseen text, which are comparable to the state-of-the-art works for English.

Since grammar engineering has many specific problems in each language, although we used the similar method applied in other languages to develop a Chinese HPSG grammar, it is very different from applying, such as statistical parsing models, to a new language. Lots of efforts have been done for the specific characteristics of Chinese. The contribution of our work is to describe these issues. As a result, a skeleton design of Chinese HPSG is proposed, and for the first time, a robust and wide-coverage Chinese HPSG grammar is developed from real-world text.

2 Design of Grammatical Constraints for Chinese HPSG

Because of the lack of a comprehensive HPSG-based syntactic theory for Chinese, we extended the original HPSG (Pollard and Sag, 1994) to analyze the specific linguistic phenomena in Chinese. Due to space limitations, we will provide a brief sampling of our extensions, and discuss several selected constructions.

2.1 Sign, Principles, and Schemas

Sign, which is a data structure to express grammatical constraints of words/phrases, is modified and extended for the analysis of Chinese specific constructions, as shown in Figure 1. *PHON, MOD, SPEC, SUBJ, MARKING,* and *SLASH* are

Coling 2008: Poster Volume, pages 1417–1425,
Beijing, August 2010

features defined in the original HPSG, and they represent the phonological information of a word, the constraints on the modifiee, the specifiee, the subject, the marker, and the long-distance dependency, respectively. *COMPS*, which represents the constraints on complements, is divided into *LCOMPS* and *RCOMPS*, to distinguish between left and right complements. Aspect, question, and negation particles are treated as markers as done in (Gao, 2000), which are distinguished by *ASPECT*, *QUESTION*, and *NEGATION*. *CONT* is also originated from Pollard and Sag (1994), although it is used to represent semantic structures with predicate-argument dependencies. *TOPIC* and *CONJ* are extended features that represent the constraints on the topic and the conjuncts of coordination. *FILLER* is another extended feature that records the grammatical function of the moved argument in a long-distance dependency.

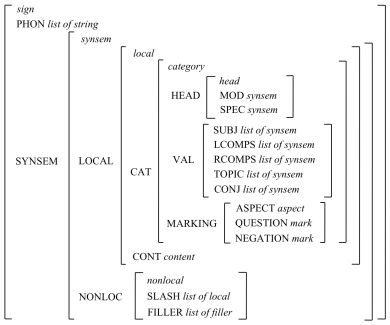

Figure 1. HPSG sign for Chinese.

The principles, including *Phonology Principle*, *Valence Principle*, *Head Feature Principle*, and *Nonlocal Feature Principle*, are implemented in our Chinese HPSG grammar as defined in (Pollard and Sag, 1994). *Semantic Principle* is slightly modified so that it composes predicate-argument structures.

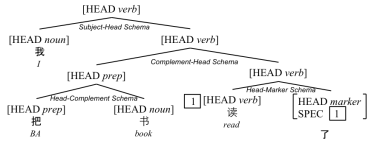
14 schemas are defined in our grammar, among which the *Coord-Empty-Conj Schema*, *Relative-Head Schema*, *Empty-Relativizer Schema*, and *Topic-Head Schema* are designed specifically for Chinese. The other 10 schemas are borrowed from the original HPSG theory.

15 Chinese constructions are considered in our current grammar (refer to Table 1). A detailed description of some particular constructions will be provided in the following subsection.

2.2 An HPSG Analysis for Chinese

2.2.1 BA Construction

The BA construction moves the object of a verb to the pre-verbal position. For example, the sentence in Figure 2 with the original word order is '我/I 读/read 了 书/book'. There were three popular ways to address the BA construction: as a verb (Huang, 1991; Bender, 2000), preposition (Gao, 1992), and case marker (Gao, 2000). Since the aspect markers, such as '了', cannot attach to BA, we exclude the analysis of treating BA as a verb. Because BA, like prepositions, always appears before a noun phrase, we therefore follow the analysis in Gao (1992), and treat BA as a preposition. As shown in Figure 2, BA takes a moved object as a complement, and attaches to the verb as a left-complement.

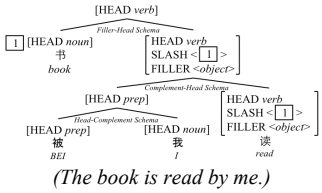


(I read the book.)

Figure 2[1]. Analysis of BA construction.

2.2.2 BEI Construction

The BEI construction is used to make the passive voice of a sentence. Because the aspect marker also cannot attach to BEI, we do not treat BEI as a verb, as done in the CTB. Similar to the analysis of BA construction, we regard BEI as a preposition that attaches to the verb as a left-complement. Additionally, because we can insert a clause '小李/Li 派/send 人/person' between the moved object '他/he' and the verb '打/beat', as is the case for '他/he 被/BEI 小李/Li 派/send 人/person 打/beat 了 (He was beaten by the person that is sent by Li)', we treat the relation between the moved object and the verb as a long-distance dependency. Figure 3 exemplifies our analysis of the BEI construction, in which the *Filler-Head Schema* is used to handle the long-distance dependency, and the *FILLER* feature is used to record that the role of the moved argument.



(The book is read by me.)

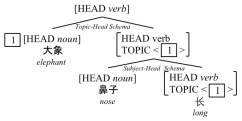
Figure 3. Analysis of BEI construction.

2.2.3 Topic Construction

As indicated in Li and Thompson (1989), a topic refers to the theme of a sentence, which always

[1] In the figures in this paper, we will show only selected features that are relevant to the explanation.

appears before the subject. The difference between the topic and subject is the subject must always have a direct semantic relationship with the verb in a sentence, whereas the topic does not. There are two types of topic constructions. In the first type, the topic does not fill any argument slots of the verb, such as the topic '大象/elephant' in Figure 4. In the second type, the topic has a semantic relationship with the verb. For example, in the sentence '他/he 我/I 喜欢/like (I like him)', the topic '他/he' is also an object of '喜欢/like'. For the first type, we define the *Topic-Head Schema* to describe the topic construction (refer to Figure 4). For the second type, we follow the same analysis as in English, and use the *Filler-Head Schema*.

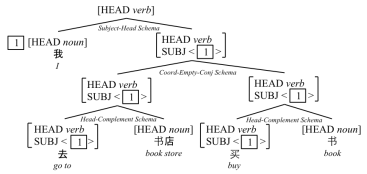


(The nose of an elephant is long.)

Figure 4. Analysis of topic construction.

2.2.4 Serial Verb Construction

In contrast to the definition of serial verb construction in Li and Thompson (1989), we specify a serial verb construction as a special type of verb phrase coordination, which describes several separate events with no conjunctions inside. Similar to ordinary coordination, the verb phrases in a serial verb construction share the same syntactic subject (Muller and Lipenkova, 2009), topic, and left-complement. We define *Coord-Empty-Conj Schema* to deal with it. Figure 5 shows an example analysis.

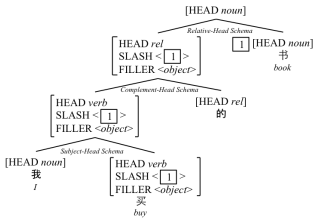


(I go to the book store and buy a book.)

Figure 5. Analysis of serial verb construction.

2.2.5 Relative Clause

In Chinese, a relative clause is marked by a relativizer '的' and exists in the left of the head noun. Because Chinese noun phrases are right-headed in general, we analyze a relative clause as a nominalization that modifies a head noun (Li and Thompson, 1989). Inside of a relative clause, the relativizer is treated as head. When the relativizer is omitted, we define a unary schema, *Empty-Relativizer Schema*, which functions by combining a relative clause with an empty relativizer. Furthermore, we introduce a *Relative-Head Schema* to handle the long-distance dependency for the extracted argument[2] (refer to Figure 6).



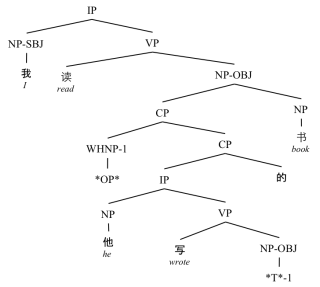
(the book that I buy)

Figure 6. Analysis of relative clause.

3 Converting the CTB into an HPSG Treebank

3.1 Partially-specified Derivation Tree Annotation

In order to convert the CTB into an HPSG treebank, we first annotate the bracketing trees in the CTB to be partially-specified derivation trees[3], which conform to the grammatical constraints designed in Section 2. Three types of rules are defined to fulfill this annotation.



(I read the book that he wrote.)

Figure 7. The CTB annotation for a sentence.

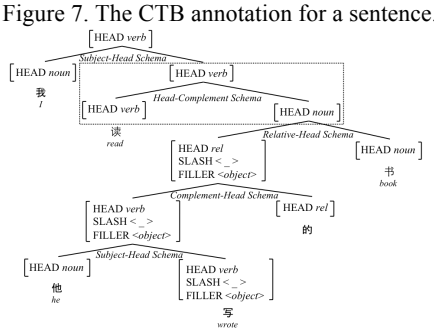


Figure 8. Partially-specified derivation tree for Figure 7.

For example, Figure 7 shows the bracketing tree of a sentence in the CTB, while Figure 8 shows the partially-specified derivation tree after re-annotation.

[2] The extracted adjunct is not treated as a long-distance dependency in our current grammar.

[3] *Partially-specified derivation tree* means a tree structure that is annotated with schema names and some features of the HPSG signs (Miyao, 2006).

3.1.1 Rules for Annotation Conversion

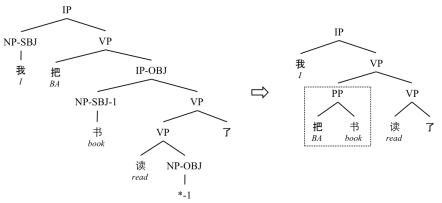
In the CTB, there exist some annotations that do not coincide with our HPSG analysis for Chinese. Therefore, we define pattern rules to convert the annotations in the CTB to fit with our HPSG analysis. 76 annotation rules are defined for 15 Chinese constructions (refer to Table 2). Due to page constraints, we focus on the constructions that we discussed in Section 2.

Construction	Rule #
Relative clause	20
BEI construction	21
Coordination	7
Subject/object control	5
Non-verbal predicate	4
Logical subject	3
Right node raising	3
Parenthesis	3
BA construction	3
Aspect/question/negation particle	2
Subordination	1
Serial Verb construction	1
Modal verb	1
Topic construction	1
Apposition	1

Table 1. Chinese constructions and annotation rules.

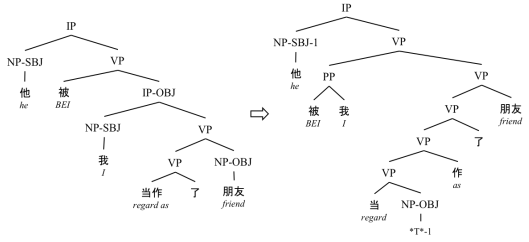
Rules for BA and BEI Construction

As analyzed in Section 2, we treat BA and BEI as prepositions that attach to the verb as left-complements. However, in the CTB, BA and BEI are annotated as verbs that take a sentential complement (Xue and Xia, 2000). By applying the annotation rules, the BA/BEI and the subject of the sentential complement of BA/BEI are re-annotated as a prepositional phrase (as indicated in the dash-boxed part in Figure 9).



(I read the book.)

Figure 9. Conversion of BA construction.



(He is regarded as a friend by me.)

Figure 10. Verb division in BEI construction.

In addition, in the CTB, some BA/BEI constructions are not annotated with trace, which makes it difficult to retrieve the semantic relation between the verb and the moved object. The principal reason for this is that the moved object in these constructions has a semantic relation with only part of the verb. For example, in Figure 10, the moved noun '他/he' is the object of '当/regard', but not for '当作/regard as'. Analysis shows that only a closed set of characters (e.g. '作/as') can be attached to verbs in such a case. Therefore, we manually collect these characters from the CTB, and then define pattern rules to automatically split the verb, which ends with the collected characters, in the BA and BEI construction. Finally, we annotate trace for the split verb. Figure 10 exemplifies the conversion of an example sentence.

Rules for Topic Construction

In the CTB, a functional tag 'TPC' is used to indicate a topic (Xue and Xia, 2000). Therefore, we use this functional tag to detect topic phrases during conversion.

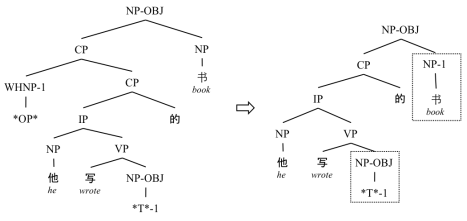
Rules for Serial Verb Construction

We define pattern rules to detect the parallel verb phrases with no conjunction inside (as shown in Figure 11), and treat these verb phrases as a serial verb construction. However, when the verb in the first phrase is a modal verb, such as the case of '我/I 想/want to 唱歌/sing (I want to sing)', the parallel verb phrases should not be treated as a serial verb construction. Therefore, a list of modal verbs is manually collected from the CTB to filter out these exceptional cases during conversion.

(go downstairs and eat meal)

Figure 11. An example of parallel verb phrases.

Rules for Relative Clause



(the book that he wrote)

Figure 12. Conversion of relative clause.

We define annotation rules to slightly modify the annotation of a relative clause in CTB, as shown in Figure 12, to make the tree structure easy to be

analyzed. Furthermore, in CTB, relative clauses are annotated with both extracted arguments and extracted adjuncts. But in our grammar, we only deal with extracted arguments, and the gap in a relative clause (as indicated in the dash-boxed part in Figure 12). When the extracted phrase is an adjunct of the relative clause, we simply view the clause as a modifier of the extracted phrase.

3.1.2 Rules for Correcting Inconsistency

There are some inconsistencies in the annotation of the CTB, which presents difficulties for performing the derivation tree annotation. Therefore, we define 49 rules, as done in (Hockenmaier and Steedman, 2002) for English, to mitigate inconsistencies before annotation (refer to Table 3).

3.1.3 Rules for Assisting Annotation

We also define 48 rules (refer to Table 2), which are similar to the rules used in (Miyao, 2006) for English, to help the derivation tree annotation. For example, 12 pattern rules are defined to assign the schemas to corresponding constituents.

Rule Type	Rule Description	Rule #
Rules for correcting inconsistent annotation	Fix tree annotation	37
	Fix phrase tag annotation	5
	Fix functional tag annotation	5
	Fix POS tag annotation	2
Rules for assisting annotation	Slash recognization	27
	Schema assignment	12
	Head/Argument/Modifier marking	8
	Binarization	1

Table 2. Rules for correcting inconsistency and assisting annotation.

3.2 HPSG Treebank Acquisition

In this phase, the schemas and principles are applied to the annotated partially-specified trees, in order to fill out unspecified constraints and validate the consistency of the annotated constraints. In effect, an HPSG treebank is obtained.

For instance, by applying the *Head-Complement Schema* to the dash-boxed nodes in Figure 8, the constraints of the right daughter are percolated to *RCOMPS* of the left daughter (as indicated as 4 in Figure 13). After applying the schemas and the principles to the whole tree in Figure 8, a HPSG derivation tree is acquired (refer to Figure 13).

3.3 Lexicon Extraction

With the HPSG treebank acquired in Section 3.2, we automatically collect lexical entries as the combination of words and lexical entry templates from the terminal nodes of the derivation trees. For example, from the HPSG derivation tree shown in Figure 13, we obtain a lexical entry for the word '写/write' as shown in Figure 14.

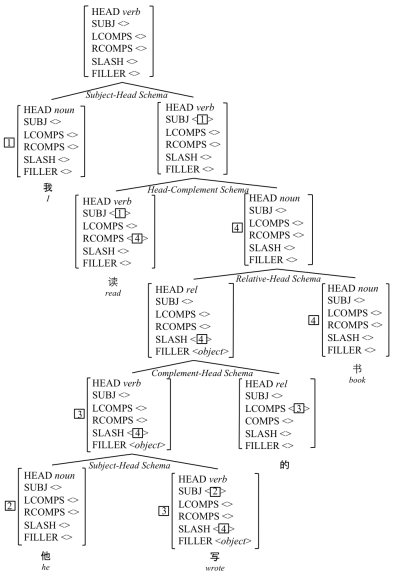


Figure 13. HPSG derivation tree for Figure 8.

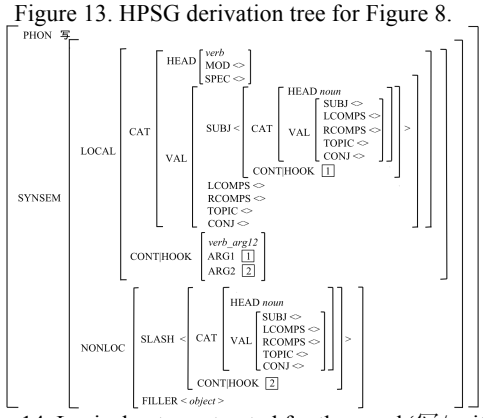

Figure 14. Lexical entry extracted for the word '写/write'.

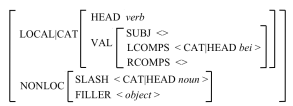
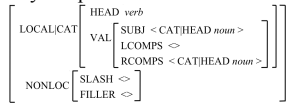
3.3.1 Lexical Entry Template Expansion



(a) Lexical entry template for the verb in BEI construction



(b) Lexical entry template for the verb in original word order

Figure 15. Application of a lexical rule.

Some Chinese constructions change the word order of sentences, such as the BA/BEI constructions. Therefore, we apply lexical rules (Nakanishi et al., 2004) to the lexical entry templates to convert them into those for the original word order, and expand the lexical entry templates consequently. 18 lexical rules are defined for the verbs in the BA/BEI constructions. For example, by applying a lexical rule to the lexical entry template in Figure 15(a), the moved object indi-

cated by *SLASH* is restored into *RCOMPS*, and the subject introduced by BEI in *LCOMPS* is restored into *SUBJ* (refer to Figure 15(b)).

3.3.2 Mapping of Semantics

In our grammar, we use predicate-argument dependencies for semantic representation. 44 types of predicate-argument relations are defined to represent the semantic structures of 13 classes of words. For example, we define a predicate-argument relation '*verb_arg12*', in which a verb takes two arguments '*ARG1*' and '*ARG2*', to express the semantics of transitive verbs. 72 semantics mapping rules are defined to associate these predicate-argument relations with the lexical entry templates. Figure 16 exemplifies a semantics mapping rule. The input of this rule is the lexical entry template (as shown in the left part), and the output is a predicate-argument relation '*verb_arg12*' (as shown in the right part), which associates the syntactic arguments *SUBJ* and *SLASH* with the semantic arguments *ARG1* and *ARG2* (as indicated by 1 and 2 in Figure 16).

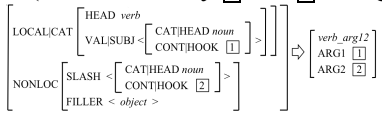


Figure 16. A semantics mapping rule.

4 Evaluation

4.1 Experimental Setting

We used the CTB 6.0 for HPSG grammar development and evaluation. We split the corpus into development, testing, and training data sets, following the recommendation from the corpus author. The development data was used to tune the design of grammar constraints and the annotation rules. However, the testing data set was reserved for further evaluation on parsing. Thus, the training data was further divided into two parts for training and testing in this work. During the evaluation, unknown words were handled in the same way as done in (Hockenmaier and Steedman, 2002).

4.2 Evaluation Metrics

In order to verify the quality of the grammar developed in our work, we evaluated the extracted lexicon by the accuracy for assessing the semi-automatic conversion process, and the coverage for quantifying the upper-bound coverage of the future HPSG parser based on this grammar.

The accuracy of the extracted lexicon was evaluated by *lexical accuracy*, which counts the number of the correct lexical entries among all the obtained lexical entries.

In addition, two evaluation metrics as used in (Hockenmaier and Steedman, 2002; Xia, 1999; Miyao, 2006) were used to evaluate the coverage of the obtained lexicon. The first one is *lexical coverage* (Hockenmaier and Steedman, 2002; Xia, 1999), which means that the percentage that the lexical entries extracted from the testing data are covered by the lexical entries acquired from the training data. The second one is *sentential coverage* (Miyao, 2006): a sentence is considered to be covered only when the lexical entries of all the words in this sentence are covered.

4.3 Results of Accuracy

Since there was no gold standard data for the automatic evaluation of accuracy, we randomly selected 100 sentences from the testing data, and manually checked the lexical entries extracted from these sentences. Results show that 1,558 lexical entries were extracted at 97.24% (1,515/1,558) accuracy.

Error analysis shows all the incorrect lexical entries came from the error in the derivation tree annotation. For example, our current design failed to find the correct boundary of coordinated noun phrases when the word '等/etc' was attached at the end, such as '产权/property right 出让/selling 、 资产/assets 出租/renting 等/etc (property right selling and assets renting etc.)'. We will improve the derivation tree annotation to solve this issue.

4.4 Results of Coverage

Table 3 shows the coverage of the extracted lexical entries, which indicates that a large HPSG lexicon was successfully extracted from the CTB for unseen text, with reasonable coverage. The statistics of the HPSG lexicon extraction in our experiments (refer to Table 4) also indicates that we successfully extracted lexical entries from more than 95% of the sentences in the CTB.

Among all the uncovered lexical entries, 78.55% are for content words, such as verb and noun. In addition, the classification of uncovered lexical entries in Table 4 indicates that about 1/3 of the uncovered lexical entries came from the unknown lexical entry templates ('+*w*/-*t*'). We analyzed the 193 '+*w*/-*t*' failures in the testing data, among which 169 failures resulted from the shortage of training data, which indicated that the correct lexical entry template did not appear in

the training data. The learning curve in Figure 17 shows that we can resolve this issue by enlarging the training data. The other 24 failures came from the error in the derivation tree annotation. For example, our current grammar failed at detecting the coordinated clauses when they were separated by a colon. We will be able to reduce this type of failure by improving the derivation tree annotation.

Sent. Cov.	Lex. Cov.	Uncovered Lexical Entries	
		+w/+t	*+w/-t*
76.51%	98.51%	1.05%	0.43%

Table 3[4]. Coverage of extracted HPSG lexicon.

Data Set	Total Sent #	Succeed Sent #	Word #	Lexical Entry Template #
Training	20,230	19,257(95.19%)	510,815	4,836
Develop	2,067	2,009(97.19%)	55,714	1,582
Testing	2,000	1,941(97.05%)	44,924	1,163

Table 4. Statistics of HPSG lexicon extraction.

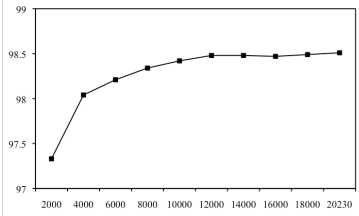

Figure 17. Lexical coverage (Y axis) vs. corpus size (X axis).

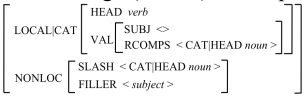

Figure 18. A lexical entry template extracted from testing data.

The other type of failures (‘*+w/+t*’) indicate that a word was incorrectly associated with a lexical entry template, even though both of them existed in the training data. Error analysis shows that 64.39% of failures were related to verbs. For example, for a relative clause ‘投资/invest 台湾/Taiwan 的 商人/businessman (the businessman that invests Taiwan)’ in the testing data, we associated a lexical entry template as shown in Figure 18 with the verb ‘投资/invest’. In the training data, however, the lexical entry template shown in Figure 18 cannot be extracted for ‘投资/invest’, since this word never appears in a relative clause with an extracted subject. Introducing lexical rules to expand the lexical entry template of verbs in a relative clause is a possible way to solve this problem.

4.5 Comparison with Previous Work

Guo’s work (Guo et al., 2007; Guo, 2009) is the only previous work on Chinese lexicalized grammar development from the CTB, which induced wide-coverage LFG resources from the CTB. By using the hand-made gold-standard f-structures of 200 sentences from the CTB 5.1, the LFG f-structures developed in Guo’s work achieved 96.34% precision and 96.46% recall for unseen text (Guo, 2009). In our work, we applied the similar strategy in evaluating the accuracy of the developed Chinese HPSG grammar, which achieved 97.24% lexical accuracy on 100 unseen sentences from the CTB 6.0. When evaluating the coverage of our grammar, we used a much larger data set (including 2,000 unseen sentences), and achieved 98.51% lexical coverage. Although these results cannot be compared to Guo’s work directly because of the different size and content of data set, it indicates that the Chinese HPSG grammar developed in our work is comparable in quality with Guo’s work.

In addition, there were previous works about developing lexicalized grammar for English. Considering the small size of the CTB, in comparison to the Penn Treebank used in the previous works, the results listed in Table 5 verify that, the quality of the Chinese HPSG grammar developed in our work is comparable to these previous works.

Previous Work	Sent. Cov.	Lex. Cov.
Miyao (2006)	82.50%	98.97%
Hockenmaier and Steedman (2002)	-	98.50%
Xia (1999)	-	96.20%

Table 5. Evaluation results of previous work.

4.6 Discussion

There are still some sentences in the CTB from which we failed to extract lexical entries. We analyzed the 59 failed sentences in the testing data and listed the reasons in Table 6.

Reason	Sent #
Error in the derivation tree annotation	31
Short of semantics mapping rule	23
Inconsistent annotation in the CTB	5

Table 6. Reasons for lexicon extraction failures.

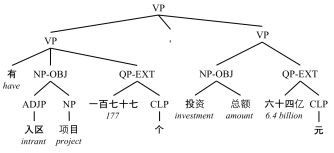
The principal reason for 31 sentence failures, is the error in the derivation tree annotation. For instance, our current annotation rules could convert the regular relative clause shown in Figure 12. Nonetheless, when the relative clause is inside of a parenthesis, such as ‘“ 原始/primitive 的 ”方法/method (the method that is primitive)’, the annotation rules failed at finding the extracted head noun to create a derivation tree. This type of failure can be reduced by improving the annotation rules.

[4] ‘*+w/+t*’ means both the word and lexical entry template have been seen in the lexicon. ‘*+w/-t*’ means only the word has been seen in the lexicon (Hockenmaier and Steedman, 2002).

The second reason, for which 23 sentences failed, is the shortage of the semantics mapping rules. For example, we did not define semantics mapping rule for a classifier that acts as a predicate with two topics. This type of failure can be reduced by adding semantic mapping rules.

The last reason for sentence failures is inconsistencies in the CTB annotation. In our future work, these inconsistencies will be collected to enrich our inconsistency correction rules.

In addition to the reasons above, some sentences with special constructions in the development and training data also could not be analyzed by our current grammar, since the special construction is difficult for the current HPSG to analyze. The special constructions include the argument-cluster coordination shown in Figure 19. Introducing the similar rules used in CCG (Hockenmaier and Steedman, 2002) could be a possible solution to this problem.



(have 177 intrant projects and 6.4 billion investments)

Figure 19. An argument-cluster coordination in CTB.

5 Related Work

To the extent of our knowledge, the only previous work about developing Chinese lexicalized grammar from treebanks is Guo's work (Guo et al., 2007; Guo, 2009). An LFG-based parsing using wide-coverage LFG approximations induced from the CTB was done in this work. However, they did not train a deep parser based on the LFG resources obtained in their work, but relied on an external PCFG parser to create c-structure trees, and then mapped the c-structure trees into f-structures using their annotation rules (Guo, 2009). In contrast to Guo's work, we paid particular attention to a different grammar framework, i.e. HPSG, with the analysis of more Chinese constructions, such as the serial verb construction. In addition, in our on-going deep parsing work, we use the developed Chinese HPSG grammar, i.e. the lexical entries, to train a full-fledged HPSG parser directly.

Additionally, there are some works that induce lexicalized grammar from corpora for other languages. For example, by using the Penn Treebank, Miyao et al. (2005) automatically extracted a large HPSG lexicon, Xia (1999), Chen and Shanker (2000), Hockenmaier and Steedman (2002), and Chiang (2000) invented LTAG/CCG specific procedures for lexical entry extraction. From the German Tiger corpus, Cramer and Zhang (2009) constructed a German HPSG grammar; Hockenmaier (2006) created a German CCGbank; and Rehbei and Genabith (2009) acquired LFG resources. In addition, Schluter and Genabith (2009) automatically obtained wide-coverage LFG resources from a French Treebank. Our work implements a similar idea to these works, but we apply different grammar design and annotation rules, which are specific to Chinese. Furthermore, we obtained a comparative result to state-of-the-art works for English.

There are some researchers who worked on Chinese HPSG grammar development manually. Zhang (2004) implemented a Chinese HPSG grammar using the LinGO Grammar matrix (Bender et al., 2002). Only a few basic constructions were considered, and a small lexicon was constructed in this work. Li (1997) and Wang et al. (2009) designed frameworks for Chinese HPSG grammar; however, only small grammars were implemented in these works.

Furthermore, some linguistic works focused mainly on the discussion of specific Chinese constructions in the HPSG or LFG framework, without implementing a grammar for real-world text (Bender, 2000; Gao, 2000; Li and McFetridge, 1995; Li, 1995; Xue and McFetridge, 1995; Wang and Liu, 2007; Ng, 1997; Muller and Lipenkova, 2009; Liu, 1996; Kit, 1998).

6 Conclusion and Future Work

In this paper, we described the semi-automatic development of a Chinese HPSG grammar from the CTB. Grammatical constraints are first designed by hand. Then, we convert the bracketing trees in the CTB into an HPSG treebank, by using pre-defined annotation rules. Lastly, we automatically extract lexical entries from the HPSG treebank. We evaluated our work on the CTB 6.0. Results indicated that a large HPSG lexicon was successfully extracted with a 97.24% accuracy. Furthermore, our grammar achieved 98.51% lexical coverage and 76.51% sentential coverage for unseen text.

This is an ongoing work, and there are some future works under consideration, including enriching the design of annotation rules, introducing more semantics mapping rules, and adding lexical rules. In addition, the work on Chinese HPSG parsing is on-going, within which the Chinese HPSG grammar developed in this work will be available soon.

Abstract

This paper is a case study on cross-lingual induction of lexical resources for deep, broad-coverage syntactic analysis of German. We use a parallel corpus to induce a classifier for German participles which can predict their syntactic category. By means of this classifier, we induce a resource of adverbial participles from a huge monolingual corpus of German. We integrate the resource into a German LFG grammar and show that it improves parsing coverage while maintaining accuracy.

1 Introduction

Parallel corpora are currently exploited in a wide range of induction scenarios, including projection of morphologic (Yarowsky et al., 2001), syntactic (Hwa et al., 2005) and semantic (Padó and Lapata, 2009) resources. In this paper, we use cross-lingual data to learn to predict whether a lexical item belongs to a specific syntactic category that cannot easily be learned from monolingual resources. In an application test scenario, we show that this prediction method can be used to obtain a lexical resource that improves deep, grammar-based parsing.

The general idea of cross-lingual induction is that linguistic annotations or structures, which are not available or explicit in a given language, can be inferred from another language where these annotations or structures are explicit or easy to obtain. Thus, this technique is very attractive for cheap acquisition of broad-coverage resources, as is proven by the approaches cited above. Moreover, this induction process can be attractive for the induction of deep (and perhaps specific) linguistic knowledge that is hard to obtain in a monolingual context. However, this latter perspective has been less prominent in the NLP community so far.

This paper investigates a cross-lingual induction method based on an exemplary problem arising in the deep syntactic analysis of German. This showcase is the syntactic flexibility of German participles, being morphologically ambiguous between verbal, adjectival and adverbial readings, and it is instructive for several reasons: first, the phenomenon is a notorious problem for linguistic analysis and annotation of German, such that standard German resources do not represent the underlying analysis. Second, in Zarrieß et al. (2010), we showed that integrating the phenomenon of adverbial participles in a naive way into a broad-coverage grammar of German leads to significant parsing problems, due to spurious ambiguities. Third, it is completely straightforward to detect adverbial participles in cross-lingual data since in other languages, e.g. English or French, adverbs are often morphologically marked.

In this paper, we use instances of adverbially translated participles in a parallel corpus to bootstrap a classifier that is able to identify an adverbially used participle based on its monolingual syntactic context. In contrast to what is commonly assumed, we show that it is possible to detect adverbial participles using only a relatively narrow context window. This classifier enables us to identify an occurence of an adverbial participle independently of its translation in a parallel corpus, going far beyond the induction methodology in Zarrieß et al. (2010). By means of the participle classifier, we can extract new types of adverbial participles from a larger corpus of German newspaper text and substantially augment the size of the resource extracted only on Europarl data. Finally, we integrate this new resource into the German LFG grammar and show that it improves coverage without negatively affecting performance.

Coling 2008: Poster Volume, pages 1426–1434,
Beijing, August 2010

The paper is structured as follows: in Section 2, we describe the linguistic and computational problems related to the parsing of adverbial participles in German. Section 3 introduces the general idea of using the translation data to find instances of different participle categories. In Section 4, we illustrate the training of the classifier, evaluating the impact of the context window and the quality of the training data obtained from cross-lingual text. In Section 5, we apply the classifier to new, monolingual data and describe the extension of the resource for adverbial participles. Section 6 evaluates the extended resource by means of parsing experiments using the German LFG grammar.

2 The Problem

In German, past perfect participles are ambiguous with respect to their morphosyntactic category. As in other languages, they can be used as part of the verbal complex (Example (1-a)) or as adjectives (Example (1-b)). Since German adjectives can generally undergo conversion into adverbs, participles can also be used adverbially (Example (1-c)). The verbal and adverbial participle forms are morphologically identical.

(1) a. Sie haben das Experiment **wiederholt**.
'They have repeated the experiment.'
b. Das **wiederholte** Experiment war erfolgreich.
'The repeated experiment was succesful.'
c. Sie haben das Experiment **wiederholt** abgebrochen.
'They cancelled the experiment repeatedly.'

Moreover, German adjectival modifiers can be generally used as predicatives that can be either selected by a verb (Example (2-a)) or that can occur as free predicatives (Example (2-b)).

(2) a. Er scheint **begeistert** von dem Experiment.
'He seems enthusiastic about the experiment.'
b. Er hat **begeistert** experimentiert.
'He has experimented enthusiastic.'

Since predicative adjectives are not inflected, the surface form of a German participle is ambiguous between a verbal, predicative or adverbial use.

2.1 Participles in the German LFG

In order to account for sentences like (1-c), an intuitive approach would be to generally allow for adverb conversion of participles in the grammar. However, in Zarrieß et al. (2010), we show that such a rule can have a strong negative effect on the overall performance of the parsing system, despite the fact that it produces the desired syntactic and semantic analysis for specific sentences. This problem was illustrated using a German LFG grammar (Rohrer and Forst, 2006) constructed as part of the ParGram project (Butt et al., 2002). The grammar is implemented in the XLE, a grammar development environment which includes a very efficient LFG parser and a stochastic disambiguation component which is based on a log-linear probability model (Riezler et al., 2002).

In Zarrieß et al. (2010), we found that the naive implementation of adverbial participles in the German LFG, i.e. in terms of a general grammar rule that allows for participles-adverb conversion, leads to spurious ambiguities that mislead the disambiguation component of the grammar. Moreover, the rule increases the number of timeouts, i.e. sentences that cannot be parsed in a predefined amount of time (20 seconds). Therefore, we observe a drop in parsing accuracy although grammar coverage is improved. As a solution, we induced a lexical resource of adverbial participles based on their adverbial translations in a parallel corpus. This resource, comprising 46 participle types, restricts the adverb conversion such that most of the spurious ambiguities are eliminated.

To assess the impact of specific rules in a broad-coverage grammar, possibly targeting medium-to-low frequency phenomena, we have established a fine-grained evaluation methodology. The challenge posed by these low-frequent phenomena is typically two-fold: on the one hand, if one takes into account the disambiguation component of the grammar and pursues an evaluation of the most probable parses on a general test set, the new grammr rule cannot be expected to show a positive effect since the phenomenon is not likely to occur very often in the test set. On the other hand, if one is interested in a linguistically precise grammar, it is very unsatisfactory to reduce grammar coverage to statistically frequent phenomena. Therefore, we combined a coverage-oriented evaluation on specialised testsuites with a quantitative evaluation including disambiguation, making sure that

the increased coverage does not lead to an overall drop in accuracy. The evaluation methodolgy will also be applied to evaluate the impact of the new participle resource, see Section 6.

2.2 The Standard Flat Analysis of Modifiers

The fact that German adjectival modifiers can generally undergo conversion into adverbs without overt morphological marking is a notorious problem for the syntactic analysis of German: there are no theoretically established tests to distinguish predicative adjectives and adverbials, see Geuder (2004). For this reason, the standard German tag set assigns a uniform tag ("ADJD") to modifiers that are morphologically ambiguous between an adjectival and adverbial reading. Moreover, in the German treebank TIGER (Brants et al., 2002) the resulting syntactic differences between the two readings are annotated by the same flat structure that does not disambiguate the sentence.

Despite certain theoretical problems related to the analysis of German modifiers, their interpretation in real corpus sentences is often unambiguous for native speakers. As an example, consider example (3) from the TIGER treebank. In the sentence, the participle *unterschrieben* (*signed*) clearly functions as a predicative modifier of the sentence's subject. The other, theoretically possible reading where the participle would modify the verb *send* is semantically not acceptable. However, in TIGER, the participle is analysed as an ADJD modifier attached under the VP node which is the general analysis for adjectival and adverbial modifiers.

(3) Die sollte **unterschrieben** an die Leitung
It should signed to the administration
zurückgesandt werden.
sent back be.
'It should be sent back signed to the administation.'

Sentence (4) (also taken from TIGER) illustrates the case of an adverbial participle. In this example, the reading where *angemessen* (*adequately*) modifies the main verb is the only one that is semantically plausible. In the treebank, the participle is tagged as ADJD and analysed as a modifier in the VP.

(4) Der menschliche Geist läßt sich rechnerisch nicht
The human mind lets itself computationally not
angemessen simulieren.
adequately simulate.
'The human mind cannot be adequately simulated in a computational way.'

The flat annotation strategy adopted for modifiers in the standard German tag set and in the treebank TIGER entails that instances of adverbs (and adverbial participles) cannot be extracted from automatically tagged, or parsed, text. Therefore, it would be very hard to obtain training material from German resources to train a system that automatically identifies adverbially used participles. However, the intuition corroborated by the examples presented in this section is that the structures can actually be disambiguated in many corpus sentences.

In the following sections, we show how we exploit parallel text to obtain training material for learning to predict occurences of adverbial participles, without any manual effort. Moreover, by means of this technique, we can substantially extend the grammatical resource for adverbial participles compared to the resource that can be directly extracted from the parallel text.

3 Participles in the Parallel Corpus

The intuition of the cross-lingual induction approach is that adverbial participles can easily be extracted from parallel corpora since in other languages (such as English or French) adverbs are often morphologically marked and easily labelled by statistical PoS taggers. As an example, consider sentence (5) extracted from Europarl, where the German participle *verstärkt* is translated by an English adverb (*increasingly*).

(5) a. Nicht ohne Grund sprechen wir **verstärkt**
Not without reason speak we increasingly
vom Europa der Regionen.
of a Europe of the Regions.
b. It is not without reason that we **increasingly** speak in terms of a Europe of the Regions.

The idea is to project specific morphological information about adverbs which is overt in languages like English onto German where adverbs cannot be directly extracted from tagged data. While this idea might seem intuitively straightfor-

ward, we also know that translation pairs in parallel data are not always lingusitically parallel, and as a consequence, word-alignment is not always reliable. To assess the impact of non-parallelism in adverbial translations of German participles, we manually annotated a sample of 300 translations. This data also constitutes the basis for the experiments reported in Section 4.

3.1 Data

Our experiments are based on the same data as in (Zarrieß et al., 2010). For convenience, we provide a short description here.

We limit our investigations to non-lexicalised participles occuring in the Europarl corpus and not yet recorded as adverbs in the lexicon of the German LFG grammar (5054 participle types in total). Given the participle candidates, we extract the set of sentences that exhibit a word alignment between a German participle and an English, French or Dutch adverb. The word alignments have been obtained with GIZA++. The extraction yields 27784 German-English sentence pairs considering all alignment links, and 5191 sentence pairs considering only bidirectional alignments between a participle and an English adverb.

3.2 Systematic Non-Parallelism

For data exploration and evaluation, we annotated 300 participle alignments out of the 5191 German-English sentences (with a bidirectional participle-adverb alignment). We distinguish the following annotation categories: (i) parallel translation, adverb information can be projected, (ii) incorrect alignment, (iii) correct alignment, but translation is a multi-word expression, (iv) correct alignment, but translation is a paraphrase (possibly involving a translation shift).

Parallel Cases In our annotated sample of English adverb - German participle pairs, 43%[1] of the translation instances are parallel in the sense that the overt adverb information from the English side can be projected onto the German participle. This means that if we base the induction technique on word-alignments alone, its precision would be relatively low.

Non-Parallel Cases Taking a closer look at the non-parallel cases in our sample (57% of the translation pairs), we find that 47% of this set are due to incorrect word alignments. The remaining 53% thus reflect regular cases of non-parallel translations. A typical configuration which makes up 30% of the the non-parallel cases is exemplified in (6) where the German main verb *vorlegen* is translated by the English multiword expression *put forward*.

(6) a. Wir haben eine Reihe von Vorschlägen **vorgelegt**.
b. We have **put forward** a number of proposals.

An example for the general paraphrase or translation shift category is given in Sentence (7). Here, the translational correspondence between *gekommen* (*arrived*) and the adverb *now* is due to language-specific, idiomatic realisations of an identical underlying semantic concept. The paraphrase translations make up 23% of the non-parallel cases in the annotated sample.

(7) a. Die Zeit ist noch nicht **gekommen** .
That time is yet not arrived.
b. That time is not **now** .

Furthermore, it is noticeable that the cross-lingual approach seems to inherently factor out the ambiguity between predicative and adverbial participles. In our annotated sample, there are no predicative participles that have been translated by an English adverb.

3.3 Filtering Mechanisms

The data analysis in the previous section, showing only 43% of parallel cases in English adverb translations for German participles, mainly confirms other studies in annotation projection which find that translational correspondences only allow for projection of linguistic analyses in a more or less limited proportion (Yarowsky et al., 2001; Hwa et al., 2005; Mihalcea et al., 2007).

In previous studies on annotation projection, quite distinct filtering methods have been proposed: in Yarowsky et al. (2001), projection errors are mainly attributed to word alignment errors and filtered based on translation probabilities.

[1] The diverging figures we report in Zarrieß et al. (2010) were due to a small bug in the script and it does not affect the overall interpretation of the data.

Hwa et al. (2005) find that errors in the projection of syntactic relations are also due to systematic grammatical divergences between languages and propose correcting these errors by means of specific, manually designed filters. Bouma et al. (2008) make similar observations to Hwa et al. (2005), but try to replace manual correction rules by filters from additional languages.

In Zarrieß et al. (2010), we compared a number of filtering techniques on our participle data. The 300 annotated translation instances are used as a test set for evaluation. In particular, we have established that a combination of syntactic dependency-based filters and multilingual filters can very accurately separate non-parallel translations from parallel ones where the adverb information can be projected. In Section 4, we show that these filtering techniques are also very useful for removing noise from the training material that we use to build a classifier.

4 Bootstrapping a German Participle Classifier from Crosslingual Data

In the previous section, we have seen that German adverbial participles can be easily found in crosslingual text by looking at their translations in a language that morphologically marks adverbials. In previous work, we exploited this observation by directly extracting types of adverbial participles based on word alignment links and the filtering mechanisms mentioned in Section 3. However, this method is very closely tied to data in the parallel corpus, which only comprises around 5000 participle-adverb translations in total, which results in 46 types of adverbial participles after filtering. Thus, we have no means of telling whether we would discover new types of adverbial participles in other corpora, from different domains to Europarl. As this corpus is rather small and genre specific, it even seems very likely that one could find additional adverbial participles in a bigger corpus. Moreover, we cannot be sure that certain adverbial participles have systematically diverging translations in other languages, due to crosslingual lexicalisation differences. Generally, it is not clear whether we have learned something general about the syntactic phenomenon of adverbial participles in German or whether we have just extracted a small, corpus-dependent subset of the class of adverbial participles.

In this section, we use instances of adverbially translated participles as training material for a classifier that learns to predict adverbial participles based on their monolingual syntactic context. Thus, we exploit the translations in the parallel corpus as a means of obtaining "annotated" or disambiguated training data without any manual effort. During training, we only consider the monolingual context of the participle, such that the final application of the classifier is not dependent on cross-lingual data anymore.

4.1 Context-based Identification of Adverbial Participles

Given the general linguistic problems related to adverbial participles (see Section 2), one could assume that it is very difficult to identify them in a given context. To assess the general difficulty of this syntactic problem, we run a first experiment comparing a grammar-based identification method against a classifier that only considers relatively narrow morpho-syntactic context. For evaluation, we use the 300 annotated participle instances described in Section 3. This test set divides into 172 negative instances, i.e. non-adverbial participles, and 128 positive instances. We report accuracy of the identification method, as well as precision and recall relating to the number of correctly predicted adverbial participles.

For the grammar-based identification, we use the German LFG which integrates the lexical resource for adverbial participles established in (Zarrieß et al., 2010). We parse the 300 Europarl sentences and check whether the most probable parse proposed by the grammar analyses the respective participle as an adverb or not. The grammar obtains a complete parse for 199 sentences out of the test set and we only consider these in the evaluation. The results are given in Table 1.

The high precision and accuracy of the grammar-based identification of adverbial participles suggests that in a lot of sentences, the adverbial analysis is the only possible reading, i.e. the only analysis that makes the sentence grammatical. But of course, we have substantially restricted the adverb participle-conversion in the grammar,

Training Data	Precision	Recall	Accuracy
Grammar	97.3	90.12	94.97
Classifier Unigram	87.10	84.38	87.92
Classifier Bigram	88.28	88.28	89.93
Classifier Trigram	89.60	87.5	90.27

Table 1: Evaluation on 300 participle instances from Europarl

so that it does not propose adverbial analyses for participles that are very unlikely to function as modifiers of verbs.

For the classifier-based identification, we use the adverbially translated participle tokens in our Europarl data (5191 tokens in total) as training material. We remove the 300 test instances from this training set, and then divide it into a set of positive and negative instances. To do this, we use the filtering mechanisms already proposed in Zarrieß et al. (2010). These filters apply on the type level, such that we first identify the positive types (46 total) and then use all instances of these types in the 4891 sentences as positive instances of adverbial participles (1978 instances). The remaining sentences are used as negative instances.

For the training of the classifier, we use maximum-entropy classification, which is also commonly used for the general task of tagging (Ratnaparkhi, 1996). In particular, we use the open source TADM tool for parameter estimation (Malouf, 2002). The tags of the words surrounding the participles are used as features in the classification task. We explore different sizes of the context window, where the trigram window is the most succesful (see Table 1). Beyond the trigram window, the results of the classifier start decreasing again, probably because of too many misleading features. Generally, this experiment shows that the grammar-based identification is more precise, but that the classifier still performs surprisingly well. Compared to the results from the grammar-based identification, the high accuracy of the classifier suggests that even the narrow syntactic contexts of adverbial vs. non-adverbial participles are quite distinct.

4.2 Designing Training Data for Participle Classification

There are several questions related to the design of the training data that we use to build our classifier. First, it is not clear how many negative instances are helpful for learning the adverbial - non-adverbial distinction. In the above experiment, we simply use the instances that do not pass the cross-lingual filters. In this section, we experiment with an augmented set of negative instances that was also obtained by extracting German participle that are bi-directionally aligned to an English participle in Europarl. This is based on the assumption that these participles are very likely to be verbal. Second, it is not clear whether we really need the filtering mechanisms proposed in Zarrieß et al. (2010) and whether we could improve the classifier by training it on a larger set of positive instances. Therefore, we also experiment with two further sets of positive instances: one where we used all participles (not necessarily bidirectionally) aligned to an adverb, one where we only use the bidirectional alignments. The results obtained for the different sizes of positive and negative instance sets are given in Table 2.

The picture that emerges from the results in Table 2 is very clear: the stricter the filtering of the training material (i.e. the positive instances) is, the better the performance of the classifier. The fact that we (potentially) loose certain positive instances in the filtering does not negatively impact on the classifier which substantially benefits from the fact that noise gets removed. Moreover, we find that if the training material is appropriately filtered, adding further negative instances does not help improving the accuracy. By contrast, if we train on a noisy set of positive instances, the classifier benefits from a larger set of negative instances. However, the positive effect that we get from augmenting the non-filtered training data is still weaker than the positive effect we get from the filtering.

5 Induction of Adverbial Participles on Monolingual Data

Given the classifier from Section 4 that predicts the syntactic category of a participle instance

Training Data	Pos. Instances	Neg. Instances	Precision	Recall	Accuracy
Non-Filtered Instances (all alignments)	27.184	10.000	43.10	100	43.10
Non-Filtered Instances (all alignments)	27.184	50.000	74.38	92.97	83.22
Non-Filtered Instances (symm. alignments)	4891	10.000	78.08	89.06	84.56
Non-Filtered Instances (symm. alignments)	4891	50.000	82.31	83.59	85.23
Filtered Instances	1978	10.000	**91.60**	**85.16**	**90.27**
Filtered Instances	1978	50.000	90.83	77.34	86.91

Table 2: Evaluation on 300 participle instances from Europarl

based on its monolingual syntactic context, we can now detect new instances or types of adverbial participles in any PoS-tagged German corpus. In this section, we investigate whether the classifier can be used to augment the resource of adverbial participles directly induced from Europarl with new types.

5.1 Data Extraction

We run our extraction experiment on the Huge German Corpus (HGC), a corpus of 200 million words of newspaper and other text. This corpus has been tagged with TreeTagger (Schmid, 1994). For each of the 5054 participle candidates, we extract all instances from the HGC which have not been tagged as finite verbs (at most 2000 tokens per participle). For each participle token, we also extract its syntactic context in terms of the 3 preceding and the 3 following tags. For classification, we use only those participles that have more than 50 instances in the corpus (2953 types).

In contrast to the cross-lingual filtering mechanisms developed in Zarrieß et al. (2010) which operate on the type-level, the classifier makes a prediction for every token of a given participle candidate. Thus, for each of the participle candidates, we obtain a percentage of instances that have been classified as adverbs. As we would expect, the percentage of adverbial instances is very low for most of the participles in our candidate set: for 75% of the 2953 types, the percentage is below 5%. This result confirms our initial intuition that the property of being used as an adverb is strongly lexically restricted to a certain class of participles.

5.2 Evaluation

Since we know that the classifier has an accuracy of 90% on the Europarl data, we only consider participles as candidates for adverbs where the classifier predicted more than 14% adverbial instances. This leaves us with a set of 210 participles, which comprises 13 of the original 46 participles extracted from Europarl, meaning we have discovered 197 new adverbial participle types.

We performed a manual evaluation of 50 randomly selected types out of the set of 197 new participle types. Therefore, we looked at the instances and their context which the classifier predicted to be adverbial. If there was at least one adverbial instance among these, the participle type was evaluated as correctly annotated by the classifier. By this means, we find that 76% of the participles were correctly classified.

This evaluation suggests that the accuracy of our classifier which we trained and tested on Europarl data is lower on the HGC data. The reason for this drop in performance will be explained in the following Section 5.3. However, assuming an accuracy of 76%, we have discovered 150 new types of adverbial participles. We argue that this is a very satisfactory result given that we have not invested any manual effort into the annotation or extraction of adverbial participles. This results also makes clear that the previous resource we induced on Europarl data, comprising only 46 participle types, was a very limited one.

5.3 Error Analysis

Taking a closer look at the 12 participle candidates that the classifier incorrectly labels as adverbial, we observe that their adverbially classified instances are mostly instances of a predicative use. This means that our Europarl training data does not contain enough evidence to learn the distinction between adverbial and predicative participles. This is not surprising since the set of negative instances used for training the classifier mainly comprises verbal instances of participles. Moreover, the syntactic contexts and constructions in which some predicatives and adverbials are used

Grammar	Prec.	Rec.	F-Sc.	Time in sec
46 Part-Adv	84.12	78.2	81.05	665
243 Part-Adv	84.12	77.67	80.76	665

Table 3: Evaluation on 371 TIGER sentences

Grammar	Parsed Sent.	Starred Sent.	Time-outs	Time in sec
No Part-Adv	665	315	64	3033
46 Part-Adv	710	269	65	3118
243 Part-Adv	767	208	69	3151

Table 4: Performance on the specialised TIGER test set (1044 sentences)

are very similar. Thus, in future work, we will have to include more data on predicatives (which is more difficult to obtain) and analyse the syntactic contexts in more detail.

6 Assessing the Impact of Resource Coverage on Grammar-based Parsing

In this section, we evaluate the classifier-based induction of adverbial participles from a grammar-based perspective. We integrate the entire set of induced adverbial participles (46 from Europarl and 197 from the HGC) into the German LFG grammar. As a consequence, the grammar allows the adverb conversion for 243 lexical participle types. We use the evaluation methodolgy explained in Section 2.

First, we conduct an accuracy-oriented evaluation on the standard TIGER test set. We compare against the German LFG that only integrates the small participle resource from Europarl. The results are given in Table 3. The difference between the 46 Part-Adv and 243 Part-Adv resource is not statistically signficant. Thus, the larger participle resource has no overall negative effect on the parsing performance. As established by an automatic upperbound evaluation in Zarrieß et al. (2010), we cannot not expect to find a positive effect in this evaluation because the phenomenon does not occur in the standard test set.

To show that the augmented resource indeed improves the coverage of the grammar, we built a specialised testsuite of 1044 TIGER sentences that contain an instance of a participle from the resource. Since this testsuite comprises sentences from the training set, we can only report a coverage-oriented evaluation here, see Table 4. The 243 Part-Adv increases the coverage by 8% on the specialised testsuite.

Moreover, we manually evaluated 20 sentences covered by the 243-Part-Adv grammar and not by 46-Part-Adv as to whether they contain a correctly analysed adverbial participle. In two sentences, the grammar obtained an adverbial analysis for clearly predicative modifiers, based on the enlarged resource. In three different sentences, it was difficult to decide whether the participle acts as an adverb or a predicative. In the remaining 15 sentences, the grammar established the the correct analysis of a clearly adverbially used participle.

7 Conclusion

We have proposed a cross-lingual induction method to automatically obtain data on adverbial participles in German. We exploited this cross-lingual data as training material for a classifier that learns to predict the syntactic category of a participle from its monolingual syntactic context. Since this category is usually not annotated in German resources and hard to describe in theory, the finding that adverbial participles can be predicted relatively precisely is of general interest for theoretic and computational approaches to the syntactic analysis of German.

We showed that, in order to obtain an accurate participle classifier, the quality of the training material induced from the parallel corpus is of crucial importance. By applying the filtering techniques from Zarrieß et al. (2010), the accuracy of the classifier increases between 5% and 7%. In future work, we plan to include more data on predicative participles to learn a more accurate distinction between predicative and adverbial participles.

Finally, we used the participle classifier to extract a lexical resource of adverbial participles for the German LFG grammar. In comparison to the relatively small resource of 46 types that can be directly induced from Europarl, we discovered a large number of new participle types (197 types in total). In a parsing experiment, we showed that this much bigger resource does not negatively impact on parsing performance and improves grammar coverage.

Abstract

This paper focuses on the Web-based English-Chinese OOV term translation pattern, and emphasizes particularly on the translation selection strategy based on the fusion of multiple features and the ranking mechanism based on Ranking Support Vector Machine (Ranking SVM). By utilizing the CoNLL2003 corpus for the English Named Entity Recognition (NER) task and selected new terms, the experiments based on different data sources show the consistent results. Our OOV term translation model can "*filter*" the most possible translation candidates with better ability. From the experimental results for combining our OOV term translation model with English-Chinese Cross-Language Information Retrieval (CLIR) on the data sets of Text Retrieval Evaluation Conference (TREC), it can be found that the obvious performance improvement for both query translation and retrieval can also be obtained.

1 Introduction

In Cross-Language Information Retrieval (CLIR), most of users' queries are generally composed of short terms, in which there are many Out-of-Vocabulary (OOV) terms like Named Entities (NEs), new words, terminologies and so on. The translation quality of OOV term directly influences the precision of querying relevant multilingual information. Therefore, OOV term translation has become a very important and challenging issue in CLIR.

With the increasing growth of Web information which includes multilingual hypertext resources with abundant topics, it appears that Web information can mitigate the problem of the restricted OOV term translation accuracy (Lu and Chien, 2002). However, how to select the correct translations from Web information and locate the appropriate translation resources rapidly is still the main goal for OOV term translation. Hence, finding the effective feature representation and the optimal ranking pattern for translation candidates is the core part for the Web-based OOV term translation.

This paper focuses on the Web-based English-Chinese OOV term translation pattern, and emphasizes particularly on the translation selection strategy based on the fusion of multiple features and the translation ranking mechanism based on Ranking Support Vector Machine (Ranking SVM). By utilizing the CoNLL2003 corpus for the English Named Entity Recognition (NER) task and manually selected new terms in various fields, the established OOV term translation model can "*filter*" the most possible translation candidates with better ability. This paper also attempts to apply the OOV term translation mechanism above in English-Chinese CLIR. It can be observed from the experimental results on the data sets of Text Retrieval Evaluation Conference (TREC) that the obvious performance improvement for query translation can be obtained, which is very beneficial to CLIR and can improve the whole retrieval performance.

2 Related Work

At present, the methods for OOV term translation have changed from the basic pattern based on bilingual dictionary, transliteration or parallel corpus to the intermediate pattern based on comparable corpus (Lee et al., 2006; Shao and Ng, 2004; Virga and Khudanpur, 2003), and

Coling 2008: Poster Volume, pages 1435–1443,
Beijing, August 2010

then become a new pattern based on Web mining (Fang et al., 2006; Sproat et al., 2006).

In recent years, many researchers have utilized Web to find the translation candidates on webpages (Wu and Chang, 2007). Al-Onaizan and Knight (2002) used Web statistics information to validate the translation candidates generated by language model, and obtained the accuracy of 72.6% in Arabic-English OOV word translation. Lu and Chien (2004) utilized the statistics information about the anchor texts in Web search results to recognize the translation candidates, and got the accuracy of 63.6% in English-Chinese title query term translation. Zhang and Vines (2004) extracted the translation candidates for OOV query terms in CLIR from Web, and improved the performance of English-Chinese/Chinese-English CLIR to some extent. Zhang et al. (2005) searched the translation candidates by using cross-language query expansion and Web, and obtained the Top-1 accuracy of 81.0% in Chinese-English OOV word translation. Chen and Chen (2006) used the combination of Web statistics and the vocabulary, and acquired the Top-1 accuracy of 87.6% in Chinese-English OOV word translation. Jiang et al. (2007) utilized the combination of Web mining, transliteration and ranking based on Maximum Entropy (ME), only focused on English-Chinese person name translation and got the Top-1 accuracy of 47.5%.

Although the methods above can improve the translation performance for OOV term to a certain degree, there are still three common problems in the OOV term translation based on Web mining. (1) **Chinese key term extraction pattern from Web documents is over complex and the complexity is always higher.** Because of the inherent property of having no segmentation delimitation in Chinese, it's very difficult for English-Chinese OOV term translation to extract Chinese key terms from Web documents. The cost for the extraction computation is generally overlarge (Wang et al., 2004; Zhang and Vines, 2004). (2) **The feature information for the evaluation of translation candidates is not enough and comprehensive.** Most of OOV term translation methods implement the evaluation for candidates through mining simple local and Boolean features, that is, inherent features in candidates and their surrounding context features. However, if only a certain Web document that an OOV term appears is explored, the global information contained in the whole Web document set will be ignored, and the inconsistency and polysemy of candidates cannot be considered. (3) **The relevance measurement for translation pairs is very simple, or the computation cost is too high.** For ranking candidates, most of OOV term translation approaches adopt the simple combination computation of the feature values used, or get assessment based on classification models. Hence, the feature weights are determined according to the corresponding induction and suitable for some specific fields, but cannot guarantee the accuracy of the final translation ranking results. However, the Ranking SVM model can effectively express multiple ranking constraints, and has better universality and applicability (Cao et al., 2006; Joachimes, 2002; Vapnik, 1995).

3 Our Solutions

To support more precise English-Chinese OOV term translation, we establish a multiple-feature-based translation pattern based on Web mining and Ranking SVM. On the one hand, a Chinese key term extraction strategy is built on the simplified extraction computation for PAT-Tree, in which the optimization processing for the confidence of word building is improved to a certain extent. On the other hand, translation candidates are chosen by the fusion of multiple features. The representation forms of local, global and Boolean feature are constructed under the consideration of the complex characteristics of English/Chinese OOV term and Web information. Moreover, for the relevance measurement between an OOV term to be translated and its translation candidates, the supervised learning based on Ranking SVM is introduced to rank candidates precisely.

At first, given an OOV term to be translated as a query, it is input into the Google search engine to acquire the returned webpage snippet set. Next, Chinese key terms are extracted from the PAT-Tree built on the snippet set to determine the translation candidates. Subsequently, local, global and Boolean features are extracted from the candidates based on the fusion of multiple features. Finally, the candidates are filtered and ranked through the supervised learning based on Ranking SVM.

4 Chinese Key Term Extraction

In Web mining of English-Chinese OOV term translation, an important problem is to extract the target translation candidates from the returned Chinese Web documents, which can be considered as a key term extraction task.

The PAT-Tree structure is an efficient indexing method in both IR and Information Extraction (IE) domains (Chien, 1997; Gonnet et al., 1992). Its superior feature is the Semi Infinite String, which can store all the strings from the whole corpus (i.e., the returned snippet set in this paper) in a binary tree. The branch node indicates the search direction and the leaf node stores the index and frequency for a string.

Generally, a Chinese character corresponds to a binary-coded form with 2 bytes (16 bits). Chinese strings can be transformed into binary strings. There is an ending tag for each string and its binary form is "00000000". Take "中文信息抽取" (*Chinese IE*) and "信息检索" (*IR*) as an example, the binary strings for them are described in Figure 1. Thus a PAT-Tree can be built based on these strings, as shown in Figure 2. The branch node stands for the comparison bit (Comp-bit), which represents the position of different bit in binary strings. Some binary strings have the value of 0 in such a bit and are classified into the left branch, while others have 1 and turn to the right branch.

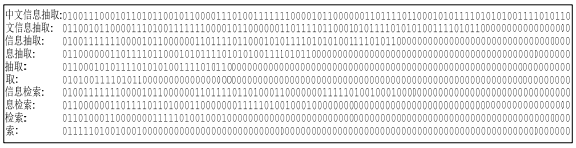

Figure 1. Binary string representation instantiation.

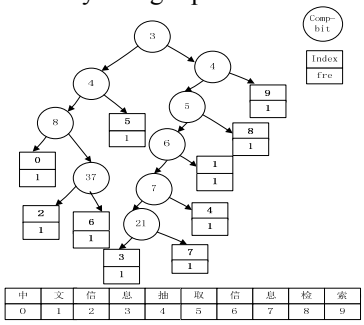

Figure 2. PAT-Tree Instantiation for Figure 1.

In the extraction process, the PAT-tree is traversed first, and the branch nodes with the Comp-bit values larger than 32 are selected. This is because the minimum length of a Chinese common string is 2 characters and each has 16 binary bits. Next, the frequency values of both two child nodes are added as the frequency of the common string (i.e., the parent branch node). At last, the common strings with the frequency values larger than 2 are extracted as the key terms. For the PAT-Tree in Figure 2, there is a branch node with the Comp-bit value of 37, which indicates that at least the prefixes of two strings contain two identical characters. It can be known from the leaf nodes that two strings are "信息抽取" (*IE*) and "信息检索" (*IR*). Hence, the prefix substring "信息" (*information*) with the frequency of 2 is extracted as the common string. Thus the key terms with the arbitrary lengths and frequency values can be retrieved from the built PAT-Tree.

However, with the common strings being extracted, large amounts of noisy terms and fragments are also extracted. To filter noisy fragments, Wang et al. (2004) used SPDCD and the Local-Maxima algorithm, but the computation cost was too expensive. Therefore, the simplified filtering manner is adopted here:

$$\alpha(c_i \cdots c_j) = \frac{f(c_i \cdots c_j) - f(c_1 \cdots c_n)}{f(c_i \cdots c_j)} \qquad (1)$$

where $c_1 \ldots c_n$ is a n-gram that contains the substring $c_i \ldots c_j$; $c_i \ldots c_j$ is the n-1-gram to be estimated, i.e., $c_i \ldots c_j = c_1 \ldots c_{n-1}$ or $c_i \ldots c_j = c_2 \ldots c_n$; $f(\ )$ denotes the string frequency; α represents the cohesion factor of the n-1-gram string, that is, the ability of independent word building. The closer to 1 the value of α is, the more possible meaningful key term $c_i \ldots c_j$ is.

5 Multiple Feature Representation

Local Feature (LF) is constructed based on neighboring tokens and the token itself. There are two types of contextual information to be considered when extracting LFs, namely internal lexical and external contextual information.

(1) **Term length** (*Len*) – Aims to consider the length of the translation candidate.

(2) **Phonetic Value** (*PV*) – Aims to investigate the phonetic similarity between an OOV term and its translation candidates. Because the associated syllabification representations can often be found between Chinese and English syllables with fewer ambiguities, the syllabification has become an effective channel in phonetic feature expression. *PV* means that for measuring the edit distance similarity between the syllabification sequences of an OOV term

and its candidates, the processing is executed according to the specific linguistic rules.

$$PV(S_{OOV}, T_{OOV}) = 1 - \frac{EditDist(S_{OOV}', T_{OOV}')}{Len(S_{OOV}') + Len(T_{OOV}')} \quad (2)$$

where S_{OOV} and T_{OOV} denote the OOV term in the source language and its translation candidate in the target language respectively, S_{OOV}' and T_{OOV}' are the character strings after the syllabification and removing the vowels, *EditDist*(,) indicates the edit distance between two strings, and *Len*( ) is the string length.

(3) **Length Ratio of OOV Term and Its Translation Candidate** (*LR*) – Aims to explore the composition possibility that the extracted key term can be regarded as the translation for an OOV term. An OOV term and its translation should have the similar length, so the *LR* value is close to 1 as possible. A Chinese term is segmented into significant pieces first, and the number of pieces is taken as its length. For example, "非典型肺炎" (*SARS*) is segmented into "非" (*non*), "典型" (*typical*) and "肺炎" (*pneumonia*), and its length is 3. For an English term, the number of words is counted as the length. If there is only one word composed of capital letters, its length is defined as the number of letters, e.g., "*SARS*" has the length of 4. Thus the *LR* value of "*SARS*" and its candidate "非典型肺炎" is 4/3=1.3.

(4) **Phonetic and Semantic Integration Feature** (*P&S_IF*) – Aims to consider the phonetic information and senses of an OOV term and its candidates synthetically. It is set up for multi-word OOV terms, especially for NEs and new terms. Each constituent can be translated by the phonetic information or senses.

$$P\&S\_IF(S_{OOV}, T_{OOV}) = \frac{LScore(S_{OOV}, T_{OOV}) + PV(S_{OOV}'', T_{OOV}'')}{LScore(S_{OOV}, T_{OOV}) + 1} \quad (3)$$

where *LScore*(,) is the matching word number of non-transliteration words in S_{OOV} and T_{OOV}, while S_{OOV}'' and T_{OOV}'' are the remaining strings of S_{OOV} and T_{OOV} after computing *LScore*. For example, given S_{OOV} "*Capitoline Museum*" and its T_{OOV} "卡比多里尼博物馆" (*Capitoline Museum*), the non-transliteration words "*Museum*" and "博物馆" (*museum*) are matched, then *LScore*(S_{OOV}, T_{OOV})=1; the *PV* value between the remaining strings "*Capitoline*" and "卡比多里尼" (*Capitoline*) is 0.8, so the final *P&S_IF* value is 1.8/2=0.9.

Global Feature (GF) is extracted from other occurrences of the same or similar tokens in the Web document set. The common case in the Web-based OOV term translation is that the translation candidates in the previous parts of Web documents will often occur with the same or similar forms in the latter parts. The contextual information from the same and other Web documents may play an important role in determining the final translation. To utilize such global information, GFs are constructed based on the characteristics of Web documents.

(1) **Global Term Frequency** (*G_Freq*) – Aims to utilize the frequency information that an OOV term and its translation candidates appear in the Web document set. It is always the most important feature and includes four parameters. $\boldsymbol{Freq_{Soov}}$ denotes the frequency of S_{OOV} in all the returned webpage snippets. $\boldsymbol{TF_{Toov}}$ indicates the number of T_{OOV}s in all the snippets. $\boldsymbol{DF_{Toov}}$ represents the number of snippets that contain T_{OOV}. ***CO_Freq*** means the number of snippets that contain both S_{OOV} and T_{OOV}, i.e, co-occurrence frequency.

(2) **Chi-Square** (χ^2) **Feature Value** (*CV*) – Aims to evaluate the semantic similarity between an OOV term and its translation candidates by their occurrence in Web documents.

$$CV_{\chi^2}(S_{OOV}, T_{OOV}) = \frac{N \times (a \times d - b \times c)^2}{(a+b) \times (a+c) \times (b+d) \times (c+d)} \quad (4)$$

where a is the number of snippets that contain both S_{OOV} and T_{OOV}, b is the number of snippets that contain S_{OOV} but do not contain T_{OOV}, c is the number of snippets that do not contain S_{OOV} but contain T_{OOV}, d is the number of snippets that do not contain neither of S_{OOV} and T_{OOV}, and $N=a+b+c+d$.

(3) **Co-occurrence Distance** (*CO_Dist*) – Aims to investigate the distance between an OOV term and its candidates in Web documents. This distance is often very closer.

For each snippet that contains both S_{OOV} and T_{OOV}, three positions are considered, that is, the first position that S_{OOV} and T_{OOV} appear ($p1$), the second position ($p2$) and the last one ($p3$). In the following snippet, S_{OOV} is "*AARP*" and T_{OOV} is "美国退休者协会" (*America Association of Retired Persons*, *AARP*).

拿什么创造《AARP杂志》的成功--传媒--人民网
2008年10月18日 ... 它是一个协会杂志，隶属于美国退休者协会（AARP）。《AARP杂志》自称是"世界上发行量 ... 笔者认为，《AARP杂志》的成功，很大程度上得益于以下几点。 ...
media.people.com.cn/GB/22114/45733/136325/8192992.html - 38k - 网页快照 - 类似网页

$p1_{SOOV}$=6, $p2_{SOOV}$=62, $p3_{SOOV}$=97;
$p1_{TOOV}$=54, $p2_{TOOV}$=-1, $p3_{TOOV}$=54.

The position is indexed from 0 and $p2_{TOOV}$=-1 means only one candidate exists in the snippet. Then the nearest position pair $p2_{SOOV}$ and $p1_{TOOV}$ can be found for this example. The distance *Dist* between S_{OOV} and T_{OOV} is computed as:

$$Dist(S_{OOV}, T_{OOV}) = \begin{cases} pi_{S_{OOV}} - pj_{T_{OOV}} - Len(T_{OOV}), & pi_{S_{OOV}} > pj_{T_{OOV}} \\ pj_{T_{OOV}} - pi_{S_{OOV}} - Len(SOOV), & pi_{S_{OOV}} < pj_{T_{OOV}} \end{cases} \quad (5)$$

Given the example above, $Dist=p2_{SOOV}-p1_{TOOV}-7=62-54-7=1$, that is, S_{OOV} and T_{OOV} are a left bracket '(' apart. Finally, the average distance *CO-Dist* in the snippet set can be computed as:

$$CO\_Dist(S_{OOV}, T_{OOV}) = AVG\_Dist(S_{OOV}, T_{OOV}) = \frac{Sum(Dist)}{CO\_Freq(S_{OOV}, T_{OOV})} \quad (6)$$

where *Sum*( ) is the sum of *Dist* in each snippet. (4) **Rank Value** (*RV*) – Aims to consider the rank for translation candidates in the Web document set. It includes five parameters. ***Top_Rank*** (*T_Rank*) is the rank of the snippet that first contains T_{OOV} and given by the search engine. ***Average_Rank*** (*A_Rank*) is the average position of T_{OOV} in the returned snippets.

$$A\_Rank(T_{OOV}) = \frac{Sum(Rank)}{DF_{T_{OOV}}(T_{OOV})} \quad (7)$$

where *Sum*( ) denotes the rank sum of each snippet. ***Simple_Rank*** (*S_Rank*) is computed as $S\_Rank(T_{OOV})=TF_{TOOV}(T_{OOV})*Len(T_{OOV})$, which aims at investigating the impact of the frequency and length of T_{OOV} on ranking. ***R_Rank*** is utilized as a comparison basis.

$$R\_Rank(T_{OOV}) = \beta \times \frac{|T_{OOV}|}{MAX\_WL} + (1-\beta) \times \frac{TF_{T_{OOV}}(T_{OOV})}{Freq_{S_{OOV}}(S_{OOV})} \quad (8)$$

where β is set as 0.25 empirically, $|T_{OOV}|$ is the length of T_{OOV}, and *MAX_WL* denotes the maximum length of candidate terms. ***DF_Rank*** (*D_Rank*) is similar to *S_Rank* and computed as $D\_Rank(T_{OOV})=DF_{TOOV}(T_{OOV})*Len(T_{OOV})$.

Boolean Feature (BF) is a binary feature and equivalent to a heuristic rule designed for the particular relationship between an OOV term and its translation candidates. BFs are used to explore the different occurrence forms with higher possibility for the translation candidates in Web documents. (1) **Position Distance with OOV Term** (*PD_S*$_{OOV}$) – If T_{OOV} occurs close to S_{OOV} (within 10 characters), then this feature is set as 1, else -1. (2) **Neighbor Relationship with OOV Term** (*NR_S*$_{OOV}$) – If T_{OOV} occurs prior or next to S_{OOV}, then this feature is set as 1. (3) **Bracket Neighbor Relationship with OOV Term** (*BNR_S*$_{OOV}$) – If T_{OOV} locates prior or next to S_{OOV} and occurs with the form "T_{OOV} (S_{OOV})" or "S_{OOV} (T_{OOV})", then this feature is set as 1. (4) **Special Mark Word** (*SMW*) – This is an intuitive feature. Within a certain co-occurrence distance (usually less than 10 characters) between an OOV term and its candidates, if there is such a term like "全称" (*full name*), "叫" (*be named as*), "译为" (*be translated as* …), "名称" (*name*), or "(或/又)称为" ((*or*/*also*) *be called as* …), or within 5 characters if there are some punctuations like "( )", "[ ]" and "（）", then this feature is set as 1.

6 Ranking based on Ranking SVM

For the OOV term translation based on Web mining, another difficulty is how to evaluate the relevance between an OOV term and its translation candidates, that is, how to rank the translation candidates from "*best*" to "*worst*".

The candidate ranking can be regarded as a binary classification problem. However, usually only highly related fragments of OOV terms can be found, rather than their correct translations. Instead of regarding the candidate ranking as binary classification, it is solved as an Ordinal Regression problem. Ranking SVM maps different objects into a certain kind of order relation. The key is modeling the judgements for user's preferences, and then the constraint relations for ranking can be derived (Herbrich et al., 1999; Xu et al., 2005).

For a given OOV term S_{OOV}, if there are two translation candidates T_{OOVi} and T_{OOVj}, the preference judgement can be formulated as $T_{OOVi} \succ_{SOOV} T_{OOVj}$. Thus more training samples are constructed, which contain multiple constraint features. The preference judgement can be transformed into the feature function as:

$$f(w, T_{OOVi}, S_{OOV}) \succ_{SOOV} f(w, T_{OOVj}, S_{OOV}) \quad (9)$$

where w is a parameter and represented as a n-dimensional vector $w=\{w_1, w_2, \ldots, w_n\}$. This feature function can also be expressed as:

$$f(w, T_{OOV}, S_{OOV}) = \sum_{k=1}^{p} w_k LF_k(T_{OOV}, S_{OOV}) + \sum_{l=p+1}^{q} w_l GF_l(T_{OOV}, S_{OOV}) + \sum_{m=q+1}^{n} w_m BF_m(T_{OOV}, S_{OOV}) \quad (10)$$

where LF_k(,), GF_l(,) and BF_m(,) are the local, global and Boolean feature representation respectively. These three kinds of feature representation are incorporated as a whole and represented as a feature function family with the multi-dimensional feature vector in (11).

$$f(w, T_{OOV}, S_{OOV}) = w \cdot h(T_{OOV}, S_{OOV}) \quad (11)$$

That is the ranking results for candidates. Thus the relevance for each feature vector x (translation candidate) containing a group of features can be evaluated through Ranking SVM.

7 Experiment and Analysis

7.1 Data Set and Evaluation Metrics

For the performance evaluation, 4,593 English NEs are selected from the English corpus of the NER task in CoNLL2003. The test set contains 446 Person Names (PRNs), 329 Location Names (LCNs) and 455 Organization Names (OGNs), and the remaining is taken as the training set (including 1,137 PRNs, 1,152 LCNs and 1,074 OGNs) through manually tagging. Additionally, 300 English new terms are chosen randomly from 9 categories, including movie name, book title, brand name, terminology, idiom, rare animal name, rare PRN and OGN. Such terms are used to investigate the generalization ability of our model.

Top-N-Inclusion-Rate is used as a measurement for the translation performance. For a set of OOV terms to be translated, its *Top-N-Inclusion-Rate* is defined as the percentage of the OOV terms whose translations could be found in the first N extracted translations.

7.2 Experiment on Parameter Setting

For Chinese key term extraction, the test on the threshold α is performed. As shown in Figure 3, when the lower bound of α is set as 0.4, the best performance can be achieved.

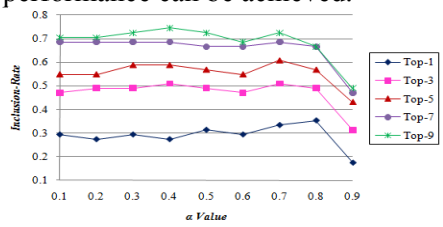

Figure 3. Results for α value setting.

To get the most relevant candidates into top-10 before the final ranking, an initial ranking test is performed on *S_Rank*, *R_Rank* and *D_Rank*. It can be seen from Figure 4 that *D_Rank* exhibits the better performance.

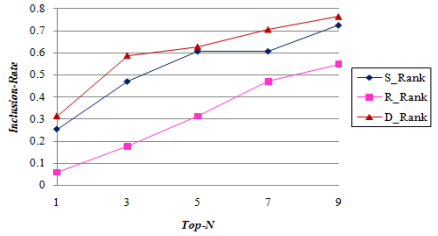

Figure 4. Results for initial ranking manner.

To find how many returned webpage snippets are suitable for the translation acquisition, the test on the snippet number is performed. As shown in Figure 5, the best performance can be obtained by using 200 snippets.

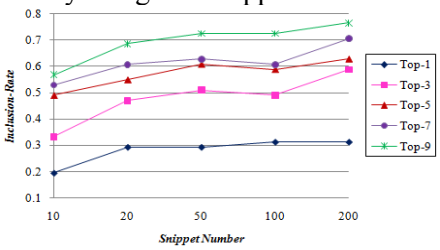

Figure 5. Results for webpage snippet number.

7.3 Experiment on Multiple Feature Fusion

To verify the effectiveness for multiple feature fusion, the test on the feature combination for OOV term translation is implemented. As shown in Table 1, the highest accuracy (the percentage of the correct translations in all the extracted translations) of 83.1367% can be acquired by using all the features.

Feature				Accuracy	Reduction
All Features				83.1367%	—
Numerical Feature	*Local Numerical Feature*	*-Len*		81.7355%	-1.4012%
		-PV		77.4494%	-5.6873%
		-LR		81.4231%	-1.7136%
		-P&S_IF		79.9002%	-3.2365%
	Global Numerical Feature	*Global Frequency*	*-TF_{Toov}*	82.9877%	-0.1490%
			-DF_{Toov}	83.2112%	+0.0745%
			-CO_Freq	83.0870%	-0.0497%
		-CV		82.3125%	-0.8242%
		-CO_Dist		81.8577%	-1.2790%
		RV	*-T_Rank*	83.0125%	-0.1242%
Boolean Feature		*-PD_S_{OOV}*		82.1806%	-0.9561%
		-NR_S_{OOV}		82.2923%	-0.8444%
		-BNR_S_{OOV}		80.7525%	-2.3842%
		-SMW		83.1740%	+0.0373%

Table 1. Results for feature combination.

In Table 1, '-' before the specific feature denotes that the OOV term is translated by combining all the other features except this feature; "*Reduction*" represents the difference value between the translation accuracy obtained by using all the features and that by removing a specific feature. The positive "*Reduction*" indicates that the accuracy is improved after removing a specific feature, while the negative shows the accuracy is decreased.

It can be seen from Table 1 that for mining the translations for OOV terms, the most important three features are *PV*, *P&S_IF* and *BNR*, then *LR*, *Len* and *CO_Dist*. As for the frequency feature, its contribution is limited, because many translation candidates with higher *PV* or *P&S_IF* values are the terms with low frequency. It shows that *PV* and *P&S_IF* play a very crucial role in mining the translation candidates with low frequency. In addition,

the contribution degree of *CV* is also positive. However, when training based on only the features that are beneficial to the whole translation performance, the best translation accuracy is 83.1243%, which is worse than that by combining all the features. From a view of the effect of the single feature on the whole translation performance, some features may have slightly negative impact. Nevertheless, through combining all the features, the multiple feature fusion mechanism can indeed efficiently improve the translation accuracy.

7.4 Experiment on OOV Term Translation

Some translation examples based on different ranking patterns are given in Table 2, in which the score represents the correlation degree between the translation pair. The closer to -1 the score is, the more irrelevant the translation pair is; while the closer to 3 the score is, the more relevant the translation pair is.

Table 2. OOV term translation examples.

Furthermore, Jiang et al. (2007) utilized the combination of Web mining, transliteration and ME-based ranking to implement English-Chinese PRN translation, which is very similar to our approach. To make a contrast with it, we accomplished this method on the same data set. The comparison results are shown in Table 3.

Ranking Pattern	**Category**	**Top-1**	**Top-2**	**Top-3**
***based on SVM* (*Multiple Features*)**	***PRN***	64.44%	85.07%	91.42%
	LCN	53.93%	73.33%	81.82%
	OGN	49.68%	70.70%	82.16%
	All	**56.10%**	**76.59%**	**85.45%**
***based on Ranking-SVM* (*Multiple Features*)**	***PRN***	77.14%	89.20%	93.96%

	OGN	63.05%	79.61%	89.17%
	All	**68.46%**	**81.87%**	**89.92%**
[Jiang et al., 2007] *based on ME* ($PV+CV+NR\_S_{OOV}+BNR\_S_{OOV}$)	***PRN* (Only)**	49.07%	57.33%	60.43%

Table 3. Performance comparison results.

From the experimental results above, it can be concluded that the ranking based on the supervised learning significantly outperforms the conventional ranking strategies, and Ranking SVM is superior to SVM and ME for translation candidate ranking. From the contrast between our model and Jiang's method, it can be found that our approach is superior to Jiang's and the better performance can be achieved based on the fusion of multiple features proposed in this paper. Meanwhile, it can also be observed from Table 3 that the performance for LCN and OGN translation is better, while the best performance is obtained for PRN translation. It shows that our translation model is sensitive to the category and the popularity degree of OOV term to some extent.

In order to test the translation performance for the other kinds of English OOV term, another test is performed based on the OOV new terms selected randomly from 9 categories. The experimental results are shown in Table 4.

Top-N-Inclusion-Rate	**Top-1**	**Top-3**	**Top-5**	**Top-7**	**Top-9**
Other OOV Terms	49.41%	71.02%	72.46%	81.51%	84.30%

Table 4. Results for other OOV terms.

Furthermore, the translations for some OOV terms based on different translation manners are compared, including our proposed model, Google Translate and the Live Trans translation model developed by WKD Lab at National Taiwan University, as shown in Table 5.

OOV Terms	**Translation from Our Model**	**Translation from Google Translate**	**Translation from Live Trans**
Forrest Gump	阿甘正传/电影	阿甘正传	阿甘正传/亚伦席维斯崔
Estee Lauder	雅诗兰黛/化妆品	雅诗兰黛	雅诗兰黛/香水/化妆品
Arteriosclerosis	动脉硬化	动脉粥样硬化	心脏/动脉硬化
Woman Pace-Setter	三八红旗手	女子的步伐/制定	三八红旗手
Dream of the Red Mansion	红楼/红楼梦	红楼梦	红楼梦/文章书目
SARS	非典型肺炎/非典	严重急性呼吸系统综合症	病毒/非典型肺炎
NASA	美国宇航局	美国航天局	美国太空总署

Table 5. Comparison for different translation manners.

The results above demonstrate that our model can be applicable to all kinds of OOV terms and has better translation performance.

7.5 Experiment on English-Chinese CLIR

To explore the applicability and usefulness of our OOV term translation model in English-Chinese CLIR, four CLIR runs based on *long query* (terms in both title and description fields) and *short query* (only terms in the title field) are carried out on the English topic set (25 topics) and Chinese corpus (127,938 documents) from TREC-9. (1) *E-C_LongCLIR*1 – using long query and the bilingual-dictionary-based query translation; (2) *E-C_LongCLIR*2 – using long query, the bilingual-dictionary-based

query translation and our OOV term translation; (3) *E-C_ShortCLIR*1 – using short query and the bilingual-dictionary-based query translation; (4) *E-C_ShortCLIR*2 – using short query, the bilingual-dictionary-based query translation and our OOV term translation. The Precision-Recall curves and Median Average Precision (MAP) values are shown in Figure 6.

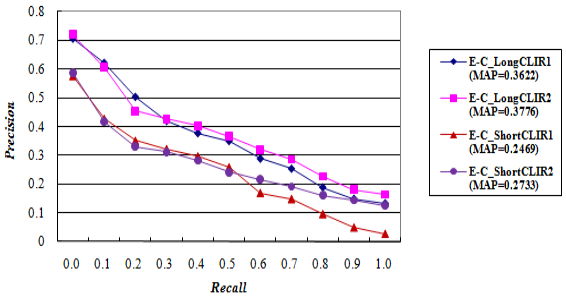

Figure 6. Results for English-Chinese CLIR combining our OOV term translation model.

It can be seen from Figure 6 that the best run is *E-C_LongCLIR*2, and its results exceed those by another run *E-C_LongCLIR*1 based on long query. By adopting both query translation based on bilingual dictionary and OOV term translation, the English-Chinese CLIR for long query has gained the significant improvement on the whole retrieval performance. Compared with the traditional query translation based on bilingual dictionary, such a combination manner is exactly a better way for query translation from the source language to the target language. Additionally, through comparing the results for the other two runs *E-C_ShortCLIR*1 and *E-C_ShortCLIR*2 based on short query, it can also be further confirmed that our OOV term translation mechanism can also support CLIR for short query effectively.

7.6 Analysis and Discussion

Through analyzing the results for translation extraction and ranking, it can be found that the translation quality is highly related to the following aspects. (1) **The translation results are associated with the search engine used, especially for some specific OOV terms.** For example, given an OOV term "*Cross-Strait Three-links*", the mining result based on Google in China is "两岸大三通", while some meaningless information is mined by Live Trans. (2) **Some terms are conventional terminologies and cannot be translated literally.** For example, "*Woman Pace-Setter*", a proper noun with the Chinese characteristic, should be translated into "三八红旗手", rather than "女子的步伐" (*women's pace*) or "制定" (*establishment*) given by Google Translate. (3) **The proposed model is sensitive to the notability degree of OOV term.** This phenomenon is the main reason why there is obvious difference among the translation performance for PRN, LCN and OGN. (4) **There is a "*fragment effect*" in PAT-Tree-based Chinese key term extraction.** The fragments of Chinese terms have become the main noisy data. Such a problem should be solved by setting the specific threshold for additional features like heuristic rules and occurrence distance. (5) **Word Sense Disambiguation (WSD) should be added to improve the translation performance.** Although most of OOV terms have a unique semantic definition, there are still a few OOV terms with ambiguity, e.g., "*AARP*" (*American Association of Retired Persons* or *AppleTalk Address Resolution Protocol*). (6) **The ranking pattern based on the supervised learning is able to synthesize various feature representations for translation candidates.** Thus the rank for a candidate can be precisely predicted through tagging and training.

8 Conclusions

In this paper, the proposed model improves the acquirement ability for OOV term translation through Web mining, and solves the translation pair selection and evaluation in a novel way by fusing multiple features and introducing the supervised learning based on Ranking SVM. Furthermore, it is significant to apply the key techniques in machine translation into OOV term translation, such as OOV term recognition, statistical machine learning, alignment of sentence and phoneme, and WSD. All these aspects will be our research focus in the future.

Abstract

This paper presents two pivot strategies for statistical machine transliteration, namely *system-based* pivot strategy and *model-based* pivot strategy. Given two independent source-pivot and pivot-target name pair corpora, the *model-based* strategy learns a direct source-target transliteration model while the *system-based* strategy learns a source-pivot model and a pivot-target model, respectively. Experimental results on benchmark data show that the *system-based* pivot strategy is effective in reducing the high resource requirement of training corpus for low-density language pairs while the *model-based* pivot strategy performs worse than the *system-based* one.

1 Introduction

Many technical terms and proper names, such as personal, location and organization names, are translated from one language into another language with approximate phonetic equivalents. This phonetic translation using computer is referred to as machine transliteration. With the rapid growth of the Internet data and the dramatic changes in the user demographics especially among the non-English speaking parts of the world, machine transliteration play a crucial role in most multilingual NLP, MT and CLIR applications (Hermjakob *et al.*, 2008; Mandl and Womser-Hacker, 2004). This is because proper names account for the majority of OOV issues and translation lexicons (even derived from large parallel corpora) usually fail to provide good coverage over diverse, dynamically increasing names across languages.

Much research effort has been done to address the transliteration issue in the research community (Knight and Graehl, 1998; Wan and Verspoor, 1998; Kang and Choi, 2000; Meng *et al.*, 2001; Al-Onaizan and Knight, 2002; Gao *et al.*, 2004; Klementiev and Roth, 2006; Sproat, 2006; Zelenko and Aone, 2006; Li *et al.*, 2004, 2009a, 2009b; Sherif and Kondrak, 2007; Bertoldi *et al.*, 2008; Goldwasser and Roth, 2008). These previous work can be categorized into three classes, i.e., grapheme-based, phoneme-based and hybrid methods. Grapheme-based method (Li *et al.*, 2004) treats transliteration as a direct orthographic mapping process and only uses orthography-related features while phoneme-based method (Knight and Graehl, 1998) treats transliteration as a phonetic mapping issue, converting source grapheme to source phoneme followed by a mapping from source phoneme to target phoneme/grapheme. Hybrid method in machine transliteration refers to the combination of several different models or decoders via re-ranking their outputs. The report of the first machine transliteration shared task (Li *et al.*, 2009a, 2009b) provides benchmarking data in diverse language pairs and systemically summarizes and compares different transliteration methods and systems using the benchmarking data.

Although promising results have been reported, one of major issues is that the state-of-the-art machine transliteration approaches rely heavily on significant source-target parallel name pair corpus to learn transliteration model. However, such corpora are not always availa-

Coling 2008: Poster Volume, pages 1444–1452,
Beijing, August 2010

ble and the amounts of the current available corpora, even for language pairs with English involved, are far from enough for training, letting alone many low-density language pairs. Indeed, transliteration corpora for most language pairs without English involved are unavailable and usually rather expensive to manually construct. However, to our knowledge, almost no previous work touches this issue.

To address the above issue, this paper presents two pivot language-based transliteration strategies for low-density language pairs. The first one is *system*-based strategy (Khapra *et al.*, 2010), which learns a source-pivot model from source-pivot data and a pivot-target model from pivot-target data, respectively. In decoding, it first transliterates a source name to *N*-best pivot names and then transliterates each pivot names to target names which are finally re-ranked using the combined two individual model scores. The second one is *model*-based strategy. It learns a direct source-target transliteration model from two independent[1] source-pivot and pivot-target name pair corpora, and then does direct source-target transliteration. We verify the proposed methods using the benchmarking data released by the NEWS2009[2] (Li *et al.*, 2009a, 2009b). Experiential results show that without relying on any source-target parallel data the system-based pivot strategy performs quite well while the model-based strategy is less effective in capturing the phonetic equivalent information.

The remainder of the paper is organized as follows. Section 2 introduces the baseline method. Section 3 discusses the two pivot language-based transliteration strategies. Experimental results are reported at section 4. Finally, we conclude the paper in section 5.

2 The Transliteration Model

Our study is targeted to be language-independent so that it can be applied to different language pairs without any adaptation effort. To achieve this goal, we use joint source-channel model (JSCM, also named as *n*-gram transliteration model) (Li *et la.*, 2004) under grapheme-based framework as our transliteration model due to its state-of-the-art performance by only using orthographical information (Li *et al.*, 2009a). In addition, unlike other feature-based methods, such as CRFs (Lafferty *et al.*, 2001), MaxEnt (Berger *et al.*, 1996) or SVM (Vapnik, 1995), the JSCM model directly computes model probabilities using maximum likelihood estimation (Dempster *et al.*, 1977). This property facilitates the implementation of the model-based strategy.

JSCM directly models how both source and target names can be generated simultaneously. Given a source name *S* and a target name *T*, it estimates the joint probability of *S* and *T* as follows:

$$\begin{aligned} P(S,T) &= P(s_1 \dots s_i \dots s_K, t_1 \dots t_i \dots t_K) \\ &= P(< s_1, t_1 >, \dots, < s_i, t_i >, \\ &\qquad \dots, < s_K, t_K >) \\ &= P(< s,t >_1, \dots, < s,t >_i, \\ &\qquad \dots < s,t >_K) \\ &= \prod_{k=1}^{K} P\left(< s,t >_k \mid < s,t >_1^{k-1}\right) \\ &\approx \prod_{k=1}^{K} P\left(< s,t >_k \mid < s,t >_{k-n+1}^{k-1}\right) \end{aligned}$$

where s_i and t_i is an aligned transliteration unit[3] pair, and *n* is the *n*-gram order.

In implementation, we compare different unsupervised transliteration alignment methods, including Giza++ (Och and Ney, 2003), the JSCM-based EM algorithm (Li *et al.*, 2004), the edit distance-based EM algorithm (Pervouchine *et al.*, 2009) and Oh et al.'s alignment tool (Oh *et al.*, 2009). Based on the aligned transliteration corpus, we simply learn the transliteration model using maximum likelihood estimation (Dempster *et al.*, 1977) and decode the transliteration result $T^* = \text{argmax}_T P(S,T)$ using stack decoder (Schwartz and Chow, 1990).

[1] Here "independent" means the source-pivot and pivot-target data are not derived from the same English name source.

[2] http://www.acl-ijcnlp-2009.org/workshops/NEWS2009/pages/sharedtask.html

[3] Transliteration unit is language dependent. It can be a Chinese character, a sub-string of English words, a Korean Hangual or a Japanese Kanji or several Japanese Katakanas.

3 Pivot Transliteration Strategies

3.1 System-based Strategy

The system-based strategy is first proposed by Khapra *et al.* (2010). They worked on system-based strategy together with CRF and did extensively empirical studies on Indic/Slavic/Semetic languages and English.

Given a source name *S*, a target name *T* and let *Z*(*S*, *Ź*) be the n-best transliterations of *S* in one or more pivot language *Ź* [4], the system-based transliteration strategy under JSCM can be formalized as follows:

$$\begin{aligned} P(S,T) &= \sum_{Ź} \sum_{Z(S,Ź)} P(S, Z(S,Ź), T) \\ &\approx \sum_{Z} P(S,Z,T) \\ &\approx \sum_{Z} P(T|S,Z) * P(S,Z) \end{aligned}$$

In the above formula, we assume that there is only one pivot language used in the derivation from the first line to the second line. Under the pivot transliteration framework, we can further simplify the above formula by assuming that T is independent of S when given Z. The assumption holds because the parallel name corpus between *S* and *T* is not available under the pivot transliteration framework. The n-best transliterations in pivot language are expected to be able to carry enough information of the source name *S* for translating *S* to target name *T*. Then, we have:

$$\begin{aligned} P(S,T) &= \sum_{Z} P(T|Z) * P(S,Z) \\ &= \sum_{Z} \frac{P(S,Z) * P(T,Z)}{P(Z)} \end{aligned} \quad (1)$$

Obviously we can train the two JSCMs of $P(S,Z)$ and $P(T,Z)$ using the two parallel corpora of (S,Z) and (T,Z), and train the language model $P(Z)$ using the monolingual corpus of Z. Following the nature of JSCM, Eq. (1) directly models how the source name *S* and pivot name *Z* and how the pivot name *Z* and the target name *T* are generated simultaneously. Since *Z* is considered twice in $P(S,Z)$ and $P(T,Z)$, the duplicated impact of *Z* is removed by dividing the model by $P(Z)$.

Given the model as described at Eq. (1), the decoder can be formulized as:

$$\begin{aligned} T^* &= \operatorname*{argmax}_T P(S,T) \\ &= \operatorname*{argmax}_T \left(\sum_Z \frac{P(S,Z) * P(T,Z)}{P(Z)} \right) \end{aligned} \quad (2)$$

If we consider multiple pivot languages, the modeling and decoding process are:

$$\begin{aligned} & P(S,T) \\ &= \sum_{Ź} \sum_{Z(S,Ź)} \left(\frac{P\left(S, Z(S,Ź)\right) * P(T, Z(S,Ź))}{P(Z(S,Ź))} \right) \end{aligned}$$

$$\begin{aligned} & T^* \\ &= \operatorname*{argmax}_T \left(\sum_{Ź} \sum_{Z(S,Ź)} \frac{P\left(S, Z(S,Ź)\right) * P\left(T, Z(S,Ź)\right)}{P\left(Z(S,Ź)\right)} \right) \end{aligned}$$

3.2 Model-based Strategy

Rather than combining the transitive transliteration results at system level, the model-based strategy aims to learn a direct model $P(S,T)$by combining the two individual models of $P(S,Z)$ and $P(T,Z)$, which are learned from the two parallel corpora of (S,Z) and (T,Z), respectively. Now let us use bigram as an example to illustrate how to learn the transliteration model $P(S,T) = \prod_{k=1}^{K} P(< s,t >_k \mid < s,t >_{k-1})$ using the model-based strategy.

$$\begin{aligned} & P(< s,t >_k \mid < s,t >_{k-1}) \\ &= \frac{P(< s,t >_k, < s,t >_{k-1})}{P(< s,t >_{k-1})} \end{aligned} \quad (3)$$

where,

$$\begin{aligned} & P(< s,t >_k, < s,t >_{k-1}) \\ &= P(s_k, s_{k-1}, t_k, t_{k-1}) \\ &= \sum_{z_k, z_{k-1}} P(s_k, s_{k-1}, t_k, t_{k-1}, z_k, z_{k-1}) \\ &= \sum_{z_k, z_{k-1}} P(t_k, t_{k-1} | s_k, s_{k-1}, z_k, z_{k-1}) \\ &\qquad * P(s_k, s_{k-1}, z_k, z_{k-1}) \end{aligned}$$

[4] There can be multiple pivot languages used in the two strategies. However, without loss of generality, we only use one pivot language to facilitate our discussion. It is very easy to extend one pivot language to multiple ones by considering all the pivot transliterations in all pivot languages.

The same as the system-based strategy, we can further simplify the above formula by assuming that T is independent of S when given Z. Indeed, $P(t_k, t_{k-1}|s_k, s_{k-1}, z_k, z_{k-1})$ cannot be estimated directly from training corpus. Then we have:

$$\begin{aligned} P(< s,t >_k, < s,t >_{k-1}) &= \sum_{z_k, z_{k-1}} P(t_k, t_{k-1}|s_k, s_{k-1}, z_k, z_{k-1}) \\ &\quad * P(s_k, s_{k-1}, z_k, z_{k-1}) \\ &\approx \sum_{z_k, z_{k-1}} P(t_k, t_{k-1}|z_k, z_{k-1}) \\ &\quad * P(s_k, s_{k-1}, z_k, z_{k-1}) \\ &\approx \sum_{z_k, z_{k-1}} P(t_k, t_{k-1}, z_k, z_{k-1}) \\ &\quad * P(s_k, s_{k-1}, z_k, z_{k-1}) \\ &\quad / P(z_k, z_{k-1}) \end{aligned} \quad (4)$$

where $P(t_i, t_{i-1}, z_i, z_{i-1})$, $P(s_i, s_{i-1}, z_i, z_{i-1})$ and $P(z_i, z_{i-1})$ can be directly learned from training corpus. $P(< s,t >_{k-1})$ for Eq (3) can also be estimatedas follows.

$$P(< s,t >_{k-1}) = \sum_{<s,t>_k} P(< s,t >_k, < s,t >_{k-1})$$

In summary, eq. (1) formulizes the system-based strategy and eq. (3), (4) and (5) formulize the model-based strategy, where we can find that they share the same nature of generating source, pivot and target names simultaneously. The difference is that the model-based strategy operates at fine-grained transliteration unit level.

3.3 Comparison with Previous Work

Almost all previous work on machine transliteration focuses on direct transliteration or transliteration system combination. There is only one recent work (Khapra *et al.*, 2010) touching this issue. They work on system-based strategy together with CRF. Compared with their work, this paper gives more formal definitions and derivations of system-based strategy from modeling and decoding viewpoints based on the JSCM model.

The pivot-based strategies at both system and model levels have been explored in machine translation. Bertoldi *et al.* (2008) studies two pivot approaches for phrase-based statistical machine translation. One is at system level and one is to re-construct source-target data and alignments through pivot data. Cohn and Lapata (2007) explores how to utilize multilingual parallel data (rather than pivot data) to improve translation performance. Wu and Wang (2007, 2009) extensively studies the model-level pivot approach and also explores how to leverage on rule-based translation results in pivot language to improve translation performance. Utiyama and Isahara (2007) compares different pivot approaches for phrase-based statistical machine translation. All of the previous work on machine translation works on phrase-based statistical machine translation. Therefore, their translation model is to calculate phrase-based conditional probabilities at unigram level ($P(t_k|s_k)$) while our transliteration model is to calculate joint transliteration unit-based conditional probabilities at bigram level ($P(< s,t >_k | < s,t >_{k-1})$).

4 Experimental Results

4.1 Experimental Settings

We use the NEWS 2009 benchmark data as our experimental data (Li *et al.*, 2009). The NEWS 2009 data includes 8 language pairs, where we select English to Chinese/Japanese /Korean data (E-C/J/K) and based on which we further construct Chinese to Japanese/Korean and Japanese to Korean for our data.

Language Pair	Training	Dev	Test
English-Chinese	31,961	2896	2896
English-Japanese	23,225	1492	1489
English-Korean	4,785	987	989
Chinese-Japanese	12,417	75	77
Chinese-Korean	2,148	32	31
Japanese-Korean	6,035	65	69

Table 1. Statistics on the data set

Table 1 reports the statistics of all the experimental data. To have a more accurate evaluation, the test sets have been cleaned up to make sure that there is no overlapping between any test set with any training set. In addition, the three E-C/J/K data are generated independently so that there is very small percentage of over-

lapping between them. This can ensures the evaluation of the pivot study fair and accurate.

We compare different alignment algorithms on the DEV set. Finally we use Pervouchine *et al.* (2009)'s alignment algorithm for Chinese-English/Japanese/Korean and Oh *et al.* (2009)'s alignment algorithm for English-Korean and Li *et al.* (2004)'s alignment algorithm for English-Japanese and Japanese-Korean. Given the aligned corpora, we directly learn each individual JSCM model (i.e., *n*-gram transliteration model) using SRILM toolkits (Stolcke, 2002). We also use SRILM toolkits to do decoding. For the system-based strategy, we output top-20 pivot transliteration results.

For the evaluation matrix, we mainly use top-1 accuracy (ACC) (Li *et al.*, 2009a) to measure transliteration performance. For reference purpose, we also report the performance using all the other evaluation matrixes used in NEWS 2009 benchmarking (Li *et al.*, 2009a), including F-score, MRR, MAP_ref, MAP_10 and MAP_sys. It is reported that F-score has less correlation with other matrixes (Li *et al.*, 2009a).

4.2 Experimental Results

4.2.1 Results of Direct Transliteration

Table 2 reports the performance of direct transliteration. The first three experiments (line 1-3) are part of the NEWS 2009 share tasks and the others are our additional experiments for our pivot studies.

Comparison of the first three experimental results and the results reported at NEWS 2009 shows that we achieve comparable performance with their best-reported systems at the same conditions of using single system and orthographic features only. This indicates that our baseline represents the state-of-the-art performance. In addition, we find that the *back*-transliteration (line 4-6) consistently performs worse than its corresponding *forward*-transliteration (line 1-3). This observation is consistent with what reported at previous work (Li *et al.*, 2004; Zhang *et al.*, 2004). The main reason is because English has much more transliteration units than foreign C/J/K languages. This makes the transliteration from English to C/J/K a many-to-few mapping issue and *back*-transliteration a few-to-many mapping issue. Therefore *back*-transliteration has more ambiguities and thus is more difficult.

Overall, the lower six experiments (line 7-12) shows worse performance than the upper six experiments which has English involved. This is mainly due to the less available training data for the language pairs without English involved. This observation motivates our study using pivot language for machine transliteration.

4.2.2 Results of System-based Strategy

Table 3 reports three empirical studies of system-based strategies: Japanese to Chinese through English, Chinese to Japanese through English and Chinese to Korean through English. Considering the fact that those language pairs with English involved have the most training data, we select English as pivot language in the system-based study. Table 3 clearly shows that:

- The system-based pivot strategy is very effective, achieving significant performance improvement over the direct transliteration by 0.09, 0.07 and 0.03 point of ACC in the three language pairs, respectively;
- Different from other pipeline methodologies, the system-based pivot strategy does not suffer heavily from the error propagation issue. Its ACC is significantly better than the product of the ACCs of the two individual systems;
- The combination of pivot system and direct system slightly improves overall ACC.

We then conduct more experiments to figure out the reasons. Our further statistics and analysis show the following reasons for the above observations:

The pivot approach is able to use source-pivot and pivot-target data whose amount is much more than that of the available direct source-target data.

- The nature of transliteration is phonetic translation. Therefore a little bit variation in orthography may not hurt or even help to improve transliteration performance in some cases as long as the orthographical variations keep the phonetic equivalent

Language Pairs	ACC	F-Score	MRR	MAP_ref	MAP_10	MAP_sys

Table 4. Performance of Model-based Pivot Transliteration Strategy

- The N-best accuracy of machine transliteration (of both to and from English) is very high[5]. It means that in most cases the correct transliteration in pivot language can be found in the top-20 results and the other 19 results hold the similar pronunciations with the correct one, which can serve as alternative "quasi-correct" inputs to the second stage transliterations and thus largely improve the overall accuracy.

The above analysis holds when using English as pivot language. Now let us see the case of using non-English as pivot language. Table 4 reports two system-based strategies using Chinese and Japanese as pivot languages, where we can find that the performance of two system-based strategies is worse than that of the direct transliterations. The main reason is because that the direct transliteration utilizes much more training data than the pivot approach. However, the good thing is that the system-based pivot strategy using non-English as pivot language still does not suffer from error propagation issue. Its ACC is significantly better than the product of the ACCs of the two individual systems.

4.2.3 Results of Model-based Strategy

Table 4 reports the performance of model-based strategy. It clearly shows that the model-based strategy is less effective and performs much worse than both the system-based strategy and direct transliteration.

While the model-based strategy works well at phrase-based statistical machine translation (Wu and Wang, 2007, 2009), it does not work at machine transliteration. To investigate the reasons, we conduct many additional experiments and do statistics on the model and

[5] Both our studies and previous work (Li et al., 2004; Zhang et al., 2004) shows that the top-20 accuracy from English to J/K is more than 0.85 and more than 0.95 in English-Chinese case. The top-20 accuracy is a little worse from C/J/K to English, but still more than 0.7.

aligned training data[6]. From this in-depth analysis, we find that main reason is due to the fact that the model-based strategy introduces too many entries (ambiguities) to the final transliteration model. For example, in the Jap→Chi→Eng experiment, the unigram and bigram entries of the transliteration model obtained by the model-based strategy are 45 and 6.6 times larger than that of the transliteration model trained directly from parallel data. This is not surprising. Given a transliteration unit in pivot language, it can generate $m * n$ source-to-target transliteration unit mappings (unigram entry of the model), where m is the number of the source units that can be mapped to the pivot unit and n is the number of the target units that can be mapped from the pivot unit.

Besides the ambiguities introduced by the large amount of entries in the model, another reason that leads to the worse performance of model-based strategy is the size inconsistence of transliteration unit of pivot language. As shown at Table 4, we conduct three experiments. In the first experiment (Chi→Eng→Jap), we use English as pivot language. We find that the English transliteration unit size in Chi→Eng model is much larger than that in Eng→Jap model. This is because from phonetic viewpoint, in Chi→Eng model, the English unit is at syllable level (corresponding one Chinese character) while in Eng→Jap model, the English unit is at sub-syllable level (consonant or vowel or syllable, corresponding one Japanese Katakana). This is the reason why we conduct two model-based experiments for Chi→Eng→Jap. One is based on the original alignments (**Model-based Pivot: O**) and one is based on the reconstructed alignments[7] (**Model-based Pivot: R**). Experimental results clearly show that the reconstruction improves performance significantly. In the second and third experiments (Jap→Chi→Eng, Eng→Jap→Kor), we use Chinese and Japanese as pivot languages. Therefore we do not need to re-construct transliteration units and alignments. However, the performance is still very poor. This is due to the first reason of the large amount of ambiguities.

The above two reasons (ambiguities and transliteration unit inconsistence) are mixed together, leading to the worse performance of the model-based strategy. We believe that the fundamental reason is because the pivot transliteration unit is too small to be able to convey enough phonetic information of source language to target language and thus generates too many alignments and ambiguities.

5 Conclusions

A big challenge to statistical-based machine transliteration is the lack of the training data, esp. to those language pairs without English involved. To address this issue, inspired by the research in the SMT research community, we study two pivot transliteration methods. One is at system level while another one is at model level. We conduct extensive experiments using NEW 2009 benchmarking data. Experimental results show that system-based method is very effective in capturing the phonetic information of source language. It not only avoids successfully the error propagation issue, but also further boosts the transliteration performance by generating more alternative pivot results as the inputs of the second stage. In contrast, the model-based method in its current form fails to convey enough phonetic information from source language to target language.

For the future work, we plan to study how to improve the model-based strategy by pruning out the so-called "bad" transliteration unit pairs and re-sampling the so-called "good" unit pairs for better model parameters. In addition, we also would like to explore other pivot-based transliteration methods, such as constructing source-target training data through pivot languages.

Discriminant Ranking for Efficient Treebanking

Yi Zhang **Valia Kordoni**

Abstract

Treebank annotation is a labor-intensive and time-consuming task. In this paper, we show that a simple statistical ranking model can significantly improve treebanking efficiency by prompting human annotators, well-trained in disambiguation tasks for treebanking but not necessarily grammar experts, to the most relevant linguistic disambiguation decisions. Experiments were carried out to evaluate the impact of such techniques on annotation efficiency and quality. The detailed analysis of outputs from the ranking model shows strong correlation to the human annotator behavior. When integrated into the treebanking environment, the model brings a significant annotation speed-up with improved inter-annotator agreement.[†]

1 Introduction

The development of a large-scale treebank (Marcus et al., 1993; Hajič et al., 2000; Brants et al., 2002) with rich syntactic annotations is a highly rewarding task. But the huge amount of manual labor required for the annotation task itself, as well as the difficulties in standardizing linguistic analyses, results in long development cycles of such valuable language resources, which typically amounts to years or even decades. Despite the profound scientific and practical value of detailed syntactic treebanks, the requirement and necessity for long-term commitment raises the risk cost of such projects, a fact which often makes them not feasible in many current economical environments.

In recent years, computational grammars have been employed to assist the construction of such language resources. A typical development model involves a parser which generates candidate analyses, and human annotators who manually identify the desired tree structure. This treebanking method dramatically reduces the cost of training annotators, for they are not required to spontaneously produce linguistic solutions to various phenomena. Instead, they are trained to associate their language intuition with specific linguistically-relevant decisions. How to select and carefully present such decisions to the annotators is thus crucial for achieving high annotation speed and quality. On the other hand, for large treebanking projects, parallel annotation with multiple annotators is usually necessary. Inter-annotator agreement is a crucial quality measure in such cases. But improvements on annotation speed should not be achieved at expense of the quality of the treebank.

With both speed and quality in mind, a good treebank annotation method should acknowledge the complexity of the decision-making process; for instance, the same tree can be disambiguated by different sets of individual decisions which are mutually dependent. The annotation method should also strive to create a distraction-free environment for annotators who can then focus on making the judgments. To this effect, we present a simple statistical model that learns from the annotation history, and offers a ranking of disambiguation decisions from the most to the least relevant

[†]The first author thanks the German Excellence Cluster of Multimodal Computing and Interaction for the support of the work.

Beijing, August 2010

ones, which enables well-trained human annotators to speed-up treebanking without compromising on the quality of the linguistic decisions guiding the annotation task.

The remaining of this paper is structured as follows: Section 2 gives an overview of the difficulties in syntactic annotation, and the potential ways of improving the annotation efficiency without damaging the quality; Section 3 presents the new annotation method which is based on a statistical discriminant ranking model; Sections 4 and 5 describe the setup and results of a series of annotation experiments; Section 6 concludes the paper and proposes future research directions.

2 Background

Large-scale full syntactic annotation has for quite some time been approached with mixed feelings by researchers. On the one hand, detailed syntactic annotation serves as a basis for corpus-linguistic study and data-driven NLP methods. Especially, when combined with popular supervised machine learning methods, richly annotated language resources, like, for instance, treebanks, play a key role in modern computational linguistics. The public availability of large-scale treebanks in recent years has stimulated the blossoming of data-driven approaches to syntactic and semantic parsing.

On the other hand, though, the creation of detailed syntactic structures turns out to be an extremely challenging task. From the choice of the appropriate linguistic framework and the design of the annotation scheme to the choice of the text source and the working protocols on the syncronization of the parallel development, as well as the quality assurance, none of these steps in the entire annotation procedure is considered a solved issue. Given the vast design choices, very few of the treebanking projects have made it through all these difficult annotation stages. Even the most outstanding projects have not been completed without receiving criticisms.

Our treebanking project is no exception. The aim of the project is to provide annotations of the Wall Street Journal (henceforward WSJ) sections of the Penn Treebank (henceforward PTB (Marcus et al., 1993)) with the help of the English Resource Grammar (henceforward ERG; (Flickinger, 2002)), a hand-written large-scale and wide-coverage grammar of English in the framework of Head-Driven Phrase Structure Grammar (HPSG; (Pollard and Sag, 1994)). Such annotations are very rich linguistically, since apart from syntax they also incorporate semantic information. The annotation cycle is organized into iterations of parsing, treebanking in the sense of disambiguating syntactic and semantic analyses of the various linguistic phenomena contained in the corpus, error analysis and grammar/treebank update cycles. That is, sentences from the WSJ are first parsed with the PET parser (Callmeier, 2001), an efficient unification-based parser, using the ERG. The parsing results are then manually disambiguated by human annotators. However, instead of considering individual trees, the annotation process is mostly invested on binary decisions which are made on either accepting or rejecting constructions or lexical types. Each of such decisions, called discriminants, as we will also see in the following, reduces the number of the trees satisfying the constraints. The process is presented in the next section in more detail. What should, though, be clear is that the aforementioned multi-cycle annotation procedure is as time-consuming and human-error prone as any other, despite the fact that at the center of the entire annotation cycle lies a valuable linguistic resource, which has been developed with a lot of effort over many years, namely the ERG. For the first period of this project, we have established an average speed of 40 sentences per annotator hour, meaning a total of $\sim$1200 hours of annotation for the entire WSJ. Including the long training period at the beginning of the project, and periodical grammar and treebank updates, the project period is roughly two years with two part-time annotators employed.

3 Statistical Discriminant Ranking

3.1 Discriminants & Decisions

One common characteristic of modern treebanking efforts – especially, in so-called dynamic treebanking platforms (cf., for instance, (Oepen et al., 2002) and http://redwoods.stanford.edu), like the one we are describing and referring

to extensively in the following, is that the candidate trees are constructed automatically by the grammar, and then manually disambiguated by human annotators. In doing so, linguistically rich annotation is built efficiently with minimum manual labor. In order to further improve the manual disambiguation efficiency, systems like `[incr tsdb()]` (Oepen, 2001) compute the difference between candidate analyses. Instead of looking at the huge parse forest, the treebank annotators select or reject the features that distinguish between different parses, until no ambiguity remains (either one analysis is accepted from the parse forest, or all of them are rejected). The number of decisions for each sentence is normally around $log_2 n$ where n is the total number of candidate trees. For a sentence with 5000 candidate readings, only about 12 treebanking decisions are required for a complete disambiguation. A similar method was also proposed in (Carter, 1997).

Formally, an attribute that distinguishes between different parses is called a *discriminant*. For Redwoods-style treebanks, this is extracted either from the syntactic derivation trees or the semantic representations (in the form of Minimal Recursion Semantics (`MRS`; (Copestake et al., 2005))).

Figure 1 shows an example graphical annotation interface. At the top of the window, a list of action buttons shows the operations permitted on the sentence level. Then the sentence in its original `PTB` bracket format is shown. $15 : 0$ indicates that at the current disambiguation state, 15 trees remain to be disambiguated while 0 has been eliminated. On the left large panel, the candidate trees are shown in their simplified phrase-structure representation. Note that the actual `HPSG` analyses are not shown in the screenshot and can be displayed on request. On the right large panel, the list of effective discriminants (see Section 3.2) up to this disambiguation state is shown. The highlighted discriminant in Figure 1 suggests a possibility of constructing the entire sentence by choosing a subject-head rule (SUBJH), taking *"ms. Haag"* as the subject and *"plays Elianti."* as the head daughter. When the discriminant is clicked, the annotator can say *yes* or *no* to it, hence narrowing the remaining trees to the *In Parses* or *Out Parses*. The *unknown* button is used to mark the uncertainties and is rarely used.

Note that in this interface, the discriminants are sorted in descending order according to their length, meaning that the discriminants related to higher level constructions are shown before the lexical type choices. When up to 500 parses are stored in the forest, the average number of discriminants per forest is about 100. Scanning through the long list manually can be time-consuming and distracting.

Kordoni and Zhang (2009) show that annotators tend to start with the decisions with the most certainty, and delay the "hard" decisions as much as possible. As the decision progresses, many of the "hard" discriminants will receive an inferred value from the certain decisions. Our annotation guideline only describes specific decisions. The order in which discriminants are chosen is left underspecified and very much depends on personal styles. In practice, we see that our annotators gradually developed complex strategies which involve both top-down and bottom-up pruning.

One potential drawback of such a discriminant-based treebanking method is that the process is very sensitive to decision errors. One wrong judgment can rule out the correct tree and ruin the analysis of the sentence. In such a case, the annotators usually resort to backtracking to previous decisions they had made. To compensate for this, we ask our annotators to double-check the treebanked analysis before saving the disambiguation result. And in case of doubt, they are instructed to avoid ambivalent decisions as much as possible.

3.2 Maximum-Entropy-Based Discriminant Ranking Model

Suppose for a sentence ω, a parse forest Y was generated by the grammar. Note that for efficiency reasons, the parse forest might have been trimmed to only contain up to n top readings ranked by the parse disambiguation model. For convenience, we note the parse forest Y as a set of parses $\{y_1, y_2, \ldots, y_n\}$. Each discriminant d defines a binary valued function δ on the parse forest ($\delta : Y \mapsto \{0, 1\}$) , which can be interpreted as whether a parse y_i has attribute d or not. By the nature of this definition, each discriminant

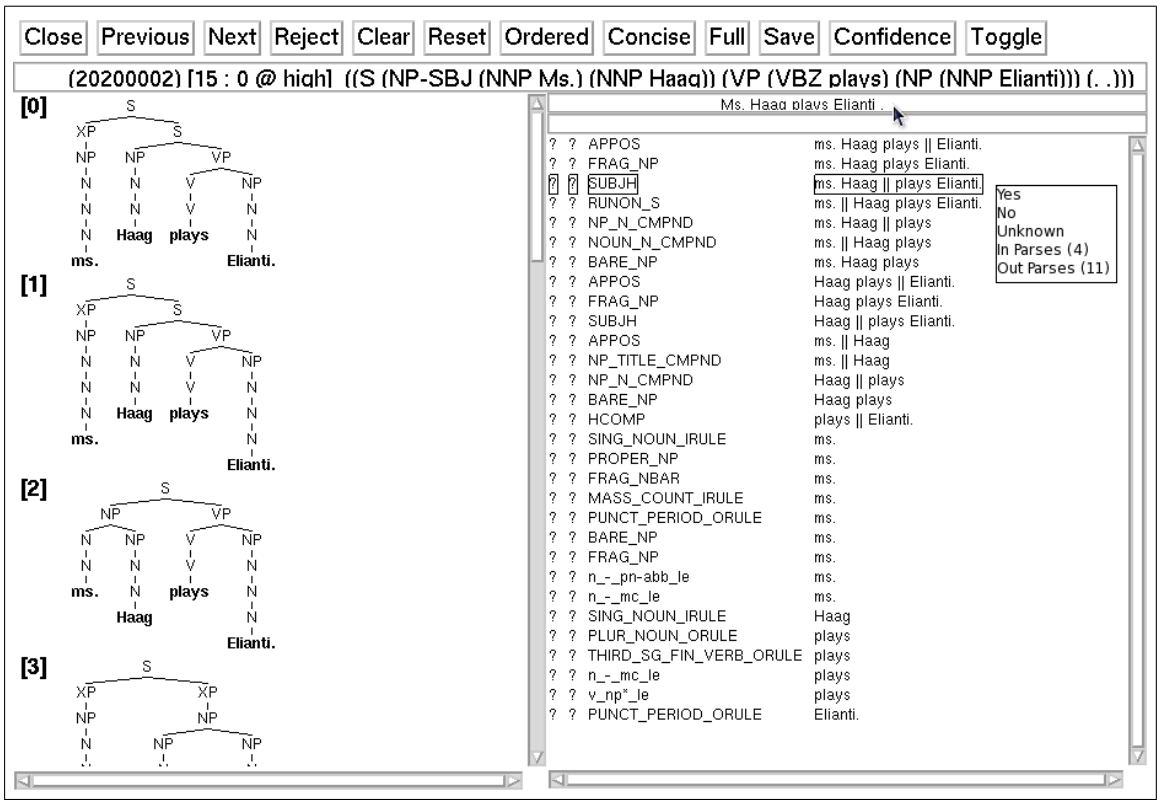

Figure 1: Screenshot of the discriminant-based treebanking graphical annotator interface

function defines a bi-partition of the parse forest. When both subsets of the partition are non-empty, i.e., there exists at least one y_p and y_q such that $\delta(y_p) = 0$ and $\delta(y_q) = 1$, the discriminant is considered *effective* on the forest Y. In the following discussion, we are only considering the set of effective discriminants D for parse forest Y.

Instead of directly predicting the outcome of disambiguation decision on each discriminant (i.e., whether the GOLD tree has discriminant function value 0 or 1), our model tries to measure the probability of a discriminant being chosen by human annotators, regardless of the *yes/no* decision. For each discriminant d, and the parse forest Y, a set of feature functions $f_1, f_2, \ldots, f_k$ receive real values, and contribute to the following log-linear model:

$$P(d|Y, D) = \frac{exp(\sum_{i=1}^{k} \lambda_i f_i(d, Y))}{\sum_{d' \in D} exp(\sum_{i=1}^{k} \lambda_i f_i(d', Y))} \quad (1)$$

where $\lambda_1, \lambda_2, \ldots, \lambda_k$ are the parameters of the model.

To estimate these model parameters, we gather the annotation logs from our treebank annotators on the completed datasets with detailed information about each discriminant. Apart from the necessary information to reconstruct the discriminants from the forest, the log also contains the status information of i) whether the discriminant takes value 0 or 1 on the gold tree; ii) whether the human annotator has said *yes* or *no* to the discriminant. Note that the human annotator does not need to manually decide on the value of each discriminant. Whenever a new decision is made, the forest will be pruned to the subset of trees compatible with the decision. And all remaining discriminants are checked for effectiveness on the pruned forest. Discriminants which become ineffective from previous decisions are said to have received *inferred* values.

The parameters of the model are estimated by the open-source maximum entropy parameter es-

timation toolkit TADM[1]. For training, we use all the manually disambiguated discriminants as positive instances, and automatically inferred discriminants as negative instances.

The discriminant ranking model is applied during the manual annotation sessions. When a parse forest is loaded and the discriminants are constructed, each discriminant is assigned an (unnormalized) score $\sum_{i=1}^{k} \lambda_i f_i(d, Y)$, and the list of discriminants is sorted by descending order of the score accordingly. The scoring and sorting adds negligible additional computation on the treebanking software, and is not noticeable to the human annotators. By putting those discriminants that are potentially to be manually judged near the top of the list, the model saves manual labor on scanning through the lengthy list by filtering out ambivalent discriminants.

Note that this discriminant ranking model predicts the possibility of a discriminant being manually disambiguated. It is not modeling the specific decision that the human annotator makes on the discriminant. Including the decision outcome in the model can potentially damage the annotation quality if annotators develop a habit of overtrusting the model prediction, making the whole manual annotation pointless. A discriminant ranking model, however, only suggestively re-orders the discriminants on the presentation level, which are much safer when the annotation quality is concerned.

3.3 Feature Model for Syntactic Discriminants

In practice, there are different ways of finding discriminants from the parse forest. For instance, the [incr tsdb()] system supports both syntax-based and semantics-based discriminants. The syntax-based discriminants are extracted from the derivation trees of the HPSG analyses. All HPSG rule applications (unary or binary) and choices of lexical entries are picked as candidate discriminants and checked for effectiveness. The semantics-based discriminants, on the other hand, represent the differences on the semantic structures (MRS in the cases of DELPH-IN[2] grammars). With a few exceptions, many DELPH-IN HPSG treebanks choose to use the syntactic discriminants which allow human annotators to pick the low-level constructions. The above proposed ranking model works for different types of discriminants (and potentially a mixture of different discriminant types). But for the evaluation of this paper, we show the feature model designed for the syntactic discriminants only.

The syntactic discriminants record the differences between derivation trees by memorizing direct rule applications and lexical choices. Beside the rule or lexical entry name, the discriminant also records the information concerning the corresponding constituent, e.g., the category and spanning of the constituent, the parent and daughters of the constituent, etc. Furthermore, given the discriminant d and the parse forest Y, we can calculate the distribution of parses over the value of the discriminant function δ, which can be characterized by $\sum_{y \in Y} \delta(y)/|Y|$. This numeric feature indicates how many parses can be ruled out with the given discriminant.

As example, for the highlighted discriminant in Figure 1, the extracted features are listed in Table 1.

4 Experiment Setup

To test the effectiveness of the discriminant ranking models, we carried out a series of experiments, investigating their effects on both annotation speed and quality. The experiment was done in the context of our ongoing annotation project of the WSJ sections of the PTB described in Section 2. Despite sharing the source of texts, the new project aims to create an independently annotated corpus. Therefore, the trees from the PTB were not used to guide the disambiguation process. In this annotation project, two annotators (both graduate students, referred to as A and B below) are employed to manually disambiguate the parsing outputs of the ERG. For quality control and adjudication in case of disagreement, a third linguist/grammarian annotates parts of the treebank in parallel.

With the help of our annotation log files, which record in details the manual decision-making process, we trained three discriminant ranking mod-

Feature	Possible Values	Example
discriminant type	RULE/LEX	RULE
edge position	FULL/FRONT/BACK	FULL
edge span	$length$(constituent)/$length$(sentence)	4/4
edge category	rule or lexical type name	SUBJH
level of discrimination	$\sum_{y \in Y} \delta(y)/\lvert Y \rvert$	4/15
branch splitting	$length$(left-dtr)/$length$(constituent)	2/4

Table 1: Features for syntactic discriminant ranking model and example values for the highlighted discriminant in Figure 1

els with the datasets completed so far: MODEL-A and MODEL-B trained with annotation logs from two annotators separately, and MODEL-BOTH trained jointly with data from both annotators. For each annotator's model (MODEL-A and MODEL-B), we used about 6,000 disambiguated parse forests for training. For each of these 6,000 forests, the log file contains about 600,000 effective discriminants, among which only $\sim$6% received a manual decision.

To evaluate the treebanking speed, we have the annotators work under a distraction-free environment and record their annotation speed. The speed is averaged over several 1-hour annotation sessions. Different discriminant ranking models were used without the annotators being informed of the details of the setting.

As testing dataset, we use the texts from the PARC 700 Dependency Bank (King et al., 2003), which include 700 carefully selected sentences from the WSJ sections of the PTB. These sentences were originally chosen for the purpose of parser evaluation. Many linguistically challenging phenomena are included in these sentences, although the sentence length is shorter in average than the sentence length in the entire WSJ. The language is also less related to the financial domain specific language observed in the WSJ. We parsed the dataset with the Feb. 2009 version of the ERG, and recorded up to 500 trees per sentence (ranked by a MaxEnt parse selection model trained on previously treebanked WSJ sections).

5 Results

Although we employed a typical statistical ranking model in our system, it is difficult to directly evaluate the absolute performance of the predicted ranking. Annotators only annotate a very small subset of the discriminants, and their order is not fully specified. To compare the behavior of models trained with data annotated by different annotators, we plot the relative ranking (normalized to $[0, 1]$ for each sentence, with 0 being the highest rank and 1 the lowest) of discriminants for 50 sentences in Figure 2.

The plot shows a strong positive linear correlation between the two ranking models. The particularly strong correlation at the low and high ends of the ranking shows that the two annotators share a similar behavior pattern concerning the most and least preferred discriminants. The correlation is slightly weaker in the middle ranking zone, where different preferences or annotation styles can be observed.

To further visualize the effect of the ranking model, we highlighted with color the discriminants which are manually annotated by annotator B under a basic setting without using the ranking models. 75% of these "prominent" discriminants are grouped within the top-25% region of the plot. Without surprise, the model B gives an average relative ranking of 0.18 as oppose to 0.21 with model A. The overall distribution of rankings for manually disambiguated discriminants are shown in Figure 3.

In Table 2, the average treebanking speed of two annotators over multiple annotation sessions is shown. The baseline model ranks the discriminants by the spanning length of the corresponding constituent, and uses the alphabetical order of the rule or lexical type names as tie-breaker. The own-model refers to the annotation sessions which have been carried out by the annotators us-

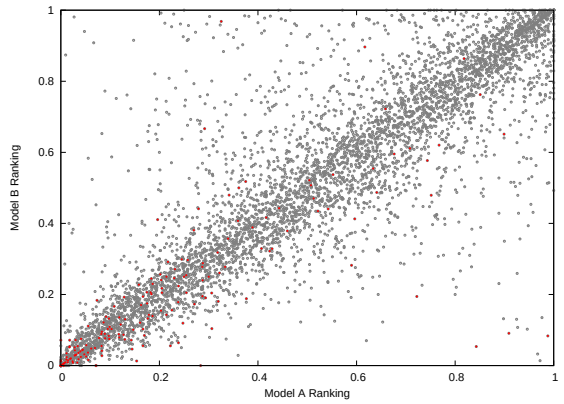

Figure 2: Correlation of discriminant ranks with different models and manual annotation

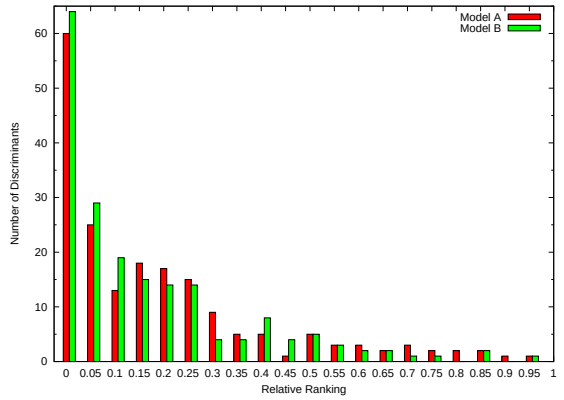

Figure 3: Histogram of rankings given by two models on discriminants manually picked by annotator B

ing their own ranking model. The peer-model refers to the annotation sessions where the annotators use their peer colleague's model. And finally, the joint-model refers to the annotations done by the jointly trained model.

The annotation efficiency was boosted by over 50% with all the discriminant ranking models. The own-model setting achieved best speed. This is probably due to the fact that the model most closely reflects the annotation habit of the annotator. But the advantage over other models is very small.

To measure the inter-annotator agreement, we calculate the Cohen's KAPPA (Carletta, 1996) on the constituents of the derivation trees:

$$\kappa = \frac{Pr(a) - Pr(e)}{1 - Pr(e)} \quad (2)$$

Ranking Model	Speed (s/h)	Speed-up (%)
Baseline	61.9	–
Own-model	**96.1**	**55%**
Peer-model	94.6	53%
Joint-model	95.0	53%

Table 2: Average annotation speed with different discriminant ranking models

where $Pr(a)$ is the relative observed agreement between annotators, and $Pr(e)$ is the probability of two annotators agreeing by chance. The calculation of $Pr(a)$ can be done in a similar way to the calculation of PARSEVAL labeled bracketing accuracy, while $Pr(e)$ is estimated by averaging the agreement over a large set of tree pairs randomly sampled from the parse forest. Since the calculation of κ takes into account the agreement occurring by chance, it is a safer (though has the tendency of being overly conservative) measure of agreement.

Ranking Model	Cohen's KAPPA (κ)
Baseline	0.5404
Own-model	**0.5798**
Peer-model	0.5567
Joint-model	0.5536

Table 3: Inter-annotator agreement measured by constituent-level Cohen's KAPPA

The numbers in Table 3 show that the use of discriminant ranking models results in a small improvement to the inter-annotator agreement, with the best agreement achieved by each annotator using the model trained with their own annotation records. These numbers are comforting in that the annotation quality is not damaged by our new way to present the linguistic decisions.

Note that the relatively low inter-annotator agreement in this experiment is due to the fact that we used a dataset which involves non-trivial linguistic phenomena that are on average more difficult than the texts in the WSJ corpus. Another fact is that these annotations were done under time pressure. The annotators are not encouraged to go backwards to check and correct the previous sentences during these sessions. On the entire WSJ, we have recorded a stable and persistently higher

agreement level at $\kappa = 0.6$. Given the highly detailed linguistic annotations specified by the grammar (over 260 rules and 800 lexical types), this figure indicates a very substantial agreement between our annotators. Our further investigation has shown that the agreement figure hits the ceiling at around $\kappa = 0.65$. Further training and discussion is not rewarded with sustainable improvement of annotation quality.

Apart from the numerical evaluation, we also interview our annotators for subjective feelings about the various ranking models. There is generally a very positive attitude towards all the ranking models over the baseline. An easily decidable discriminant is usually found within the top-3 with very few exceptions, which leads to a self-noticeable speed-up that confirms our numeric findings. It is also interesting to note that, despite the substantial difference between the statistical models, the difference is hardly noticed by the annotators. And the results only show small variations in both the annotation speed, as well as the inter-annotator agreement.

The annotators also claim that the speed-up is somewhat diminished over the "rejected" sentences, for which none of the candidate trees are acceptable. In such cases, the annotators still have to go through a long sequence of discriminants, and sometimes have to redo the previous steps in fear of the chain-effect of wrong decisions. How to compensate for the psychological insatisfaction of rejecting all analyses while maintaining good annotation speed and quality is a new topic for our future research.

6 Conclusion & Future Work

We propose to use a statistical ranking model to assist the discriminant-based treebank annotation. Our experiment shows that such a model, trained on annotation history, brings a huge efficiency improvement together with slightly improved inter-annotator agreement.

Although the reported experiments were carried out on the specific `HPSG` treebank, we believe that the proposed ranked discriminant-based annotation method can be applied in annotation tasks concerning different linguistic frameworks, or even different layers of linguistic representation. Apart from the specific features presented in Section 3.3, the model itself does not assume a phrase-structure tree annotation, and the discriminants can take various forms. Assuming a "grammar" produces a number of candidate analyses, the annotators can rely on the ranking model to efficiently pick relevant discriminants, and focus on making linguistically relevant decisions. This is especially suitable for large annotation tasks aiming for parallel rich annotation by multiple annotators, where fully manual annotation is not feasible and high inter-annotator agreement hard to achieve.

The ranking model is based on annotation history and influences the future progress of treebanking. It can be dynamically integrated into the treebank development cycles in which the annotation habit evolves over time. Such a model can also shorten the training period for new annotators, which is an interesting aspect for our future investigation.

From a different point of view, the rankings of the discriminants show annotators' confidence on various ambiguities. The clearly uneven distribution over discriminants can also provide grammar writers with interesting feedback, helping with the improvement of the linguistic analysis. We would also like to integrate confidence measures into the computer-assisted treebank annotation process, which could potentially help annotators make difficult decisions, such as whether to reject all trees for a sentence.

Abstract

An important task of opinion mining is to extract people's opinions on features of an entity. For example, the sentence, "*I love the GPS function of Motorola Droid"* expresses a positive opinion on the "*GPS function*" of the Motorola phone. "*GPS function*" is the feature. This paper focuses on mining features. *Double propagation* is a state-of-the-art technique for solving the problem. It works well for medium-size corpora. However, for large and small corpora, it can result in low precision and low recall. To deal with these two problems, two improvements based on *part-whole* and "*no*" patterns are introduced to increase the recall. Then feature ranking is applied to the extracted feature candidates to improve the precision of the top-ranked candidates. We rank feature candidates by feature importance which is determined by two factors: feature relevance and feature frequency. The problem is formulated as a bipartite graph and the well-known web page ranking algorithm HITS is used to find important features and rank them high. Experiments on diverse real-life datasets show promising results.

1 Introduction

In recent years, opinion mining or sentiment analysis (Liu, 2010; Pang and Lee, 2008) has been an active research area in NLP. One task is to extract people's opinions expressed on features of entities (Hu and Liu, 2004). For example, the sentence, "*The picture of this camera is amazing*", expresses a positive opinion on the *picture* of the camera. "*picture*" is the feature. How to extract features from a corpus is an important problem. There are several studies on feature extraction (e.g., Hu and Liu, 2004, Popescu and Etzioni, 2005, Kobayashi et al., 2007, Scaffidi et al., 2007, Stoyanov and Cardie. 2008, Wong et al., 2008, Qiu et al., 2009). However, this problem is far from being solved.

Double Propagation (Qiu et al., 2009) is a state-of-the-art unsupervised technique for solving the problem. It mainly extracts noun features, and works well for medium-size corpora. But for large corpora, this method can introduce a great deal of noise (low precision), and for small corpora, it can miss important features. To deal with these two problems, we propose a new feature mining method, which enhances that in (Qiu et al., 2009). Firstly, two improvements based on *part-whole* patterns and "*no*" patterns are introduced to increase recall. Part-whole or *meronymy* is an important semantic relation in NLP, which indicates that one or more objects are parts of another object.

Coling 2008: Poster Volume, pages 1462–1470,
Beijing, August 2010

For example, the phrase "*the engine of the car*" contains the part-whole relation that "*engine*" is part of "*car*". This relation is very useful for feature extraction, because if we know one object is part of a product class, this object should be a feature. "*no*" pattern is another extraction pattern. Its basic form is the word "no" followed by a noun/noun phrase, for instance, "no noise". People often express their short comments or opinions on features using this pattern. Both types of patterns can help find features missed by double propagation. As for the low precision problem, we present a feature ranking approach to tackle it. We rank feature candidates based on their importance which consists of two factors: feature relevance and feature frequency. The basic idea of feature importance ranking is that if a feature candidate is correct and frequently mentioned in a corpus, it should be ranked high; otherwise it should be ranked low in the final result. Feature frequency is the occurrence frequency of a feature in a corpus, which is easy to obtain. However, assessing feature relevance is challenging. We model the problem as a bipartite graph and use the well-known web page ranking algorithm HITS (Kleinberg, 1999) to find important features and rank them high. Our experimental results show superior performances. In practical applications, we believe that ranking is also important for feature mining because ranking can help users to discover important features from the extracted hundreds of fine-grained candidate features efficiently.

2 Related work

Hu and Liu (2004) proposed a technique based on association rule mining to extract product features. The main idea is that people often use the same words when they comment on the same product features. Then frequent itemsets of nouns in reviews are likely to be product features while the infrequent ones are less likely to be product features. This work also introduced the idea of using opinion words to find additional (often infrequent) features.

Popescu and Etzioni (2005) investigated the same problem. Their algorithm requires that the product class is known. The algorithm determines whether a noun/noun phrase is a feature by computing the pointwise mutual information (PMI) score between the phrase and class-specific discriminators, e.g., "*of xx*", "*xx has*", "*xx comes with*", etc., where *xx* is a product class. This work first used part-whole patterns for feature mining, but it finds part-whole based features by searching the Web. Querying the Web is time-consuming. In our method, we use predefined part-whole relation patterns to extract features in a domain corpus. These patterns are domain-independent and fairly accurate.

Following the initial work in (Hu and Liu 2004), several researchers have further explored the idea of using opinion words in product feature mining. A dependency based method was proposed in (Zhuang et al., 2006) for a movie review analysis application. Qiu et al. (2009) proposed a double propagation method, which exploits certain syntactic relations of opinion words and features, and propagates through both opinion words and features iteratively. The extraction rules are designed based on different relations between opinion words and features, and among opinion words and features themselves. Dependency grammar was adopted to describe these relations. In (Wang and Wang, 2008), another bootstrapping method was proposed. In (Kobayashi et al. 2007), a pattern mining method was used. The patterns are relations between feature and opinion pairs (they call *aspect-evaluation* pairs). The patterns are mined from a large corpus using pattern mining. Statistics from the corpus are used to determine the confidence scores of the extraction.

In general information extraction, there are two approaches: rule-based and statistical. Early extraction systems are mainly based on rules (e.g., Riloff, 1993). In statistical methods, the most popular models are Hidden Markov Models (HMM) (Rabiner, 1989), Maximum Entropy Models (ME) (Chieu et al., 2002) and Conditional Random Fields (CRF) (Lafferty et al., 2001). CRF has been shown to be the most effective method. It was used in (Stoyanov et al., 2008). However, a limitation of CRF is that it only captures local patterns rather than long range patterns. It has been shown in (Qiu et al., 2009) that many feature and opinion word pairs have long range dependencies. Experimental results in (Qiu et al., 2009) indicate that CRF does not perform well.

Other related works on feature extraction mainly use topic modeling to capture topics in

reviews (Mei et al., 2007). In (Su et al., 2008), the authors also proposed a clustering based method with mutual reinforcement to identify features. However, topic modeling or clustering is only able to find some general/rough features, and has difficulty in finding fine-grained or precise features, which is more related to information extraction.

3 The Proposed Method

As discussed in the introduction section, our proposed method deals with the problems of double propagation. So let us give a short explanation why double propagation can cause problems in large or small corpora.

Double propagation assumes that features are nouns/noun phrases and opinion words are adjectives. It is shown that opinion words are usually associated with features in some ways. Thus, opinion words can be recognized by identified features, and features can be identified by known opinion words. The extracted opinion words and features are utilized to identify new opinion words and new features, which are used again to extract more opinion words and features. This propagation or bootstrapping process ends when no more opinion words or features can be found. The biggest advantage of the method is that it requires no additional resources except an initial seed opinion lexicon, which is readily available (Wilson et al., 2005, Ding et al., 2008). Thus it is domain independent and unsupervised, avoiding laborious and time-consuming work of labeling data for supervised learning methods. It works well for medium–size corpora. But for large corpora, this method may extract many nouns/noun phrases which are not features. The precision of the method thus drops. The reason is that during propagation, adjectives which are not opinionated will be extracted as opinion words, e.g., "*entire*" and "*current*". These adjectives are not opinion words but they can modify many kinds of nouns/noun phrases, thus leading to extracting wrong features. Iteratively, more and more noises may be introduced during the process. The other problem is that for certain domains, some important features do not have opinion words modifying them. For example, in reviews of mattresses, a reviewer may say "*There is a valley on my mattress*", which implies a negative opinion because "*valley*" is undesirable for a mattress. Obviously, "*valley*" is a feature, but "*valley*" may not be described by any opinion adjective, especially for a small corpus. Double propagation is not applicable in this situation.

To deal with the problem, we propose a novel method to mine features, which consists of two steps: feature extraction and feature ranking. For feature extraction, we still adopt the double propagation idea to populate feature candidates. But two improvements based on part-whole relation patterns and a "no" pattern are made to find features which double propagation cannot find. They can solve part of the recall problem. For feature ranking, we rank feature candidates by feature importance.

A part-whole pattern indicates one object is part of another object. For the previous example "*There is a valley on my mattress*", we can find that it contains a part-whole relation between "*valley*" and "*mattress*". "*valley*" belongs to "*mattress*", which is indicated by the preposition "*on*". Note that "*valley*" is not actually a part of mattress, but an effect on the mattress. It is called a *pseudo part-whole* relation. For simplicity, we will not distinguish it from an actual part-whole relation because for our feature mining task, they have little difference. In this case, "$noun_1$ on $noun_2$" is a good indicative pattern which implies $noun_1$ is part of $noun_2$. So if we know "*mattress*" is a class concept, we can infer that "*valley*" is a feature for "*mattress*". There are many phrase or sentence patterns representing this type of semantic relation which was studied in (Girju et al, 2006). Beside part-whole patterns, "no" pattern is another important and specific feature indicator in opinion documents. We introduce these patterns in detail in Sections 3.2 and 3.3.

Now let us deal with the first problem: noise. With opinion words, part-whole and "no" patterns, we have three feature indicators at hands, but all of them are ambiguous, which means that they are not hard rules. We will inevitably extract wrong features (also called noises) by using them. Pruning noises from feature candidates is a hard task. Instead, we propose a new angle for solving this problem: feature ranking. The basic idea is that we rank the extracted feature candidates by feature importance. If a feature candidate is correct and important, it should be ranked high. For unimportant feature or

noise, it should be ranked low in the final result. Ranking is also very useful in practice. In a large corpus, we may extract hundreds of fine-grained features. But the user often only cares about those important ones, which should be ranked high. We identified two major factors affecting the feature importance: one is feature relevance and the other is feature frequency.

Feature relevance: it describes how possible a feature candidate is a correct feature. We find that there are three strong clues to indicate feature relevance in a corpus. The first clue is that a correct feature is often modified by multiple opinion words (adjectives or adverbs). For example, in the mattress domain, "*delivery*" is modified by "*quick*" "*cumbersome*" and "*timely*". It shows that reviewers put emphasis on the word "*delivery*". Thus we can infer that "*delivery*" is a possible feature. The second clue is that a feature could be extracted by multiple part-whole patterns. For example, in the car domain, if we find following two phrases, "*the engine of the car*" and "*the car has a big engine*", we can infer that "*engine*" is a feature for car, because both phrases contain part-whole relations to indicate "*engine*" is a part of "*car*". The third clue is the combination of opinion word modification, part-whole pattern extraction and "no" pattern extraction. That is, if a feature candidate is not only modified by opinion words but also extracted by part-whole or "no" patterns, we can infer that it is a feature with high confidence. For example, for sentence "*there is a bad hole in the mattress*", it strongly indicates that "*hole*" is a feature for a mattress because it is modified by opinion word "*bad*" and also in the part-whole pattern. What is more, we find that there is a mutual enforcement relation between opinion words, part-whole and "no" patterns, and features. If an adjective modifies many correct features, it is highly possible to be a good opinion word. Similarly, if a feature candidate can be extracted by many opinion words, part-whole patterns, or "no" pattern, it is also highly likely to be a correct feature. This indicates that the Web page ranking algorithm HITS is applicable.

Feature frequency: This is another important factor affecting feature ranking. Feature frequency has been considered in (Hu and Liu, 2004; Blair-Goldensohn et al., 2008). We consider a feature f_1 to be more important than feature f_2 if f_1 appears more frequently than f_2 in opinion documents. In practice, it is desirable to rank those frequent features higher than infrequent features. The reason is that missing a frequently mentioned feature in opinion mining is bad, but missing a rare feature is not a big issue.

Combining the above factors, we propose a new feature mining method. Experiments show good results on diverse real-life datasets.

3.1 Double Propagation

As we described above, double propagation is based on the observation that there are natural relations between opinion words and features due to the fact that opinion words are often used to modify features. Furthermore, it is observed that opinion words and features themselves have relations in opinionated expressions too (Qiu et al., 2009). These relations can be identified via a dependency parser (Lin, 1998) based on the dependency grammar. The identification of the relations is the key to feature extraction.

Dependency grammar: It describes the dependency relations between words in a sentence. After parsed by a dependency parser, words in a sentence are linked to each other by a certain relation. For a sentence, "*The camera has a good lens*", "*good*" is the opinion word and "*lens*" is the feature of camera. After parsing, we can find that "*good*" depends on "*lens*" with relation ***mod***. Here ***mod*** means that "*good*" is the adjunct modifier for "*lens*". In some cases, an opinion word and a feature are not directly dependent, but they directly depend on a same word. For example, from the sentence "*The lens is nice*", we can find that both feature "*lens*" and opinion word "*nice*" depend on the verb "*is*" with the relation ***s*** and ***pred*** respectively. Here ***s*** means that "*lens*" is the surface subject of "*is*" while ***pred*** means that "*nice*" is the predicate of the "*is*" clause.

In (Qiu et al., 2009), it defines two categories of dependency relations to summarize all types of dependency relations between two words, which are illustrated in Figure 1. Arrows are used to represent dependencies.

Direct relations: It represents that one word depends on the other word directly or they both depend on a third word directly, shown in (a) and (b) of Figure 1. In (a), *B* depends on *A* directly, and in (b) they both directly depend on *D*.

Indirect relation: It represents that one word

depends on the other word through other words or they both depend on a third word indirectly. For example, in (c) of Figure 1, *B* depends on *A* through *D*; in (d) of Figure 1, *A* depends on *D* through I_1 while *B* depends on *D* through I_2. For some complicated situations, there can be more than one I_1 or I_2.

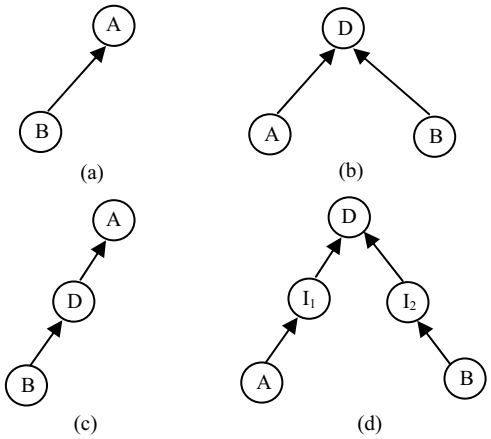

Fig.1 Different relations between A and B

Parsing indirect relations is error-prone for Web corpora. Thus we only use direct relation to extract opinion words and feature candidates in our application. For detailed extraction rules, please refer to the paper (Qiu et al., 2009).

3.2 Part-whole relation

As we discussed above, a part-whole relation is a good indicator for features if the class concept word (the "whole" part) is known. For example, the compound nominal "*car hood*" contains the part-whole relation. If we know "*car*" is the class concept word, then we can infer that "*hood*" is a feature for *car*. Part-whole patterns occur frequently in text and are expressed by a variety of lexico-syntactic structures (Girju et al, 2006; Popescu and Etzioni, 2005). There are two types of lexico-syntactic structures conveying part-whole relations: unambiguous structure and ambiguous structure. The unambiguous structure clearly indicates a part-whole relation. For example, for sentences "*the camera consists of lens, body and power cord.*" and "*the bed was made of wood*". In these cases, the detection of the patterns leads to the discovery of real part-whole relations. We can easily find features of the camera and the bed. Unfortunately, this kind of patterns is not very frequent in a corpus. However, there are many ambiguous expressions that are explicit but convey part-whole relations only in some contexts. For example, for two phrases "*valley on the mattress*" and "*toy on the mattress*", "*valley*" is a part of "*mattress*" whereas "*toy*" is not a part of "*mattress*". Our idea is to use both the unambiguous and ambiguous patterns. Although ambiguous patterns may bring some noise, we can rank them low in the ranking procedure. The following two kinds of patterns are what we have utilized for feature extraction.

3.2.1 Phrase pattern

In this case, the part-whole relation exists in a phrase.

NP + Prep + CP: noun/noun phrase (NP) contains the *part* word and the class concept phrase (CP) contains the *whole* word. They are connected by the preposition word (Prep). For example, "*battery of the camera*" is an instance of this pattern where NP (battery) is the *part* noun and CP (camera) is the *whole* noun. For our application, we only use three specific prepositions: "of", "in" and "on".

CP + with + NP: likewise, CP is the class concept phrase, and NP is the noun/noun phrase. They are connected by the word "*with*". Here NP is likely to be a feature. For example, in a phrase, "*mattress with a cover",* "*cover*" is a feature for mattress.

NP CP or CP NP: noun/noun phase (NP) and class concept phrase (CP) forms a compound word. For example, "*mattress pad*". Here "*pad*" is a feature of "*mattress*".

3.2.2 Sentence pattern

In these patterns, the part-whole relation is indicated in a sentence. The patterns contain specific verbs. The *part* word and the *whole* word can be found inside noun phrases or prepositional phrases which contain specific prepositions. We utilize the following patterns in our application.

"**CP Verb NP**": CP is the class concept phrase that contains the *whole* word, NP is the noun phrase that contains the *part* word and the verb is restricted and specific. For example, in a sentence, "*the phone has a big screen*", we can infer that "*screen*" is a feature for "*phone*", which is a class concept. In sentence patterns, verbs play an important role. We use indicative verbs to find part-whole relations in a sentence,

i.e., “has”, “have” “include” “contain” “consist”, “comprise” and so on (Girju et al, 2006).

It is worth mentioning that in order to use part-whole relations, the class concept word for a corpus is needed, which is fairly easy to find because the noun with the most frequent occurrences in a corpus is always the class concept word based on our experiments.

3.3 “no” Pattern

Besides opinion word and part-whole relation, “no” pattern is also an important pattern indicating features in a corpus. Here “no” represents word *no*. The basic form of the pattern is “no” word followed by noun/noun phrase. This simple pattern actually is very useful to feature extraction. It is a specific pattern for product reviews and forum posts. People often express their comments or opinions on features by this short pattern. For example, in a mattress domain, people always say that “*no noise*” and “*no indentation*”. Here “*noise*” and “*indentation*” are all features for the mattress. We discover that this pattern is frequently used in corpora and a very good indicator for features with a fairly high precision. But we have to take care of the some fixed “no” expression, like “*no problem*” “*no offense*”. In these cases, “*problem*” and “*offense*” should not be regarded as features. We have a list of such words, which are manually compiled.

3.4 Bipartite Graph and HITS Algorithm

Hyperlink-induced topic search (HITS) is a link analysis algorithm that rates Web pages. As discussed in the introduction section, we can apply the HITS algorithm to compute feature relevance for ranking.

Before illustrating how HITS can be applied to our scenario, let us first give a brief introduction to HITS. Given a broad search query q, HITS sends the query to a search engine system, and then collects k (k = 200 in the original paper) highest ranked pages, which are assumed to be highly relevant to the search query. This set is called the root set R; then it grows R by including any page pointed to a page in R, then forms a base set S. HITS then works on the pages in S. It assigns every page in S an **authority score** and a **hub score**. Let the number of pages to be studied be n. We use $G = (V, E)$ to denote the (directed) link graph of S. V is the set of pages (or nodes) and E is the set of directed edges (or links). We use L to denote the adjacency matrix of the graph.

$$L_{ij} = \begin{cases} 1 & if\ (i,j) \in E \\ 0 & otherwise \end{cases} \quad (1)$$

Let the authority score of the page i be $A(i)$, and the hub score of page i be $H(i)$. The mutual reinforcing relationship of the two scores is represented as follows:

$$A(i) = \sum_{(j,i)\in E} H(j) \quad (2)$$

$$H(i) = \sum_{(i,j)\in E} A(j) \quad (3)$$

We can write them in a matrix form. We use $\mathbf{A}$ to denote the column vector with all the authority scores, $\mathbf{A} = (A(1), A(2), \ldots, A(n))^T$, and use $\mathbf{H}$ to denote the column vector with all the hub scores, $\mathbf{H} = (H(1), H(2), \ldots, H(n))^T$,

$$\mathbf{A} = L^T\mathbf{H} \quad (4)$$

$$\mathbf{H} = L\mathbf{A} \quad (5)$$

To solve the problem, the widely used method is power iteration, which starts with some random values for the vectors, e.g., $A_0 = H_0 = (1, 1, 1, \ldots 1,)$. It then continues to compute iteratively until the algorithm converges.

From the formulas, we can see that the authority score estimates the importance of the content of the page, and the hub score estimates the values of its links to other pages. An authority score is computed as the sum of the scaled hub scores that point to that page. A hub score is the sum of the scaled authority scores of the pages it points to. The key idea of HITS is that a good hub points to many good authorities and a good authority is pointed by many good hubs. Thus, authorities and hubs have a mutual reinforcement relationship.

For our scenario, we have three strong clues for features in a corpus: opinion words, part-whole patterns, and the “no” pattern. Although all these three clues are not hard rules, there exist mutual enforcement relations between them. If an adjective modify many features, it is highly likely to be a good opinion word. If a feature candidate is modified by many opinion words, it is likely to be a genuine feature. The same goes with part-whole patterns, the “no” pattern, or the combination for these three clues. This kind of mutual enforcement relation can be naturally modeled in the HITS framework.

Applying the HITS algorithm: Based on the key idea of HITS algorithm and feature indicators, we can apply the HITS algorithm to obtain the feature relevance ranking. Features act as authorities and feature indicators act as hubs. Different from the general HITS algorithm, features only have authority scores and feature indicators only have hub scores in our case. They form a directed bipartite graph, which is illustrated in Figure 2. We can run the HITS algorithm on this bipartite graph. The basic idea is that if a feature candidate has a high authority score, it must be a highly-relevant feature. If a feature indicator has a high hub score, it must be a good feature indicator.

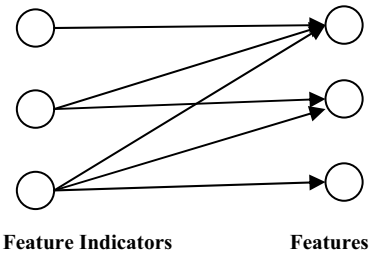

Fig. 2 Relations between feature indicators and features

3.5 Feature Ranking

Although the HITS algorithm can rank features by feature relevance, the final ranking is not only determined by relevance. As we discussed before, feature frequency is another important factor affecting the final ranking. It is highly desirable to rank those correct and frequent features at top because they are more important than the infrequent ones in opinion mining (or even other applications). With this in mind, we put everything together to present the final algorithm that we use. We use two steps:

Step 1: Compute feature score using HITS without considering frequency. Initially, we use three feature indicators to populate feature candidates, which form a directed bipartite graph. Each feature candidate acts as an authority node in the graph; each feature indicator acts as a hub node. For node s in the graph, we let H_s be the hub score and A_s be the authority score. Then, we initialize H_s and A_s to 1 for all nodes in the graph. We update the scores of H_s and A_s until they converge using power iteration. Finally, we normalize A_s and compute the score S for a feature.

Step 2: The final score function considering the feature frequency is given in Equation (6).

$$S = S(f)\log(freq(f)) \quad (6)$$

where $freq(f)$ is the frequency count of ture f, and $S(f)$ is the authority score of the candidate feature f. The idea is to push the frequent candidate features up by multiplying the log of frequency. Log is taken in order to reduce the effect of big frequency count numbers.

4 Experiments

This section evaluates the proposed method. We first describe the data sets, evaluation metrics and then the experimental results. We also compare our method with the double propagation method given in (Qiu et al., 2009).

4.1 Data Sets

We used four diverse data sets to evaluate our techniques. They were obtained from a commercial company that provides opinion mining services. Table 1 shows the domains (based on their names) and the number of sentences in each data set ("Sent." means the sentence). The data in "Cars" and "Mattress" are product reviews extracted from some online review sites. "Phone" and "LCD" are forum discussion posts extracted from some online forum sites. We split each review/post into sentences and the sentences are POS-tagged using the Brill's tagger (Brill, 1995). The tagged sentences are the input to our system.

Data Sets	Cars	Mattress	Phone	LCD
# of Sent.	2223	13233	15168	1783

Table 1. Experimental data sets

4.2 Evaluation Metrics

Besides precision and recall, we adopt the **precision@N** metric for experimental evaluation (Liu, 2006). It gives the percentage of correct features that are among the top N feature candidates in a ranked list. We compare our method's results with those of double propagation which ranks extracted candidates only by occurrence frequency.

4.3 Experimental Results

We first compare our results with double propa-

gation on recall and precision for different corpus sizes. The results are presented in Tables 2, 3, and 4 for the four data sets. They show the precision and recall of 1000, 2000, and 3000 sentences from these data sets. We did not try more sentences because manually checking the recall and precision becomes prohibitive. Note that there are less than 3000 sentences for "Cars" and "LCD" data sets. Thus, the columns for "Cars" and "LCD" are empty in Table 4. In the Tables, "DP" represents the double propagation method; "Ours" represents our proposed method; "Pr" represents precision, and "Re" represents recall.

	Cars		Mattress		Phone		LCD	
	Pr	**Re**	**Pr**	**Re**	**Pr**	**Re**	**Pr**	**Re**
DP	0.79	0.55	0.79	0.54	0.69	0.23	0.68	0.43
Ours	0.78	0.56	0.77	0.64	0.68	0.44	0.66	0.55

Table 2. Results of 1000 sentences

	Cars		Mattress		Phone		LCD	
	Pr	**Re**	**Pr**	**Re**	**Pr**	**Re**	**Pr**	**Re**
DP	0.70	0.65	0.70	0.58	0.67	0.42	0.64	0.52
Ours	0.66	0.69	0.70	0.66	0.70	0.50	0.62	0.56

Table 3. Results of 2000 sentences

	Cars	Mattress		Phone		LCD
		Pr	**Re**	**Pr**	**Re**	
DP		0.65	0.59	0.64	0.48	
Ours		0.66	0.67	0.62	0.51	

Table 4. Results of 3000 sentences

From the tables, we can see that for corpora in all domains, our method outperforms double propagation on recall with only a small loss in precision. In data sets for "Phone" and "Mattress", the precisions are even better. We also find that with the increase of the data size, the recall gap between the two methods becomes smaller gradually and the precisions of both methods also drop. However, in this case, feature ranking plays an important role in discovering important features.

Ranking comparison between the two methods is shown in Tables 5, 6, and 7, which give the precisions of top 50, 100 and 200 results respectively. Note that the experiments reported in these tables were run on the whole data sets. There were no more results for the "LCD" data beyond top 200 as there were only a limited number of features discussed in the data. So the column for "LCD" in Table 7 is empty. We rank the extracted feature candidates based on frequency for the double propagation method (DP). Using occurrence frequency is the natural way to rank features. The more frequent a feature occurs in a corpus, the more important it is. However, frequency-based ranking assumes the extracted candidates are correct features. The tables show that our proposed method (Ours) outperforms double propagation considerably. The reason is that some highly-frequent feature candidates extracted by double propagation are not correct features. Our method considers the feature relevance as an important factor. So it produces much better rankings.

	Cars	Mattress	Phone	LCD
DP	0.84	0.81	0.64	0.68
Ours	0.94	0.90	0.76	0.76

Table 5. Precision at top 50

	Cars	Mattress	Phone	LCD
DP	0.82	0.80	0.65	0.68
Ours	0.88	0.85	0.75	0.73

Table 6. Precision at top 100

	Cars	Mattress	Phone	LCD
DP	0.75	0.71	0.70	
Ours	0.80	0.79	0.76	

Table 7. Precision at top 200

5 Conclusion

Feature extraction for entities is an important task for opinion mining. The paper proposed a new method to deal with the problems of the state-of-the-art double propagation method for feature extraction. It first uses part-whole and "no" patterns to increase recall. It then ranks the extracted feature candidates by feature importance, which is determined by two factors: feature relevance and feature frequency. The Web page ranking algorithm HITS was applying to compute feature relevance. Experimental results using diverse real-life datasets show promising results. In our future work, apart from improving the current methods, we also plan to study the problem of extracting features that are verbs or verb phrases.

Abstract

Given the increasing need to process massive amounts of textual data, efficiency of NLP tools is becoming a pressing concern. Parsers based on lexicalised grammar formalisms, such as TAG and CCG, can be made more efficient using supertagging, which for CCG is so effective that every derivation consistent with the supertagger output can be stored in a packed chart. However, wide-coverage CCG parsers still produce a very large number of derivations for typical newspaper or Wikipedia sentences. In this paper we investigate two forms of chart pruning, and develop a novel method for pruning complete cells in a parse chart. The result is a wide-coverage CCG parser that can process almost 100 sentences per second, with little or no loss in accuracy over the baseline with no pruning.

1 Introduction

Many NLP tasks and applications require the processing of massive amounts of textual data. For example, knowledge acquisition efforts can involve processing billions of words of text (Curran, 2004). Also, the increasing need to process large amounts of web data places an efficiency demand on existing NLP tools. TextRunner, for example, is a system that performs open information extraction on the web (Lin et al., 2009). However, the text processing that is performed by TextRunner, in particular the parsing, is rudimentary: finite-state shallow parsing technology that is now decades old. TextRunner uses this technology largely for efficiency reasons.

Many of the popular wide-coverage parsers available today operate at around one newspaper sentence per second (Collins, 1999; Charniak, 2000; Petrov and Klein, 2007). There are dependency parsers that operate orders of magnitude faster, by exploiting the fact that accurate dependency parsing can be achieved by using a shift-reduce linear-time process which makes a single decision at each point in the parsing process (Nivre and Scholz, 2004).

In this paper we focus on the Combinatory Categorial Grammar (CCG) parser of Clark and Curran (2007). One advantage of the CCG parser is that it is able to assign rich structural descriptions to sentences, from a variety of representations, e.g. CCG derivations, CCG dependency structures, grammatical relations (Carroll et al., 1998), and first-order logical forms (Bos et al., 2004). One of the properties of the grammar formalism is that it is lexicalised, associating CCG lexical categories, or CCG *supertags*, with the words in a sentence (Steedman, 2000). Clark and Curran (2004) adapt the technique of supertagging (Bangalore and Joshi, 1999) to CCG, using a standard maximum entropy tagger to assign small sets of supertags to each word. The reduction in ambiguity resulting from the supertagging stage results in a surprisingly efficient parser, given the rich structural output, operating at tens of newspaper sentences per second.

In this paper we demonstrate that the CCG parser can be made more than twice as fast, with little or no loss in accuracy. A noteworthy feature of the CCG parser is that, after the supertagging

Coling 2008: Poster Volume, pages 1471–1479,
Beijing, August 2010

stage, the parser builds a complete packed chart, storing all sentences consistent with the assigned supertags and the parser's CCG combinatory rules, *with no chart pruning whatsoever*. The use of chart pruning techniques, typically some form of beam search, is essential for practical parsing using Penn Treebank parsers (Collins, 1999; Petrov and Klein, 2007; Charniak and Johnson, 2005), as well as practical parsers based on linguistic formalisms, such as HPSG (Ninomiya et al., 2005) and LFG (Kaplan et al., 2004). However, in the CCG case, the use of the supertagger means that enough ambiguity has already been resolved to allow the complete chart to be represented.

Despite the effectiveness of the supertagging stage, the number of derivations stored in a packed chart can still be enormous for typical newspaper sentences. Hence it is an obvious question whether chart pruning techniques can be profitably applied to the CCG parser. Some previous work (Djordjevic et al., 2007) has investigated this question but with little success.

In this paper we investigate two types of chart pruning: a standard beam search, similar to that used in the Collins parser (Collins, 1999), and a more aggressive strategy in which complete cells are pruned, following Roark and Hollingshead (2009). Roark and Hollingshead use a finite-state tagger to decide which words in a sentence can end or begin constituents, from which whole cells in the chart can be removed. We develop a novel extension to this approach, in which a tagger is trained to infer the maximum length constituent that can begin or end at a particular word. These lengths can then be used in a more agressive pruning strategy which we show to be significantly more effective than the basic approach.

Both beam search and cell pruning are highly effective, with the resulting CCG parser able to process almost 100 sentences per second using a single CPU, for both newspaper and Wikipedia data, with little or no loss in accuracy.

2 The CCG Parser

The parser is described in detail in Clark and Curran (2007). It is based on CCGbank, a CCG version of the Penn Treebank developed by Hockenmaier and Steedman (2007).

The stages in the parsing pipeline are as follows. First, a POS tagger assigns a single POS tag to each word in a sentence. Second, a CCG supertagger assigns lexical categories to the words in the sentence. Third, the parsing stage combines the categories, using CCG's combinatory rules, and builds a packed chart representation containing all the derivations which can be built from the lexical categories. Finally, the Viterbi algorithm finds the highest scoring derivation from the packed chart, using the normal-form log-linear model described in Clark and Curran (2007).

Sometimes the parser is unable to build an analysis which spans the whole sentence. When this happens the parser and supertagger interact using the adaptive supertagging strategy described in Clark and Curran (2004): the parser effectively asks the supertagger to provide more lexical categories for each word. This potentially continues for a number of iterations until the parser does create a spanning analysis, or else it gives up and moves to the next sentence.

The parser uses the CKY algorithm (Kasami, 1965; Younger, 1967) described in Steedman (2000) to create a packed chart. The CKY algorithm applies naturally to CCG since the grammar is binary. It builds the chart bottom-up, starting with two-word constituents (assuming the supertagging phase has been completed), incrementally increasing the span until the whole sentence is covered. The chart is packed in the standard sense that any two equivalent constituents created during the parsing process are placed in the same equivalence class, with pointers to the children used in the creation. Equivalence is defined in terms of the category and head of the constituent, to enable the Viterbi algorithm to efficiently find the highest scoring derivation.[1] A textbook treatment of CKY applied to statistical parsing is given in Jurafsky and Martin (2000).

3 Data and Evaluation Metrics

We performed efficiency and accuracy tests on newspaper and Wikipedia data. For the newspaper data, we used the standard test sections from

[1] Use of the Viterbi algorithm in this way requires the features in the parser model to be local to a single rule application; Clark and Curran (2007) has more discussion.

Figure 1: Example Wikipedia test sentence annotated with grammatical relations.

CCGbank. Following Clark and Curran (2007) we used the CCG dependencies for accuracy evaluation, comparing those output by the parser with the gold-standard dependencies in CCGbank. Unlike Clark and Curran, we calculated recall scores over all sentences, including those for which the parser did not find an analysis. For the WSJ data the parser fails on a small number of sentences (less than 1%), but the chart pruning has the effect of reducing this failure rate further, and we felt that this should be factored into the calculation of recall and hence F-score.

In order to test the parser on Wikipedia text, we created two test sets. The first, Wiki 300, for testing accuracy, consists of 300 sentences manually annotated with grammatical relations (GRs) in the style of Briscoe and Carroll (2006). An example sentence is given in Figure 1. The data was created by manually correcting the output of the parser on these sentences, with the annotation being performed by Clark and Rimell, including checks on a subset of these cases to ensure consistency across the two annotators. For the accuracy evaluation, we calculated precision, recall and balanced F-measure over the GRs in the standard way.

For testing speed on Wikipedia, we used a corpus of 2500 randomly chosen sentences, Wiki 2500. For all speed tests we measured the number of sentences per second, using a single CPU and standard hardware.

4 Beam Search

The beam search approach used in our experiments prunes all constituents in a cell having scores below a multiple (β) of the score of the highest scoring constituent for that cell.[2] The scores for a constituent are calculated using the same model used to find the highest scoring derivation. We consider two scores: the Viterbi score, which is the score of the highest scoring sub-derivation for that constituent; and the inside score, which is the sum over all sub-derviations for that constituent. We investigated the following: the trade-off between the aggressiveness of the beam search and accuracy; the comparison between the Viterbi and inside scores; and whether applying the beam to only certain cells in the chart can improve performance.

β	Speed	Gain	F-score	Gain
Baseline	43.0		85.55	
0.001	48.6	13%	85.82	0.27
0.002	54.2	26%	85.88	0.33
0.005	59.0	37%	85.73	0.18
0.01	66.7	55%	85.53	-0.02

Table 1: Accuracy and speed results using different beam values β.

δ	Speed	Gain	F-score	Gain
Baseline	43.0		85.55	
10	60.1	39%	85.55	0.00
20	70.6	64%	85.66	0.11
30	72.3	68%	85.65	0.10
40	76.4	77%	85.63	0.08
50	76.7	78%	85.62	0.07
60	74.5	73%	85.71	0.16
80	68.4	59%	85.71	0.16
100	62.0	44%	85.73	0.18
None	59.0	37%	85.73	0.18

Table 2: Accuracy and speed results for different values of δ where $\beta = 0.005$.

Table 1 shows results on Section 00 of CCGbank, using the Viterbi score to prune. As expected, the parsing speed increases as the value of β increases, since more constituents are pruned with a higher β value. The pruning is effective, with a β value of 0.01 giving a 55% speed increase with neglible loss in accuracy.[3]

[2] One restriction we apply in practice is that only constituents resulting from the application of a CCG binary rule, rather than a unary rule, are pruned.

[3] The small accuracy increase for some β values could be attributable to two factors: one, the parser may select a lower

	Speed			F-score		
Dataset	Baseline	Beam	Gain	Baseline	Beam	Gain
WSJ 00	43.0	76.4	77%	85.55	85.63	0.08

Wiki 2500	47.6	90.3	89%			

Table 4: Beam search results on WSJ 00, 02-21, 23 and Wikipedia texts with $\beta = 0.005$ and $\delta = 40$.

	β	δ	Speed	F-score
Baseline			24.7	85.55
inside scores	0.01		37.7	85.52
	0.001		25.3	85.79
	0.005	10	33.4	85.54
	0.005	20	39.5	85.64
	0.005	50	42.9	85.58
Viterbi scores	0.01		38.1	85.53
	0.001		28.2	85.82
	0.005	10	33.6	85.55
	0.005	20	39.4	85.66
	0.005	50	43.1	85.62

Table 3: Comparison between using Viterbi scores and inside scores as beam scores.

We also studied the effect of the beam search at different levels of the chart. We applied a selective beam in which pruning is only applied to constituents of length less than or equal to a threshold δ. For example, if $\delta = 20$, pruning is applied only to constituents spanning 20 words or less. The results are shown in Table 2. The selective beam is also highly effective, showing speed gains over the baseline (which does not use a beam) with no loss in F-score. For a δ value of 50 the speed increase is 78% with no loss in accuracy.

Note that for δ greater than 50, the speed reduces. We believe that this is due to the cost of calculating the beam scores and the reduced effectiveness of pruning for cells with longer spans (since pruning shorter constituents early in the chart-parsing process prevents the creation of many larger, low-scoring constituents later).

Table 3 shows the comparison between the inside and Viterbi scores. The results are similar, with Viterbi marginally outperforming the inside score in most cases. The interesting result from these experiments is that the summing used in calculating the inside score does not improve performance over the max operator used by Viterbi.

Table 4 gives results on Wikipedia text, compared with a number of sections from CCGbank. (Sections 02-21 provide the training data for the parser which explains the high accuracy results on these sections.) Despite the fact that the pruning model is derived from CCGbank and based on WSJ text, the speed improvements for Wikipedia were even greater than for WSJ text, with parameters $\beta = 0.005$ and $\delta = 40$ leading to almost a doubling of speed on the Wiki 2500 set, with the parser operating at 90 sentences per second.

5 Cell Pruning

Whole cells can be pruned from the chart by tagging words in a sentence. Roark and Hollingshead (2009) used a binary tagging approach to prune a CFG CKY chart, where tags are assigned to input words to indicate whether they can be the start or end of multiple-word constituents. We adapt their method to CCG chart pruning. We also show the limitation of binary tagging, and propose a novel tagging method which leads to increased speeds and accuracies over the binary taggers.

5.1 Binary tagging

Following Roark and Hollingshead (2009), we assign the binary begin and end tags separately using two independent taggers. Given the input "We like playing cards together", the pruning effects of each type of tag on the CKY chart are shown in Figure 2. In this chart, rows repre-

scoring but more accurate derivation; and two, a possible increase in recall, discussed in Section 3, can lead to a higher F-score.

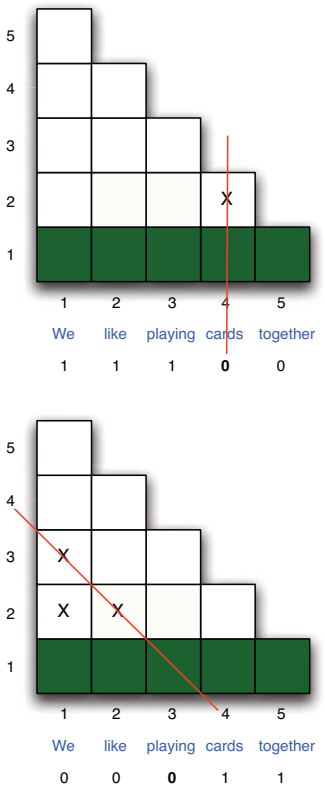

Figure 2: The pruning effect of begin (top) and end (bottom) tags; X indicates a removed cell.

sent consituent sizes and columns represent initial words of constituents. No cell in the first row of the chart is pruned, since these cells correspond to single words, and are necessary for finding a parse. The begin tag for the input word "cards" is 0, which means that it cannot begin a multi-word constituent. Therefore, no cell in column 4 can contain any constituent. The pruning effect of a binary begin tag is to cross out a column of chart cells (ignoring the first row) when the tag value is zero. Similarly, the end tag of the word "playing" is 0, which means that it cannot be the end of a multi-word constituent. Consequently cell (2, 2), which contains constituents for "like playing", and cell (1, 3), which contains constituents for "We like playing", must be empty. The pruning effect of a binary end tag is to cross out a diagonal of cells (ignoring the first row) when the tag value is zero.

We use a maximum entropy trigram tagger (Ratnaparkhi, 1996; Curran and Clark, 2003) to assign the begin and end tags. Features based on the words and POS in a 5-word window, plus the two previously assigned tags, are extracted from the trigram ending with the current tag and the five-word window with the current word in the middle. In our development experiments, both the begin and the end taggers gave a per-word accuracy of around 96%, similar to the accuracy reported in Roark and Hollingshead (2009).

Model	Speed	F-score
baseline	25.10	84.89
begin only	27.49	84.71
end only	30.33	84.56
both	33.90	84.60
oracle	33.60	85.67

Table 5: Accuracy and speed results for the binary taggers on Section 00 of CCGbank.

Table 5 shows accuracy and speed results for the binary taggers.[4] Using begin or end tags alone, the parser achieved speed increases with a small loss in accuracy. When both begin and end tags are applied, the parser achieved further speed increases, with no loss in accuracy compared to the end tag alone. Row "oracle" shows what happens using the perfect begin and end taggers, by using gold-standard constituent information from CCGbank. The F-score is higher, since the parser is being guided away from incorrect derivations, although the speed is no higher than when using automatically assigned tags.

5.2 Level tagging

A binary tag cannot take effect when there is any chart cell in the corresponding column or diagonal that contains constituents. For example, the begin tag for the word "card" in Figure 3 cannot be 0 because "card" begins a two-word constituent "card games". Hence none of the cells in the column can be pruned using the binary begin tag, even though all the cells from the third row above are empty. We propose what we call a level tagging approach to address this problem.

Instead of taking a binary value that indicates

[4]The baseline differs slightly to the previous section because gold-standard POS tags were used for the beam-search experiments.

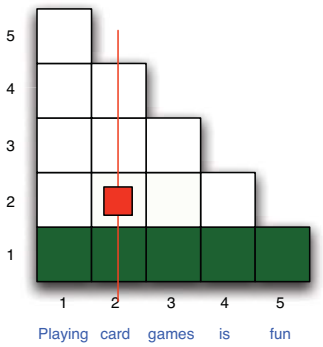

Figure 3: The limitation of binary begin tags.

whether a whole column or diagonal of cells can be pruned, a level tag (begin or end) takes an integer value which indicates the row from which a column or diagonal can be pruned in the upward direction. For example, a level begin tag with value 2 allows the column of chart cells for the word "card" in Figure 3 to be pruned from the third row upwards. A level tag (begin or end) with value 1 prunes the corresponding row or diagonal from the second row upwards; it has the same pruning effect as a binary tag with value 0. For convenience, value 0 for a level tag means that the corresponding word can be the beginning or end of any constituent, which is the same as a binary tag value 1.

A comparison of the pruning effect of binary and level tags for the sentence "Playing card games is fun" is shown in Figure 4. With a level begin tag, more cells can be pruned from the column for "card". Therefore, level tags are potentially more powerful for pruning.

We now need a method for assigning level tags to words in a sentence. However, we cannot achieve this with a straighforward classifier since level tags are related; for example, a level tag (begin or end) with value 2 implies level tags with values 3 and above. We develop a novel method for calculating the probability of a level tag for a particular word. Our mechanism for calculating these probabilities uses what we call *maxspan* tags, which can be assigned using a maximum entropy tagger.

Maxspan tags take the same values as level tags. However, the meanings of maxspan tags and level

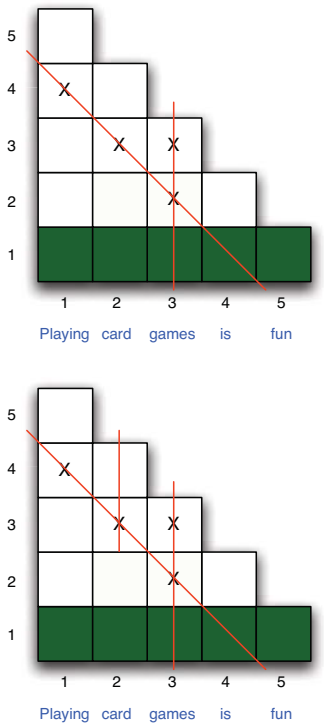

Figure 4: The pruning effect of binary (top) and level (bottom) tags.

tags are different. While a level tag indicates the row from which a column or diagonal of cells is pruned, a maxspan tag represents the size of the largest constituent a word begins or ends. For example, in Figure 3, the level end tag for the word "games" has value 3, since the largest constituent this words ends spans "playing card games".

We use the standard maximum entropy trigram tagger for maxspan tagging, where features are extracted from tag trigrams and surrounding five-word windows, as for the binary taggers. Parse trees can be turned directly into training data for a maxspan tagger. Since the level tag set is finite, we a require a maximum value N that a level tag can take. We experimented with $N = 2$ and $N = 4$, which reflects the limited range of the features used by the taggers.[5]

During decoding, the maxspan tagger uses the forward-backward algorithm to compute the probability of maxspan tag values for each word in the

[5]Higher values of N did not lead to improvements during development experiments.

Model	Speed	F-score
baseline	25.10	84.89
binary	33.90	84.60
binary oracle	33.60	85.67
level $N = 2$	32.79	84.92
level $N = 4$	34.91	84.95
level $N = 4$ oracle	47.45	86.49

Table 6: Accuracy and speed results for the level taggers on Section 00 of CCGbank.

input. Then for each word, the probability of its level tag t_l having value x is the sum of the probabilities of its maxspan t_m tag having values $1..x$:

$$P(t_l = x) = \sum_{i=1}^{x} P(t_m = i)$$

Maxspan tag values i from 1 to x represent disjoint events in which the largest constituent that the corresponding word begins or ends has size i. Summing the probabilities of these disjoint events gives the probability that the largest constituent the word begins or ends has a size between 1 and x, inclusive. That is also the probability that all the constituents the word begins or ends are in the range of cells from rows 1 to row x in the corresponding column or diagonal. And therefore that is also the probability that the chart cells above row x in the corresponding column or diagonal do not contain any constituents, which means that the column and diagonal can be pruned from row x upward. Therefore, it is also the probability of a level tag with value x.

The probability of a level tag having value x increases as x increases from 1 to N. We set a probability threshold Q and choose the smallest level tag value x with probability $P(t_l = x) \geq Q$ as the level tag for a word. If $P(t_l = N) < Q$, we set the level tag to 0 and do not prune the column or diagonal. The threshold value determines a balance between pruning power and accuracy, with a higher value pruning more cells but increasing the risk of incorrectly pruning a cell. During development we arrived at a threshold value of 0.8 as providing a suitable compromise between pruning power and accuracy.

Table 6 shows accuracy and speed results for the level tagger, using a threshold value of 0.8.

Model	Speed	F-score
baseline	36.64	84.23
binary gold	49.59	84.36
binary self 40K	48.79	83.64
binary self 200K	51.51	83.71
binary self 1M	47.78	83.75
level gold	58.23	84.12
level self 40K	54.76	83.83
level self 200K	48.57	83.39
level self 1M	52.54	83.71

Table 7: Accuracy tests on Wiki 300 comparing gold training (gold) with self training (self) for different sizes of parser output for self-training.

We compare the effect of the binary tagger and level taggers with $N = 2$ and $N = 4$. The accuracies with the level taggers are higher than those with the binary tagger; they are also higher than the baseline parsing accuracy. The parser achieves the highest speed and accuracy when pruned with the $N = 4$ level tagger. Comparing the oracle scores, the level taggers lead to higher speeds than the binary tagger, reflecting the increased pruning power of the level taggers compared with the binary taggers.

5.2.1 Final experiments using gold training and self training

In this section we report our final tests using Wikipedia data. We used two methods to derive training data for the taggers. The first is the standard method, which is to transform gold-standard parse trees into begin and end tag sequences. This method is the method that we used for all previous experiments, and we call it "gold training". In addition to gold training, we also investigate an alternative method, which is to obtain training data for the taggers from the output of the parser itself, in a form of self-training (McClosky et al., 2006). The intuition is that the tagger will learn what constituents a trained parser will eventually choose, and as long as the constituents favoured by the parsing model are not pruned, no reduction in accuracy can occur. There is the potential for an increase in speed, however, due to the pruning effect.

For gold training, we used sections 02-21 of

Model	Speed
baseline	47.6
binary gold	80.8
binary 40K	75.5
binary 200K	77.4
binary 1M	78.6
level gold	93.7
level 40K	92.8
level 200K	92.5
level 1M	96.6

Table 8: Speed tests with gold and self-training on Wiki 2500.

CCGBank (which consists of about 40K training sentences) to derive training data. For self training, we trained the parser on sections 02-21 of CCGBank, and used the parser to parse 40 thousand, 200 thousand and 1 million sentences from Wikipedia, respectively. Then we derive three sets of self training data from the three sets of parser outputs. We then used our Wiki 300 set to test the accuracy, and the Wiki 2500 set to test the speed of the parser.

The results are shown in Tables 7 and 8, where each row represents a training data set. Rows "binary gold" and "level gold" represent binary and level taggers trained using gold training. Rows "binary self X" and "level self X" represent binary and level taggers trained using self training, with the size of the training data being X sentences.

It can be seen from the Tables that the accuracy loss with self-trained binary or level taggers was not large (in the worst case, the accuracy dropped from 84.23% to 83.39%), while the speed was significantly improved. Using binary taggers, the largest speed improvement was from 47.6 sentences per second to 80.8 sentences per second (a 69.7% relative increase). Using level taggers, the largest speed improvement was from 47.6 sentences per second to 96.6 sentences per second (a 103% relative increase).

A potential advantage of self-training is the availability of large amounts of training data. However, our results are somewhat negative in this regard, in that we find training the tagger on more than 40,000 parsed sentences (the size of CCGbank) did not improve the self-training results. We did see the usual speed improvements from using the self-trained taggers, however, over the baseline parser with no pruning.

6 Conclusion

Using our novel method of level tagging for pruning complete cells in a CKY chart, the CCG parser was able to process almost 100 Wikipedia sentences per second, using both CCGbank and the output of the parser to train the taggers, with little or no loss in accuracy. This was a 103% increase over the baseline with no pruning.

We also demonstrated that standard beam search is highly effective in increasing the speed of the CCG parser, despite the fact that the supertagger has already had a significant pruning effect. In future work we plan to investigate the gains that can be achieved from combining the two pruning methods, as well as other pruning methods such as the self-training technique described in Kummerfeld et al. (2010) which reduces the number of lexical categories assigned by the supertagger (leading to a speed increase). Since these methods are largely orthogonal, we expect to achieve further gains, leading to a remarkably fast wide-coverage parser outputting complex linguistic representations.

Metaphor Interpretation and Context-based Affect Detection

Li Zhang
School of Computing
Teesside University
l.zhang@tees.ac.uk

Abstract

Metaphorical and contextual affect detection from open-ended text-based dialogue is challenging but essential for the building of effective intelligent user interfaces. In this paper, we report updated developments of an affect detection model from text, including affect detection from one particular type of metaphorical affective expression and affect detection based on context. The overall affect detection model has been embedded in an intelligent conversational AI agent interacting with human users under loose scenarios. Evaluation for the updated affect detection component is also provided. Our work contributes to the conference themes on sentiment analysis and opinion mining and the development of dialogue and conversational agents.

1 Introduction

Affect sensing from open-ended text-based natural language input is a rising research area. Zhang et al. (2008a) reported an affect detection component on detecting simple and complex emotions, meta-emotions, value judgments etc from literal expressions. Recently, metaphorical language has drawn researchers' attention since it has been widely used to provide effective vivid description. Fainsilber and Ortony (1987) commented that "an important function of metaphorical language is to permit the expression of that which is difficult to express using literal language alone". In Wallington et al's work (2008), several metaphorical affective expressions (such as animal metaphor ("X is a rat") and affects as external entities metaphor ("joy ran through me")) have been intensively studied and affect has been derived from some simple animal metaphorical expressions.

The work presented here reports developments on affect detection from one particular comparatively complex metaphorical phenomenon with affect implication, i.e. the cooking metaphor ("the lawyer grilled the witness on the stand", "I knew I was cooked when the teacher showed up at the door") (http://knowgramming.com/cooking_metaphors.htm). Since context plays an important role in the interpretation of the affect conveyed by the user during the interaction, we have used linguistic contextual analysis and cognitive emotional modeling based on Markov chain modeling and a dynamic algorithm to interpret affect from context in our application.

Our developments have been incorporated into an affect detection component, which can detect affect and emotions from literal text input and has been embedded in an intelligent conversational agent, engaged in a drama improvisation with human users under loose scenarios (school bullying and Crohn's disease). The conversational AI agent also provides appropriate responses based on the detected affect from users' input in order to stimulate the improvisation. In both scenarios, the AI agent plays a minor role in drama improvisation. E.g. it plays a close friend of the bullied victim (the leading role) in school bullying scenario, who tries to stop the bullying.

We have also analyzed affect detection performance based on previously collected (other) transcripts from user testing by calculating agreements via Cohen's Kappa between two human judges and between human judges and the AI agent with and without the new devel-

Coling 2008: Poster Volume, pages 1480–1488,
Beijing, August 2010

opment respectively in order to verify the efficiency of the metaphorical and contextual affect sensing.

The content is arranged as follows. We report relevant work in section 2 and the new developments on affect detection from the cooking metaphor in section 3. Contextual affect sensing is discussed in section 4. System evaluation and conclusion are presented in section 5.

2 Related Work

There is well-known research work in the related fields. ConceptNet (Liu and Singh, 2004) is a toolkit to provide practical textual reasoning for affect sensing for six basic emotions, text summarization and topic extraction. Shaikh et al. (2007) provided sentence-level textual affect sensing to recognize evaluations (positive and negative). They adopted a rule-based domain-independent approach, but they haven't made attempts to recognize different affective states from open-ended text input.

Although Façade (Mateas, 2002) included shallow natural language processing for characters' open-ended utterances, the detection of major emotions, rudeness and value judgements is not mentioned. Zhe and Boucouvalas (2002) demonstrated an emotion extraction module embedded in an Internet chatting environment. It used a part-of-speech tagger and a syntactic chunker to detect the emotional words and to analyze emotion intensity for the first person (e.g. 'I'). The detection focused only on emotional adjectives and first-person emotions, and did not address deep issues such as figurative expression of emotion. There is also work on general linguistic cues useful for affect detection (e.g. Craggs and Wood, 2004).

In addition, there is well-known research work on the development of emotional conversational agents. Egges et al. (2003) provided virtual characters with conversational emotional responsiveness. Aylett et al. (2006) also focused on the development of affective behavior planning for their synthetic characters. Cavazza et al. (2008) reported on a conversational agent embodied in a wireless robot to provide suggestions for users on a healthy living life-style. Hierarchical Task Networks (HTN) planner and semantic interpretation have been used in this work. The cognitive planner plays an important role in assisting with dialogue management. The user's response has also been considered for the generation of a new plan. However, the system will hesitate when open-ended user input going beyond the planner's knowledge has been used intensively during interaction. The system we present here intends to deal with such challenge.

Our work focuses on the following aspects: (1) affect detection from metaphorical expressions; (2) real-time affect sensing for basic and complex emotions in improvisational role-play situations; (3) affect detection for second and third person cases (e.g. 'you', 'she'); and (4) affect interpretation based on context profiles.

3 Further Development on Metaphorical Affect Detection

Without pre-defined constrained scripts, our original system has been developed for 14-16 year old school students to conduct creative improvisation within highly emotionally charged scenarios. Various metaphorical expressions were used to convey emotions (Kövecses, 1998), which are theoretically and practically challenging and draw our attention.

Metaphorical language can be used to convey emotions implicitly and explicitly, which also inspires cognitive semanticists (Kövecses, 1998). In our previous study (Zhang et al. 2008b; 2009), we detected affect from several comparatively simple metaphorical affective phenomena. Another type of comparatively complex metaphor has also drawn our attention, i.e. the cooking metaphor. Very often, the agent himself/herself would become the victim of slow or intensive cooking (e.g. grilled, cooked). Or one agent can perform cooking like actions towards another agent to realize punishment or torture. Examples are as follows, "he basted her with flattery to get the job", "she knew she was fried when the teacher handed back her paper".

In these examples, the suffering agents have been figuratively conceptualized as food. They bear the results of intensive or slow cooking. Thus, these agents who suffer from such cooking actions carried out by other agents tend to feel pain and sadness, while the 'cooking performing' agents may take advantage of such actions to achieve their intentions, such as persuasion, punishment or even enjoyment. The syntactic structures of some of the above exam-

ples also indicate the submissive stance of the suffering agents. E.g. in the instances, passive sentences ("he knew he was cooked when he saw his boss standing at the door") have been used to imply unwillingness and victimization of the subject agents who are in fact the objects of the cooking actions described by the verb phrases ("X + copular form + passive cooking action"). In other examples, the cooking actions have been explicitly performed by the subject agents towards the object agents to imply the former's potential willingness and enjoyment and the latter's potential suffering and pain ("A + [cooking action] + B").

Thus in our application, we focus on the above two particular types of expressions. We use Rasp (Briscoe & Carroll, 2002) to recognize user input with such syntactic structures ('A + copular form + VVN', 'A + VV0/VVD/VVZ (verb) + B'). Many sentences could possess such syntactic structures (e.g. "Lisa was bullied", "he grills Lisa", "I was hit by a car", "Lisa was given the task to play the victim role", "I steamed it" etc), but few of them are cooking metaphors. Therefore we need to resort to semantic profiles to recognize the metaphorical expressions. Rasp has also provided a syntactic label for each word in the user input. Thus the main verbs were identified by their corresponding syntactic labels (e.g. 'given' labeled as 'past participle form of lexical verbs (VVN)', 'likes' and 'grills' labeled as '-s form of lexical verbs (VVZ)') and the semantic interpretation for their base forms is discovered from WordNet (Fellbaum, 1998). Since WordNet has provided hypernyms (Y is a hypernym of X if every X is a (kind of) Y) for the general noun and verb lexicon, 'COOK' has been derived as the hypernym of the verbs' described cooking actions. E.g. 'boil', 'grill', 'steam', and 'simmer' are respectively interpreted as one way to 'COOK'. 'Toast' is interpreted as one way to 'HEAT UP' while 'cook' is interpreted as one way to 'CREAT', or 'CHEAT' etc. One verb may recover several hypernyms and in our application, we collect all of them. Another evaluation resource (Esuli and Sebastiani, 2006) is resorted to in order to recover the evaluation values of all the hypernyms for a particular verb. If some hypernyms are negative (such as 'CHEAT') and the main object of the overall input refers to first/third person cases or singular proper nouns ('him', 'her', or 'Lisa'), then the user input (e.g. "he basted her with flattery to get the job") conveys potential negative affect (e.g. pain and sadness) for the human objects and potential positive affect (e.g. persuasion or enjoyment) for the subjects. If the evaluation dictionary fails to provide any evaluation value for any hypernyms (such as 'COOK' and 'HEAT UP') of the main verbs, then we still assume that 'verbs implying COOK/HEAT UP + human objects' or 'human subjects + copular form + VVN verbs implying COOK/HEAT UP' may indicate negative emotions both for the human objects in the former and the human subjects in the latter. E.g. for the input "I was fried by the head teacher", the processing is as follows:

1. Rasp identifies the input has the following structure: 'PPIS1 (I) + copular form (was) + VVN (fried)';
2. 'Fry' (base form of the main verb) is sent to WordNet to obtain its hypernyms, which include 'COOK', 'HEAT' and 'KILL';
3. The input has the following syntactic semantic structure: 'PPIS1 (I) + copular form (was) + VVN (Hypernym: COOK)', thus it is recognized as a cooking metaphor;
4. The three hypernyms are sent to the evaluation resource to obtain their evaluation values. 'KILL' is labeled as negative while others can't obtain any evaluation values from the profile;
5. The input is transformed into: ''PPIS1 (I) + copular form (was) + VVN (KILL: negative)'
6. The subject is a first person case, then the input indicates the user who is speaking suffered from a negative action and may have a 'negative' emotional state.

Although our processing is limited to the verb metaphor examples and hasn't considered other instances like "tasty tidbits of information", it points out promising directions for figurative language processing. After our intention to improve the performance of affect sensing from individual turn-taking input, we focus on improvement of the performance using context profiles. In future work, we intend to use a metaphor ontology to recognize metaphors.

4 Affect Sensing from Context Profiles

Our previous affect detection (Zhang et al. 2008a) has been performed solely based on in-

dividual turn-taking input. Thus the context information has been ignored. However, the contextual and character profiles may influence the affect implied in the current input. In this section, we will discuss relationships between characters, linguistic contextual indicators, cognitive emotion simulation from a communication context and our approach developed based on these features to interpret affect from context.

4.1 Relationship Interpretation

Relationships between characters in drama improvisation are very crucial for the contextual affect interpretation for the emotionally ambiguous users' input. During the improvisation of each scenario, like any other drama progression, normally the recorded transcripts for creative roleplays are composed of three main improvisational sections, including the starting of the drama, the climax and the final ending. Relationships in these three drama progression stages between characters are different from one another. E.g. in the climax of the improvisation of the school bullying scenario, we normally expect very negative relationships between the bully and the bullied victim (Lisa) & her friends since the big bully is very aggressive at Lisa and her friends who try to stop the bullying. Moreover, in nearly the end of the improvisational session, sometimes the big bully feels sorry for his behavior and is cared by Lisa and her friends since he is abused by his uncle. The intense negative relationships between the big bully and Lisa & her friends are changed to those with at least less negativity or even normal relationships. Because of the creative nature of the improvisation, sometimes the bully and the victim may even have a positive relationship towards the ending of the drama improvisation.

However in our current study, we only assume consistent negative relationships between the bully and the bullied victim & her friends throughout the improvisation to simplify the processing. We will report our work on relationship interpretation using fuzzy logic to dynamically capture the changing relationships between characters as the drama progresses in the near future.

4.2 Linguistic Contextual Indicators

In our study, we noticed some linguistic indicators for contextual communication in the recorded transcripts. One useful indicator is (i) imperatives, which are often used to imply negative or positive responses to the previous speaking characters, such as "shut up", "go on then", "let's do it" and "bring it on". Other useful contextual indicators are (ii) prepositional phrases (e.g. "by who?"), semi-coordinating conjunctions (e.g. "so we are good then"), subordinating conjunctions ("because Lisa is a dog") and coordinating conjunctions ('and', 'or' and 'but'). These indicators are normally used by the current 'speaker' to express further opinions or gain further confirmation.

In addition, (iii) short phrases for questions are also used frequently in the transcripts to gain further communication based on context, e.g. "where?", "who is Dave" or "what". (iv) Character names are also normally used in the user input to indicate that the current input is intended for particular characters, e.g. "Dave go away", "Mrs Parton, say something", "Dave what has got into you?" etc. Very often, such expressions have been used to imply potential emotional contextual communication between the current speaking character and the named character. Therefore the current speaking characters may imply at least 'approval' or 'disapproval' towards the opinions/comments provided by the previous named speaking characters. Finally there are also (v) some other well known contextual indicators in Internet relay chat such as 'yeah/yes followed by a sentence ("yeah, we will see")', "I think so", 'no/nah followed by a sentence', "me too", "exactly", "thanks", "sorry", "grrrr", "hahahaha", etc. Such expressions are normally used to indicate affective responses to the previous input.

Since natural language is ambiguous and there are cases in which contextual information is required in order to appropriately interpret the affect conveyed in the input (e.g. "go on then"), our approach reported in the following integrates the above contextual linguistic indicators with cognitive contextual emotion prediction to uncover affect conveyed in emotionally ambiguous input.

4.3 Emotion Modeling in Communication Context

There are also other aspects which may influence the affect conveyed in the communication context. E.g. in our application, the affect con-

veyed by the speaking character himself/herself in the recent several turn-taking, the 'improvisational mood' that the speaking character is created, and emotions expressed by other characters, especially by the contradictory ones (e.g. the big bully), have great potential to influence the affect conveyed by the current speaking character (e.g. the bullied victim). Sometimes, the story themes or topics also have potential impact to emotions or feelings expressed by characters. For example, people tend to feel 'happy' when involved in discussions on positive topics such as harvest or raising salary, while people tend to feel 'sad' when engaged in the discussions on negative themes such as economy breakdown, tough examination etc.

In our application, although the hidden story sub-themes used in the scenarios are not that dramatic, they are still highly emotionally charged and used as the signals for potential changes of emotional context for each character. E.g. In the school bullying scenario (which is mainly about the bully, Mayid, is picking on the new comer to the school, Lisa. Lisa's friends, Elise and Dave, are trying to stop the bullying. The school teacher, Mrs Parton, also tries to find out what is going on), the director mainly provided interventions based on several main sub-themes of the story to push the improvisation forward, i.e. "Mayid starts bullying Lisa", "why Lisa is crying", "why Mayid is so nasty/a bully", "how Mayid feels when his uncle finds out about his behavior" etc. From the inspection of the recorded transcripts, when discussing the topic of "why Lisa is crying", we noticed that Mayid (the bully) tends to be really aggressive and rude, while Lisa (the bullied victim) tends to be upset and other characters (Lisa's friends and the school teacher) are inclined to show anger at Mayid. For the improvisation of the hidden story sub-theme "why Mayid is so nasty/a bully", the big bully changes from rude and aggressive to sad and embarrassed (e.g. because he is abused by his uncle), while Lisa and other characters become sympathetic (and sometimes caring) about Mayid. Usually all characters are trying to create the 'improvisational mood' according to the guidance of the hidden story sub-themes (provided via director's intervention). Therefore, the story sub-themes could be used as the indicators for potential emotional context change. The emotion patterns expressed by each character within the improvisation of each story sub-theme could be very useful for the prediction of the affect shown in a similar topic context, although the improvisation of the characters is creative within the loose scenario. It will improve the performance of the emotional context prediction if we allow more emotional profiles for each story sub-theme to be added to the training data to reflect the creative improvisation (e.g. some improvisations went deeper for a particular topic).

Therefore, a Markov chain is used to learn from the emotional context shown in the recorded transcripts for each sub-theme and for each character, and generate other possible reasonable unseen emotional context similar to the training data for each character. Markov chains are usually used for word generation. In our application, they are used to record the frequencies of several emotions showing up after one particular emotion. A matrix has been constructed dynamically for neutral and the 12 most commonly used emotions in our application (caring, arguing, disapproving, approving, grateful, happy, sad, threatening, embarrassed, angry/rude, scared and sympathetic) with each row representing the previous emotion followed by the subsequent emotions in columns. The Markov chains employ roulette wheel selection to ensure to produce a greater probability to select emotions with higher frequencies than emotions with lower occurrences. This will allow the generation of emotional context to probabilistically follow the training data, which may reflect the creative nature of the improvisation.

Then a dynamic algorithm is used to find the most resembling emotional context for any given new situation from the Markov chain's training and generated emotional contexts. I.e. by using the algorithm, a particular series of emotions for a particular story sub-theme has been regarded as the most resembling context to the test emotional situation and an emotional state is recommended as the most probable emotion for the current user input. Since the most recent affect histories of other characters and relationships between characters may also have an impact on the affect conveyed by the speaking character, the recommended affect will be further evaluated (e.g. a most recent 'insulting' input from Mayid could make Lisa 'angry').

At the training stage, first of all, the school bullying transcripts collected from previous user testing have been divided into several topic sections with each of them belonging to one of the story sub-themes. The classification of the sub-themes is mainly based on the human director's intervention which was recorded in the transcripts. Then we used two human annotators to mark up the affect of every turn-taking input in the transcripts using context inference. Thus, for each character, we have summarized a series of emotions expressed throughout the improvisation of a particular story sub-theme. Since the improvisation is creative under the loose scenario, some of the sub-themes (e.g. "why Mayid is so nasty") have been suggested for improvisation for one than once in some transcripts and some of the topics (e.g. "why Lisa is crying") are only shown in a few of the collected transcripts. We made attempts to gather as many emotional contexts as possible for each character for the improvisation of each sub-theme in order to enrich the training data.

The following is a small portion of one recorded transcript used for the training of the Markov chain. The human annotators have marked up the affect expressed in each turn-taking input.

DIRECTOR: why is Lisa crying?

Elise Brown [caring]: lisa stop cryin

Lisa Murdoch [disagree]: lisa aint crying!!!!

Dave Simons [caring]: i dunno! y u cryin lisa?

Mayid Rahim [rude]: cuz she dnt realise she is lucky to b alive

Elise Brown [angry]: beat him up! itss onlii fat..he'll go down straight away

Mayid Rahim [insulting]: lisa, y u crying? u big baby!

Mrs Parton [caring]: lisa, r u ok?

For example, the emotional context for Mayid from the above example is: 'rude' and 'insulting' (we use one letter to represent each emotional label, thus in this example, i.e. 'R I'), and in the similar way, the emotional contexts for other characters have been derived from the above example, which are used as the training data for the Markov chain for the topic "why Lisa is crying". We have summarized the emotional context for each story sub-theme for each character from 4 school bullying transcripts and used them for the training of the Markov chain. The topics considered at the training stage include: "Mayid starts bullying", "why is Lisa crying", "why is Mayid nasty/a bully" and "how does Mayid feel if his uncle knew about his behavior?"

At the test stage, our affect detection component, EMMA, is integrated with an AI agent and detects affect for each user input solely based on the analysis of individual turn-taking input itself. The above algorithms for context-based affect sensing will be activated when the affect detection component recognizes 'neutral' from the current input during the emotionally charged proper improvisation after all the characters have known each other and went on the virtual drama stage. First of all, the linguistic indicators are used to identify if the input with 'neutral' implication is a contextual-based input. E.g. we mainly focus on the checking of the five contextual implications we mentioned previously, including imperatives, prepositional phrases, conjunctions, simplified question sentences, character names, and other commonly used contextual indicators (e.g. "yeah", "I think so"). If any of the above contextual indicators exists, then we further analyze the affect embedded in the input with contextual emotion modeling reported here.

For example, we have collected the following transcript for testing. Normally the director intervened to suggest a topic change (e.g. "find out why Mayid is a bully"). Thus for a testing situation for a particular character, we use the emotion context attached with his/her user input starting right after the most recent director's intervention and ending at his/her last second input, since such a context may belong to one particular topic.

DIRECTOR: U R IN THE PLAYGROUND (indicating bullying starts)

1. Lisa Murdoch: leave me alone! [angry]
2. Mayid Rahim: WAT U GONNA DU? [neu] -> [angry]
3. Mayid Rahim: SHUT UR FAT MOUTH [angry]
4. Elise Brown: grrrrr [angry]
5. Elise Brown: im telin da dinna lady! [threatening]
6. Mayid Rahim: go on den [neutral] -> [angry]
7. Elise Brown: miss[sssssssssssssss] [neu]
8. Elise Brown: lol [happy]

9. Lisa Murdoch: mayid u gna gt banned [threatening]

10. Mayid Rahim: BY HU [neu] -> [angry]

The affect detection component detected that Lisa was 'angry' by saying "leave me alone!". It also sensed that Mayid was 'neutral' by saying "WAT U GONNA DU (what are you going to do)?" without consideration of context. From Rasp, we obtained that the input is a simplified question sentence (a linguistic contextual indicator). Thus, it implies that it could be an emotional situation caused by the previous context (e.g. previous input from Lisa) and the further processing for emotion prediction is activated. Since we don't have an emotional context yet at this stage for Mayid (the very first input from Mayid after the director's intervention), we cannot resort to the Markov chain and the dynamic algorithm currently to predict the affect. However, we could use the emotional context of other characters to predict the affect for Mayid's current input since we believe that an emotional input from a character, especially from an opponent character, has great potential to affect the emotions expressed by the current speaking character.

In the most recent chat history, there is only one input from Lisa after the director's intervention, which implied 'anger'. Since Lisa and Mayid have a negative relationship (pre-defined by character profiles), then we predict Mayid currently experiences negative emotion. Since capitalizations have been used in Mayid's input, we conclude that the affect implied in the input could be 'angry'. However, EMMA could be fooled if the affect histories of other characters fail to provide any useful indication for prediction (e.g. if Lisa implied 'neutral' in the most recent input, the interpretation of the affect conveyed by Mayid would be still 'neutral').

EMMA also detected affect for the 3rd, 4th, and 5th user input in the above example (based on individual turn-taking) until it detected 'neutral' again from the 6th input "go on den (go on then)" from Mayid. Since it is an imperative mood sentence (a linguistic contextual indicator), the input may imply a potential (emotional) response to the previous speaking character. Since we couldn't obtain the affect embedded in the imperative purely based on the analysis of the input itself, the contextual processing is required. Thus the emotional context profile for Mayid is retrieved, i.e. [angry (the 2nd input) and angry (the 3rd input)]. The Markov chain is used to produce the possible emotional context based on the training data for each sub-theme for Mayid.

The following are generated example emotional profiles for the sub-theme "Mayid starts bullying" for the Mayid character:

1. T A A N A A ['threatening, angry, angry, neutral, angry and angry']

2. N A A A ['neutral, angry, angry, and angry']

3. D A I A A A N A ['disapproval, angry, insulting, angry, angry, angry, neutral, and angry']

4. I A A N ['insulting, angry, angry and neutral']

The dynamic algorithm is used to find the smallest edit distance between the test emotional context [angry and angry] and the training and generated emotional context for the Mayid character for each sub-theme. In the above example, the second and fourth emotional sequences have the smallest edit distance (distance = 2) to the test emotional context and the former suggests 'angry' as the affect conveyed in the current input ("go on den") while the latter implies 'neutral' expressed in the current input. Thus we need to resort to the emotional context of other characters to justify the recommended affects. From the chatting log, we find that Lisa was 'angry' in her most recent input (the 1st input) while Elise was 'threatening' in her most recent input (the 5th input). Since the bully, Mayid, has a negative relationships with Lisa (being 'angry') and Elise (being 'threatening'), the imperative input ("go on den") may indicate 'angry' rather than 'neutral'. Therefore our processing adjusts the affect from 'neutral' to 'angry' for the 6th input.

In this way, by considering the linguistic contextual indicators, the potential emotional context one character was in, relationships with others and recent emotional profiles of other characters, our affect detection component has been able to inference emotion based on context to mark up the rest of the above test example transcript (e.g. Mayid being 'angry' for the 10th input). However our processing could be fooled easily by various diverse ways for affective expressions and creative improvisation (test emotional patterns not shown in the training and

generated sets). We intend to adopt better emotion simulation tools, more linguistic hints, psychological (context-based) emotional theories for further improvements. Also, our processing currently only focused on the school bullying scenario. We are on our way to extend the context-based affect sensing to the Crohn's disease scenario to further evaluate its efficiency.

5 Evaluation and Conclusion

We carried out user testing with 220 secondary school students from Birmingham and Darlington schools for the improvisation of school bullying and Crohn's disease scenarios. Generally, our previous statistical results based on the collected questionnaires indicate that the involvement of the AI character has not made any statistically significant difference to users' engagement and enjoyment with the emphasis of users' notice of the AI character's contribution throughout. Briefly, the methodology of the testing is that we had each testing subject have an experience of both scenarios, one including the AI minor character only and the other including the human-controlled minor character only. After the testing sessions, we obtained users' feedback via questionnaires and group debriefings. Improvisational transcripts were automatically recorded during the testing so that it allows further evaluation of the performance of the affect detection component.

Therefore, we produce a new set of results for the evaluation of the updated affect detection component with metaphorical and context-based affect detection based on the analysis of some recorded transcripts of school bullying scenario. Generally two human judges (not engaged in any development stage) marked up the affect of 150 turn-taking user input from the recorded another 4 transcripts from school bullying scenario (different from those used for the training of Markov chains). In order to verify the efficiency of the new developments, we provide Cohen's Kappa inter-agreements for EMMA's performance with and without the new developments for the detection of the most commonly used 12 affective states. In the school bullying scenario, EMMA played a minor bit-part character (Lisa's friend: Dave). The agreement for human judge A/B is 0.45. The inter-agreements between human judge A/B and EMMA with and without the new developments are presented in Table 1.

	Human Judge A	Human Judge B
EMMA (previous version)	0.38	0.30
EMMA (new version)	0.40	0.32

Table 1: Inter-agreements between human judges and EMMA with and without the new developments

Although further work is needed, the new developments on metaphorical and contextual affect sensing have improved EMMA's performance of affect detection in the test transcripts comparing with the previous version.

The evaluation results indicated that most of the improvements (approximately 80%) are obtained for negative affect detection based on the inference of context information. But there are still some cases: when the two human judges both believed that user inputs carried negative affective states (such as angry, threatening, disapproval etc), EMMA regarded them as neutral. One most obvious reason is that some of the previous pipeline processing (such as dealing with mis-spelling, acronyms etc, and syntactic processing from Rasp etc) failed to recover the standard user input or recognize the complex structure of the input which led to less interesting and less emotional context and may affect the performance of contextual affect sensing. (The work of Sproat et al. (2001) can point out helpful directions on this aspect.) Currently we achieved 69% average accuracy rate for the contextual affect sensing for the emotion interpretation of all the human controlled characters in school bullying scenario. We also aim to extend the evaluation of the context-based affect detection using transcripts from other scenarios. Moreover, some of the improvements (nearly 20%) in the updated affect sensing component are made by the metaphorical processing. However, since the test transcripts contained a very small number of metaphorical language phenomena comparatively, we intend to use other resources (e.g. The Wall Street Journal and other metaphorical databases (such as ATT-Meta, 2008)) to further evaluate the new development on metaphorical affect sensing.

Sentence Ordering with Event-Enriched Semantics and Two-Layered Clustering for Multi-Document News Summarization

Renxian Zhang **Wenjie Li** **Qin Lu**

Abstract

We propose an event-enriched model to alleviate the semantic deficiency problem in the IR-style text processing and apply it to sentence ordering for multi-document news summarization. The ordering algorithm is built on event and entity coherence, both locally and globally. To accommodate the event-enriched model, a novel LSA-integrated two-layered clustering approach is adopted. The experimental result shows clear advantage of our model over event-agonistic models.

1 Introduction

One of the crucial steps in multi-document summarization (MDS) is information ordering, right after content selection and before sentence realization (Jurafsky and Martin, 2009:832–834). Problems with this step are the culprit for much of the dissatisfaction with automatic summaries. While textual order may guide the ordering in single-document summarization, no such guidance is available for MDS ordering.

A sensible solution is ordering sentences by enhancing coherence since incoherence is the source of disorder. Recent researches in this direction mostly focus on local coherence by studying lexical cohesion (Conroy et al., 2006) or entity overlap and transition (Barzilay and Lapata, 2008). But global coherence, i.e., coherence between sentence groups with the whole text in view, is largely unaccounted for and few efforts are made at levels higher than entity or word in measuring sentence coherence.

On the other hand, event as a high-level construct has proved useful in MDS content selection (Filatova and Hatzivassiloglou, 2004; Li et al., 2006). But the potential of event in summarization has not been fully gauged and few publications report using event in MDS information ordering. We will argue that event is instrumental for MDS information ordering, especially multi-document news summarization (MDNS). Ordering algorithms based on event and entity information outperform those based only on entity information.

After related works are surveyed in section 2, we will discuss in section 3 the problem of semantic deficiency in IR-based text processing, which motivates building event information into sentence representation. The details of such representation are provided in section 4. In section 5, we will explicate the ordering algorithms, including layered clustering and cluster-based ordering. The performance of the event-enriched model will be extensively evaluated in section 6. Section 7 will conclude the work with directions to future work.

2 Related Work

In MDS, information ordering is often realized on the sentence level and treated as a coherence enhancement task. A simple ordering criterion is the chronological order of the events represented in the sentences, which is often augmented with other ordering criteria such as lexical overlap (Conroy et al., 2006), lexical cohesion (Barzilay et al., 2002) or syntactic features (Lapata 2003).

A different way to capture local coherence in sentence ordering is the Centering Theory (CT, Grosz et al. 1995)-inspired entity-transition approach, advocated by Barzilay and Lapata (2005, 2008). In their entity grid model, syntactic roles played by entities and transitions between these syntactic roles underlie the coherence patterns between sentences and in the

Coling 2008: Poster Volume, pages 1489–1497,
Beijing, August 2010

whole text. An entity-parsed corpus can be used to train a model that prefers the sentence orderings that comply with the optimal entity transition patterns.

Another important clue to sentence ordering is the sentence positional information in a source document, or "precedence relation", which is utilized by Okazaki et al. (2004) in combination with topical clustering.

Those works are all relevant to the current work because we seek ordering clues from chronological order, lexical cohesion, entity transition, and sentence precedence. But we also add an important member to the panoply – event.

Despite its intuitive and conceptual appeal, event is not as extensively used in summarization as term or entity. Filatova and Hatzivassiloglou (2004) use "atomic events" as conceptual representations in MDS content selection, followed by Li et al. (2006) who treat event terms and named entities as graph nodes in their PageRank algorithm. Yoshioka and Haraguchi (2004) report an event reference-based approach to MDS content selection for Japanese articles. Although "sentence reordering" is a component of their model, it relies merely on textual and chronological order. Few published works report using event information in MDS sentence ordering.

Our work will represent text content at two levels: event vectors and sentence vectors. This is close in spirit to Bromberg's (2006) enriched LSA-coherence model, where both sentence and word vectors are used to compute a centroid as the topic of the text.

3 Semantic Deficiency in IR-Style Text Processing

As automatic summarization traces its root to Information Retrieval (IR), it inherits the vector space model (VSM) of text representation, according to which a sentence is treated as a bag of words or stoplist-filtered terms. The order or relation among the terms is ignored. For example,

1a) *The storm killed 120,000 people in Jamaica and five in the Dominican Republic before moving west to Mexico*.

1b) [*Dominican*, *Mexico*, *Jamaica*, *Republic*, *five*, *kill*, *move*, *people*, *storm*, *west*]

1c) [*Dominican Republic*, *Mexico*, *Jamaica*, *people*, *storm*]

1b) and 1c) are the term-based and entity-based representations of 1a) respectively. They only indicate what the sentence is about (i.e., some happening, probably a storm, in some place that affects people), but "aboutness" is a far cry from informativeness. For instance, no message about "people in which place, Mexico or Jamaica, are affected" or "what moves to where" can be gleaned from 1b) although such message is clearly conveyed in 1a). In other words, the IR-style text representation is semantically deficient.

We argue that a natural text, especially a news article, is not only about somebody or something. It also tells what happened to somebody or something in a temporal-spatial manner. A natural approach to meeting the "what happened" requirement is to introduce event.

4 Event-Enriched Sentence Representation

In summarization, an event is an activity or episode associated with participants, time, place, and manner. Conceptually, event bridges sentence and term/entity and partially fills the semantic gap in the sentence representation.

4.1 Event Structure and Extraction

Following (Li et al. 2006), we define an event E as a structured semantic unit consisting of one event term $Term(E)$ and a set of event entities $Entity(E)$. In the news domain, event terms are typically action verbs or deverbal nouns. Light verbs such as "take", "give", etc. (Tan et al., 2006) are removed.

Event entities include named entities and high-frequency entities. Named entities denote people, locations, organizations, dates, etc. High-frequency entities are common nouns or NPs that frequently participate in news events. Filatova and Hatzivassiloglou (2004) take the top 10 most frequent entities and Li et al. (2006) take the entities with frequency > 10. Rather than using a fixed threshold, we reformulate "high-frequency" as relative statistics based on (assumed) Gaussian distribution of the entities and consider those with z-score > 1 as candidate event entities.

Event extraction begins with shallow parsing and named entity recognition, analyzing each

sentence S into ordered lists of event terms $\{t_1, t_2, \ldots\}$. Low-frequency common entities are removed. If a noun is decided to be an event term, it cannot be (the head noun of) an entity.

The next step is to identify events with event terms and entities. Filatova and Hatzivassiloglou (2003) treat events as triplets with two event entities sandwiching one connector (event term). But the number restriction on entities is counterintuitive and is dropped in our method. We first identify $n + 1$ Seg_i segmented by n event terms t_j.

$$\underbrace{\ldots}_{Seg_0}\ t_1 \ldots \ldots\ t_{j-1}\ \underbrace{\ldots}_{Seg_j}\ t_j\ \underbrace{\ldots}_{Seg_j}\ t_{j+1}\ \ldots \ldots\ t_n\ \underbrace{\ldots}_{Seg_n}$$

Figure 1. Segments among Event Terms

For each t_j, the corresponding event E_j are extracted by taking t_j and the event entities in its nearest entity-containing Seg_p and Seg_q.

$E_j = [t_j, Entity(Seg_p) \cup Entity(Seg_q)]$ (Eq. 1)

where $p = \text{argmax}_{0 \le i \le j-1} Entity(Seg_i) \neq \emptyset$ and $q = \text{argmin}_{j+1 \le i \le n} Entity(Seg_i) \neq \emptyset$ if such p and q exist. 1d) is the event-extracted result of 1a).

1d) {[*killed*, [*storm*, *people*, *Jamaica*, *Dominican Republic*]], [*moving*, [*people*, *Jamaica*, *Dominican Republic*, *west*, *Mexico*]]}

From this representation, it is easy to identify the two events in sentence 1a) led by the event terms "killed" and "moving". Unlike the triplets (two named entities and one connector) in (Filatova and Hatzivassiloglou 2003), an event in our model can have an unlimited number of event entities, as is often the real case. Moreover, we can tell that the "killing" involves "people", "storm", "Jamaica", etc. and the "moving" involves "Jamaica", "Dominique Republic", etc.

The shallow parsing-based approach is admittedly coarse-grade (e.g., "storm" is missing from the "moving" event), but the extracted event-enriched representations help to alleviate the semantic deficiency problem in IR.

4.2 Event Relations

The relations between two events include event term relation and event entity relation. Two events are similar if their event terms are similar and/or their event entities are similar. Such similarities are in turn defined on the word level. For event terms, we first find the root verbs of deverbal nouns and then measure verb similarity by using the fine-grained relations provided by VerbOcean (Chklovski and Pantel, 2004), which has proved useful in summarization (Liu et al., 2007). But unlike (Liu et al., 2007), we count in all the verb relations except *antonymy* because considering two antonymous verbs as similar is counterintuitive. The other four relations – *similarity*, *strength*, *enablement*, *before* – are all considered in our measurement of verb similarity. If we denote the normalized score of two verbs on relation i as $VO_i(V_1, V_2)$ with i = 1, 2, 3, 4 corresponding to the above four relations, the term similarity of two events $\mu_t(E_1, E_2)$ is defined as in Eq. 2, where ε is a small number to suppress zeroes. ε = 0.01 if $VO_i(V_1, V_2) = 1$ and otherwise $\varepsilon = 0$.

$\mu_t(E_1, E_2) = \mu_t(Term(E_1), Term(E_2)) = 1 - \prod_{i=1}^{4}(1 - VO_i(Term(E_1), Term(E_2)) + \varepsilon)$ (Eq. 2)

Entity similarity is measured by the shared entities between two events. Li et al. (2006) define entity similarity as the number of shared entities, which may unfairly assign high scores to events with many entities in our model. So we decide to use the normalized result as shown in Eq. 3, where $\mu_e(E_1, E_2)$ denotes the event entity-based similarity between events E_1 and E_2.

$$\mu_e(E_1, E_2) = \frac{|Entity(E_1) \cap Entity(E_2)|}{|Entity(E_1) \cup Entity(E_2)|} \quad \text{(Eq. 3)}$$

$\mu(E_1, E_2)$, the score of event similarity, is a linear combination of $\mu_t(E_1, E_2)$ and $\mu_e(E_1, E_2)$.

$\mu(E_1, E_2) = \alpha_1 \times \mu_t(E_1, E_2) + (1 - \alpha_1) \times \mu_e(E_1, E_2)$ (Eq. 4)

4.3 Statistical Evidence for News Events

In this work, we introduce events as a middle-layer representation between words and sentences under the assumptions that 1) events are widely distributed in a text and that 2) they are natural clusters of salient information in a text. They guarantee the relevance of event to our task – summaries are condensed collections of salient information in source documents.

In order to confirm them, we scan the whole dataset in our experiment, which consists of 42 200w human extracts and 39 400w human extracts for the DUC 02 multi-document extract task. Detailed information about the dataset can be found in Section 6. Table 1 lists the statistics.

	200w	**400w**	**200w + 400w**	**Source Docs**
Entity/Sent	8.78	8.48	8.47	6.01
Entity/Word	0.34	0.33	0.33	0.30
Event/Sent	2.43	2.26	2.28	1.42

Event/Word	0.09	0.09	0.09	0.07
Sents with events/Sents	86.9%	85.1%	84.6%	71.3%

Table 1. Statistics from DUC 02 Dataset

There are on average 1.42 events per sentence in the source documents, and more than 70% of all the sentences contain events. The high event density confirms our first assumption about the distribution of events. For the 200w+400w category consisting of all the human-selected sentences, there are on average 2.28 events per sentence, a 60% increase from the same ratio in the source documents. The proportion of event-containing sentences reaches 84.6%, 13% higher than that in the source documents. Such is evidence that events count into the extract-worthiness of sentences, which confirms our second assumption about the relevance of events to summarization. The data also show higher entity density in the extracts than in the source documents. As entities are still reliable and domain-independent clues of salient content, we will consider both event and entity in the following ordering algorithm.

5 MDS Sentence Ordering with Event and Entity Coherence

In this section, we discuss how event can facilitate MDS sentence ordering with layered clustering on the event and sentence levels and then how event and entity information can be integrated in a coherence-based algorithm to order sentences based on sentence clusters.

5.1 Two-layered Clustering

After sentences are represented as collections of events, we need to vectorize events and sentences to facilitate clustering and cluster-based sentence ordering.

For a document set, event vectorization begins with aggregating all the event terms and entities in a set of **event units** (*eu*). Given m distinct event terms, n distinct named entities, and p distinct high-frequency common entities, the $m + n + p$ *eu*'s are a concatenation of the event terms and entities such that eu_i is an event term for $1 \le i \le m$, a named entity for $m + 1 \le i \le m + n$, and a high-frequency entity for $m + n + 1 \le i \le m + n + p$. The *eu*'s define the $m + n + p$ dimensions of an event vector in an eu-by-event matrix $\boldsymbol{E} = [e_{ij}]$, as shown in Figure 2.

$$\begin{array}{l} \\ eu_1 \\ \cdots \\ eu_m \\ \cdots \\ eu_{m+n} \\ \cdots \\ eu_{m+n+p} \end{array} \overbrace{\begin{bmatrix} e_{11} & \cdots & e_{1q} \\ \vdots & \ddots & \vdots \\ e_{m1} & \cdots & e_{mq} \\ \vdots & & \vdots \\ e_{m+n,1} & \cdots & e_{m+n,q} \\ \vdots & & \vdots \\ e_{m+n+p,1} & \cdots & e_{m+n+p,q} \end{bmatrix}}^{E_1, E_2, \ldots E_q}$$

Figure 2. eu-by-Event Matrix

We further define $Entity_N(E_j)$ and $Entity_H(E_j)$ to be the set of named entities and set of high-frequency entities of E_j. Then,

$$e_{ij} = \begin{cases} \mu_t(eu_i, Term(E_j)) & 1 \le i \le m \\ \dfrac{\sum_{e \in Entity_N(E_j)} v_n(eu_i, e)}{|Entity_N(E_j)|} & m + 1 \le i \le m + n \\ \dfrac{\sum_{e \in Entity_H(E_j)} v_h(eu_i, e)}{|Entity_H(E_j)|} & m + n + 1 \le i \le m + n + p \end{cases} \quad \text{(Eq. 5)}$$

$$v_n(w_1, w_2) = \begin{cases} 2 & w_1 \text{ is identical to } w_2 \\ 1 & w_1\ (w_2) \text{ is a part of } w_2\ (w_1) \text{ or they are in a hypernymy / holonymy relationship} \\ 0 & \text{otherwise} \end{cases} \quad \text{(Eq. 6)}$$

$$v_h(w_1, w_2) = \begin{cases} 1 & w_1 \text{ is identical to } w_2 \\ 0.5 & w_1 \text{ are } w_2 \text{ are synonyms} \\ 0 & \text{otherwise} \end{cases} \quad \text{(Eq. 7)}$$

In Eq. 5, $\mu_t(w_1, w_2)$ is defined as in Eq. 2. Both the entity-based $v_n(w_1, w_2)$ and $v_h(w_1, w_2)$ are measured in terms of total equivalence (identity) and partial equivalence. For named entities, partial equivalence applies to structural subsumption (e.g., "Britain" and "Great Britain") and hypernymy/holonymy (e.g., "South Africa" and "Zambia"). For common entities, it applies to synonymy (e.g., "security" and "safety"). Partial equivalence is considered because of the lexical variations frequently employed in journalist writing. The named entity scores are doubled because they represent the essential elements of a news story.

Since the events are represented as vectors, sentence vectorization based on events is not as straightforward as on entities or terms. In this work we propose a novel approach of **two-layered clustering** for the purpose. The basic idea is clustering events at the first layer and then using event clusters as a feature to vectorize and cluster sentences at the second

layer. Hard clustering of events, such as K-means, not only results in binary values in event vectors and data sparseness but also is inappropriate. For example, if EC_1 clusters events all with event terms similar to t^* and EC_2 clusters events all with event entity sets similar to e^* (a set), what about event $\{t^*, e^*\}$? Assigning it to either EC_1 or EC_2 is problematic as it is partially similar to both. So we decide to do soft clustering at the first layer.

A well-studied soft clustering technique is the Expectation-Maximization (EM) algorithm which iteratively estimates the unknown parameters in a probability mixture model. We assume a Gaussian mixture model for the q event vectors $\boldsymbol{V}_1$, $\boldsymbol{V}_2$, …, $\boldsymbol{V}_q$, with hidden variables $\boldsymbol{H}_i$, initial means $\boldsymbol{M}_i$, priors $\boldsymbol{\pi}_i$, and covariance matrix $\boldsymbol{C}_i$. The E-step is to calculate the hidden variables $\boldsymbol{H}_i^t$ for each $\boldsymbol{V}_t$ and the M-step re-estimates the new priors $\boldsymbol{\pi}_i'$, means $\boldsymbol{M}_i'$, and covariance matrix $\boldsymbol{C}_i'$. We iterate the two steps until the log-likelihood converges within a threshold = 10^{-6}. The performance of the EM algorithm is sensitive to the initial means, which are pre-computed by a conventional K-means.

In a preliminary study, we found that the event vectors display pronounced sparseness. A solution to this problem in an effort to leverage the latent "event topics" among *eu*'s is the Latent Semantic Analysis (LSA, Landauer and Dumais, 1997) approach. We apply LSA-style dimensionality reduction to the eu-by-event matrix $\boldsymbol{E}$ by doing Singular Value Decomposition (SVD). A problem is with the number h of the largest singular values, which affects the performance of dimensionality reduction. In this work, we adopt a utility-based metric to find the best h^* by maximizing intra-cluster similarity (Φ_h) and minimizing inter-cluster similarity (Ψ_h) corresponding to the h-dimensionality reduction

$$h^* = \text{argmax}_h \ \Phi_h/\Psi_h \qquad \text{(Eq. 8)}$$

Φ_h is defined as the mean of average cluster similarities measured by cosine distance and Ψ_h is the mean of cluster centroid similarities. Because the EM clustering assigns a probability to every event vector, we also take those probabilities into account when calculating Φ_h and Ψ_h.

Based on the EM clustering of events, we vectorize a sentence by summing up the probabilities of its constituent event vectors over all event clusters (ECs) and obtaining an EC-by-sentence (S_n) matrix $\boldsymbol{S} = [s_{ij}]$.

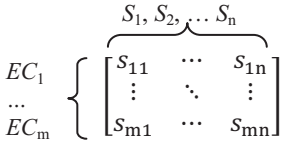

Figure 3. EC-by-Sentence Matrix

$s_{ij} = \sum_{E_r \in S_j} P(\overrightarrow{E_r}|EC_i))$ where $\overrightarrow{E_r}$ is E_r's vector.

At the sentence layer, hard clustering is sufficient because we need definitive, not probabilistic, membership information for the next step – sentence ordering. We use K-means for the purpose. The LSA-style dimensionality reduction is still in order as possible performance gain is expected from the discovery of latent EC "topics". The decision of the best dimensionality is the same as before, except that no probabilities are included.

5.2 Coherence-Based Sentence Ordering

Our ordering algorithm is based on sentence clusters, which is designed on the observation that human writers and summarizers organize sentences by blocks (paragraphs). Sentences within a block are conceptually close to each other and adjacent sentences cohere with each other. Local coherence is thus realized within blocks. On the other hand, blocks are not randomly ordered. Two blocks are put next to each other if their contents are close enough to ensure text-level coherence. So text-level, or global coherence is realized among blocks.

We believe in MDNS, the block-style organization is a sensible strategy taken by human extractors to sort sentences from different sources. Sentence clusters are simulations of such blocks and our ordering algorithm will be based on local coherence and global coherence described above.

First we have to pinpoint the leading sentence for an extract. Using the heuristic of time and textual precedence, we first generate a set of possible leading sentences $L = \{L_i\}$ as the intersection of the document-leading extract sentence set L_{Doc} and the time-leading sentence set L_{Time}. Note that $|L_{Doc}|$ = the number of documents, L_{Time} is in fact a sentence collection of time-leading documents, and $L_{Doc} \cap L_{Time} \neq \emptyset$.

If L is a singleton, finding the leading sentence S_L is trivial. If not, S_L is decided to be the sentence in L most similar to all the other sentences in the extract sentence set P so that it qualifies as a good topic sentence.

$$S_L = \text{argmax}_{L_i \in L} \sum_{L' \in P \setminus \{L_i\}} Sim_{\mu+\nu}(L_i, L') \quad \text{(Eq. 9)}$$

where $Sim_{\mu+\nu}(S_1, S_2)$ is the similarity between S_1 and S_2 in terms of their event similarity $\mu(S_1, S_2)$ and entity similarity $\nu(S_1, S_2)$. $\mu(S_1, S_2)$ is an extended version of $\mu(E_1, E_2)$ (Eq. 4) by averaging the $\mu_t(E_i, E_j)$ and $\mu_e(E_i, E_j)$ for all (E_i, E_j) pairs in $S_1 \times S_2$.

$$\mu(S_1, S_2) = \alpha_2 \times \frac{\sum_{E_i \in S_1, E_j \in S_2} \mu_t(E_i, E_j)}{|Event(S_1) \times Event(S_2)|} + (1 - \alpha_2) \times \frac{\sum_{E_i \in S_1, E_j \in S_2} \mu_e(E_i, E_j)}{|Event(S_1) \times Event(S_2)|} \quad \text{(Eq. 10)}$$

where $Event(S)$ is the set of all events in S. Next, $\nu(S_1, S_2)$ is the cosine similarity between their entity vectors $\overrightarrow{S_1}$ and $\overrightarrow{S_2}$ with entity weights constructed according to Eq. 6 and 7. Then,

$$Sim_{\mu+\nu}(S_1, S_2) = \alpha_3 \times \mu(S_1, S_2) + (1 - \alpha_3) \times \nu(S_1, S_2) \quad \text{(Eq. 11)}$$

After the leading sentence is determined, we identify the leading cluster it belongs to and our local coherence-based ordering starts with this cluster. We adopt a greedy algorithm, which selects each time from the unordered sentence set a sentence that best coheres with the sentence just selected, called **anchor sentence**.

Matching each candidate sentence with the anchor sentence only in terms of $Sim_{\mu+\nu}$ would assume that the sentences are isolated and decontextualized. But the anchor sentence did not come from nowhere and in order to find its best successor, we should also seek clues from its source context, which is inspired by the "sentence precedence" by Okazaki et al. (2004).

More formally, given an anchor sentence S_i at the end of the ordered sentence list, we select the next best sentence S_{i+1} according to their **associative similarity** and **substitutive similarity**, two crucial measures invented by us.

Associative similarity $Sim_{ASS}(S_i, S_j)$ measures how S_i and S_j associate with each other in terms of their event and entity coherence, which almost is $Sim_{\mu+\nu}(S_i, S_j)$. But to better capture the transition between entities and the flow of topic, we also consider a topic-continuity score $tc(S_i, S_j)$ according to the Centering Theory. If the topic continuity is measured in terms of entity change, local coherence can be captured by the centering transitions (*CB* and *CP*) in adjacent sentences. Based on (Taboada and Wiesemann, 2009), we assign 0.2 to the *Establish* and *Continue* transitions, 0.1 to *Smooth Shift* and *Retain*, and 0 to other centering transitions.

Since $tc(S_i, S_j)$ only applies to entities, it is treated as a bonus affiliated to $\nu(S_i, S_j)$.

$$Sim_{ASS}(S_i, S_j) = \alpha_4 \times \mu(S_i, S_j) + (1 - \alpha_4) \times \nu(S_i, S_j) \times (1 + tc(S_i, S_j)) \quad \text{(Eq. 12)}$$

Substitutive similarity accommodates what we earlier emphasized about the "source context" of the extracted sentences by measuring to what degree S_i and S_j resemble each other's relevant source context. More formally, let $LC(S_i)$ and $RC(S_i)$ be the left and right source contexts of S_i respectively, and the substitutive similarity $Sim_{SUB}(S_i, S_j)$ is defined as follows.

$$Sim_{SUB}(S_i, S_j) = Sim_{\mu+\nu}(S_i, LC(S_j)) + Sim_{\mu+\nu}(RC(S_i), S_j) \quad \text{(Eq. 13)}$$

In this work, we simply take $LC(S_i)$ and $RC(S_i)$ to be the left adjacent sentence and right adjacent sentence of S_i in the source document. Note that $tc(S_i, S_j)$ does not apply here. In view of the chronological order widely accepted in MDS ordering, a time penalty, $tp(S_i, S_j)$, is used to discount the score by 0.8 if S_i's document date is later than S_j's document date. Finally, Eq. 14 summarizes our intra-cluster ordering method in a sentence cluster SC_k.

$$S_{i+1} = \text{argmax}_{S_j \in SC_k \setminus \{S_i\}} \left(\alpha_5 \times Sim_{ASS}(S_i, S_j) + (1 - \alpha_5) \times Sim_{SUB}(S_i, S_j)\right) \times tp(S_i, S_j) \quad \text{(Eq. 14)}$$

After all the sentences in the current sentence cluster are ordered, we move on by considering the similarity of sentence clusters. Given a processed sentence cluster SC_i, the next best sentence cluster SC_{i+1} is the one that maximizes the cluster similarity $Sim_{CLU}(SC_i, SC_j)$ among the set of all clusters U. Since clusters are collections of sentences, their similarity is the mean of cross-cluster pairwise sentence similarities, each calculated according to Eq. 14. Eq. 15 shows how SC_{i+1} is computed.

$$SC_{i+1} = \text{argmax}_{SC_j \in U \setminus \{SC_i\}} Sim_{CLU}(SC_i, SC_j) \quad \text{(Eq. 15)}$$

This is how we incorporate (block-style) global coherence into MDS sentence ordering. Starting from the second chosen sentence cluster, we choose the first sentence in the current cluster with reference to the last sentence in the previous processed cluster and apply Eq. 14. We continue the whole process until all the extract sentences are ordered.

6 Evaluation

In this section, we report the experimental result on the DUC 02 dataset.

6.1 Data

We use the dataset of the DUC 02 summarization track for MDS because it includes an extraction task for which model extracts are provided. For every document set, 2 model extracts are provided each for the 200w and 400w length categories. We use 1 randomly chosen model extract per document set per length category as the gold standard.

We intended to use all the 59 document sets on DUC 02 but found that for some categories, both model extracts contain material from sections such as the *title*, *lead*, or even *byline*. Those extracts are incompatible with our design tailored for news body extracts. Therefore we have to filter them and retain only those extracts with all units selected from the news body. As a result, we collect 42 200w extracts and 39 400w extracts as our experimental dataset.

6.2 Peer Orderings

We evaluate the role played by various key elements in our approach, including event, topic continuity, time penalty, and LSA-style dimensionality reduction. In addition, we produce a random ordering and a baseline ordering according to chronological and textual order only. Table 2 lists the 9 peer orderings to be evaluated, with their codes.

A	Random
B	Baseline (time order + textual order)
C	Entity only (no LSA)
D	Event only (no LSA)
E	Entity + Event – topic continuity (no LSA)
F	Entity + Event – time penalty (no LSA)
G	Entity + Event (no LSA)
H	Entity + Event (event clustering LSA)
I	Entity + Event (event + sentence clustering LSA)

Table 2. Peer Orderings

6.3 Metrics

A popular metric used in sequence evaluation is Kendall's τ (Lapata, 2006), which measures ordering differences in terms of the number of adjacent sentence inversions necessary to convert a test ordering to the reference ordering.

$$\tau = 4m/(n(n-1)) \qquad \text{(Eq. 16)}$$

where m is the number of inversions described above and n is the total number of sentences.

The second metric we use is the Average Continuity (AC) developed by Bollegala et al. (2006), which captures the intuition that the ordering quality can be estimated by the number of correctly arranged continuous sentences.

$$AC = \exp\left(\frac{1}{k-1}\sum_{n=2}^{k}\log(P_n + \varepsilon)\right) \qquad \text{(Eq. 17)}$$

where k is the maximum number of continuous sentences, ε is a small value in case $P_n = 1$. P_n, the proportion of continuous sentences of length n in an ordering, is defined as $m/(N - n + 1)$ where m is the number of continuous sentences of length n in both the test and reference orderings and N is the total number of sentences. We set $k = 4$ and $\varepsilon = 0.01$.

6.4 Result

We empirically determine all the parameters (α_i) and produce all the peer orderings. Table 3 lists the result, where we also show the statistical significance between the full model peer ordering "I" and all other versions, marked by * ($p < .05$) and ** ($p < .01$) on a two-tailed t-test.

Peer Code	200w		400w	
	Kendall's τ	*AC*	Kendall's τ	*AC*
A	0.014**	0.009**	-0.019**	0.004**
B	0.387	0.151*	0.259**	0.151*
C	0.369*	0.128*	0.264*	0.156*
D	0.380	0.163	0.270*	0.158*
E	0.375*	0.156*	0.267*	0.157*
F	0.388	0.159*	0.264*	0.157*
G	0.385	0.158*	0.269*	0.162
H	0.384	0.164	0.292*	0.170
I	**0.395**	**0.170**	**0.350**	**0.176**

Table 3. Evaluation Result

Almost all versions with entity and event information outperform the baseline. The LSA-style dimensionality reduction proves effective for our task, as the full model (Peer I) ranks first and significantly beats versions without event information, topic continuity, or LSA. Applying LSA to both event and sentence clustering is better than applying it only to event clustering (Peer H), which produces unstable results and is sometimes outperformed by no-LSA versions (Peer G).

Event (Peer D) proves to be more valuable than entity (Peer C) as the event-only versions outperform the entity-only version in all categories, which is predicable because events

1) Thursday's **acquittals** in the McMartin Pre-School **molestation** case outraged parents who said prosecutors botched it, while those on the defense side proclaimed a triumph of justice over hysteria and hype.
2) Originally, there were seven defendants, including Raymond Buckey's sister, Peggy Ann Buckey, and Virginia McMartin, the founder of the school, mother of Mrs. Buckey and grandmother of Raymond Buckey.
3) Seven jurors who spoke with reporters in a joint news conference after **acquitting** Raymond Buckey and his mother, Peggy McMartin Buckey, on 52 **molestation** charges Thursday said they felt some children who testified may have been **molested** _ but not at the family-run McMartin Pre-School.
4) ``The children were never allowed to say in their own words what happened to them,'' said juror John Breese.
5) Ray Buckey and his mother, Peggy McMartin Buckey, were found not guilty Thursday of **molesting** children at the family-run McMartin Pre-School in Manhattan Beach, a verdict which brought to a close the longest and costliest criminal trial in history .
6) As it becomes apparent that McMartin cases will stretch out for years to come, parents and the former criminal defendants alike are trying to **resign** themselves to the inevitability that the matter may be one they can never leave behind.

Figure 4. Extract sentences of d80ae, 200w

are high-level constructs that incorporate most of the document-level important entities.

When entity is used, extra bonus can be gained from topic continuity concerns from CT (Peer E vs. Peer G) because the centering transition effectively captures the coherence pattern between adjacent sentences. The effect of the chronological order seems less clear (Peer F vs. P) as removing it hurts longer extracts rather than short extracts. Therefore chronological clues are more valuable for arranging more sentences from the same source document.

Our ordering algorithm achieves even better result with long extracts because the importance of order and coherence grows with text length. Measured by Kendall's τ, the full model ordering in the 400w category is significantly better than all other orderings.

For a qualitative evaluation, we select the 200w extract d080ae and list all the sentences in Figure 4. The event terms are boldfaced and the event entities are underlined.

Limited by space, let's focus on the baseline (1 2 3 4 5 6), entity-only (3 5 2 4 6 1), and full-model versions (3 5 4 2 1 6). The news extract is about the acquitting of child molesters. Both the "acquitting" and "molesting" events are found in 1) and 3) but only the latter qualifies as the topic sentence because it contains important event entities. Choosing 3) instead of 1) as the leading sentence shows the advantage of our event-enriched model over the baseline. The same choice is made by the entity-only version because 3) happens to be also entity-intensive. In order to see the advantage of the full model over the entity-only model, let's consider 2) and 4). 2) is chosen by the entity-only model after 5) because of the heavy entity overlap between 5) and 2). But semantically, 2) is not as close to 5) as 4) because only 4) contains entities for both the "acquitting" ("juror") and "molesting" ("children") events and intuitively, 4) continues the main trial-acquittal event topic but 2) supplies only secondary information. We examined the sentence clusters before the ordering and found that 3), 5), and 4) are clustered together only by the full model, leading to better coherence, locally and globally.

7 Conclusion and Future Work

We set out by realizing the semantic deficiency of IR and propose a low-cost approach of building event semantics into sentence representation. Event extraction relies on shallow parsing and external knowledge sources. Then we propose a novel approach of two-layered clustering to use event information, coupled with LSA-style dimensionality reduction. MDS sentence ordering is guided by local and global coherence to simulate the block-style writing and is realized by a greedy algorithm. The evaluation shows clear advantage of our event-enriched model over baseline and event-agonistic models, quantitatively and qualitatively.

The extraction approach can be refined by deep parsing and rich verb (frame) semantics. In a follow-up project, we will expand our dataset and experiment with more data and incorporate human evaluation in comparative tasks.

Abstract

Temporal expressions in texts contain significant temporal information. Understanding temporal information is very useful in many NLP applications, such as information extraction, documents summarization and question answering. Therefore, the temporal expression normalization which is used for transforming temporal expressions to temporal information has absorbed many researchers' attentions. But previous works, whatever the hand-crafted rules-based or the machine-learnt rules-based, all can not address the actual problem about temporal reference in real texts effectively. More specifically, the reference time choosing mechanism employed by these works is not adaptable to the universal implicit times in normalization. Aiming at this issue, we introduce a new reference time choosing mechanism for temporal expression normalization, called reference time dynamic-choosing, which assigns the appropriate reference times to different classes of implicit temporal expressions dynamically when normalizing. And then, the solution to temporal expression defuzzification by scenario dependences among temporal expressions is discussed. Finally, we evaluate the system on a substantial corpus collected by Chinese news articles and obtained more promising results than compared methods.

1 Introduction

Temporal expression normalization is very important for temporal information processing because it is in charge of transforming temporal expressions in surface texts to temporal information behind surface texts. Temporal information is defined as the knowledge about time or duration, which can be abstracted into some objects defined as temporal attributes in TIMEX2 Standard [Ferro et al., 2005]. Human being can take temporal relation reasoning and anchor events on the time line with this information. Meanwhile, temporal expressions are defined as chunks of texts which convey explicit or implicit temporal information. So TERN evaluation plan[1] gives the task of temporal expression normalization that is annotating the appropriate temporal attributes for each temporal expression in texts. For example, a simple temporal expression, "May 1, 2009", can be normalized as <TIMEX2 VAL = "2009-05-01"> May 1, 2009 </TIMEX2>.

Unfortunately, temporal expressions in real texts are more complicated because they contain a large number of Implicit Times besides Explicit Times. Here,

(1) *Explicit Time*: Explicit Time can directly be laid in the timeline. Basically, it is a direct entry in the timeline and need not to be transformed. E.g., "May 1, 2009".

(2) *Implicit Time*: Implicit Time can be mapped as an entry in the timeline with help of real contexts and some predefined knowledge and need to be transformed. E.g., "May 1", "tomorrow" and "two day ago".

Consequently, temporal expression normalization is mainly aiming at Implicit Times that

[1] http://timex2.mitre.org/tern.html

Coling 2008: Poster Volume, pages 1498–1506,
Beijing, August 2010

need to be transformed with referring to some specific times. However, the previous works on temporal expression normalization which basically adopt two mechanisms for choosing reference time, static time-value [Mani and Wilson, 2000; Wu et al., 2005; Wu et al., 2005] and static choosing-rules [Vozov, 2001; Jang et al., 2004; Lin et al., 2008], are not compatible with the real texts. The static time-value mechanism refers to taking the report time or publication time of the document as the fixed reference time for the whole text when normalizing. And the static choosing-rules mechanism means that the machine always uses fixed rules by contexts to choose reference time for each Implicit Time whatever its temporal semantics is. The rule based on the nearest narrative time [Lin et al., 2008] is the most typical and effective one, which uses the nearest narrative time in text above as the reference time all the while. But actually the context-free assumption or the rote operation is unsuitable for universal Implicit Times. For example, a news report is as Figure 1 shows:

(*Beijing, May 6, 2009*) B company took over A company totally on March 8, 2000. After one week, B company listed in Hong Kong, and became the first listed company in that industry. However, owing to the decision-making mistakes in the leadership and the company later poor management, B company got into debt for several hundred million dollars, and was forced to announce bankruptcy this Monday.

Figure 1. Example of news reports

For these two Implicit Times in the text, "after one week" and "this Monday", obviously there will be critical conflicts when using these two mechanisms referred above to choose reference time. The static time-value is unsuited for the "after one week", and "this Monday" makes mistakes when taking the nearest narrative time (i.e., "after one week") as the reference time to normalize according to the static choosing-rules.

Motivated by this issue, we propose a new reference time choosing mechanism for temporal expression normalization. Firstly, we segment the Implicit Time into two parts, modifier and temporal noun, and then train a classifier with referential features of these two parts to classify Implicit Times. As a result, we choose the corresponding reference time for each temporal expression depending on its class when normalizing. Meanwhile an acceptable defuzzification solution is introduced to normalize fuzzy times in our method. And the contributions of this paper are:

(1) We introduce a simple but effective reference time choosing method, called dynamic-choosing mechanism, which can choose the appropriate reference times automatically for universal Implicit Times as well as be compatible with the dynamically changeable contexts.

(2) Going beyond traditional normalization approaches, we develop a new way to deal with the defuzzification in order to figure out the *fuzzy reference time* (the reference time is vague or has imprecise start and end in timeline), which makes the normalization robust and improve the accuracy of reference times.

The rest of this paper is organized as follows. Section 2 discusses related works. In section 3 we describe the reference time dynamic-choosing mechanism. The temporal expression normalization is presented in section 4. Section 5 gives the description about experiments and evaluations. Finally, conclusion and future work are presented in section 6.

2 Related Work

In general, several research works on normalizing temporal expressions, which are involved in English [Mani and Wilson, 2000], French [Vozov, 2001], Spanish [Saquete et al., 2002], Korean [Jang et al., 2004] and Chinese [Wu et al., 2005; Lin et al., 2008], have been reported in recent years. Among them, the hand-crafted rules-based methods [Saquete et al., 2002; Schilder and Habel, 2001; Mani and Wilson, 2000] can deal with various temporal expressions, but the procedure to build a robust rules system is quite time-consuming. With regard to the machine learning for normalization [Jang et al., 2004; Wu et al., 2005; Vicente-Diez et al., 2008], the potential task is the classification which is deciding one explanation of a temporal expression from several alternatives.

However, these works on temporal expression normalization do not give an effective reference time choosing method for Implicit Times in real texts. More specifically, the pioneer work by Lacarides [1992] investigated various contextual effects on different temporal-reference relations. Then Hitzeman et al. [1995] discussed the refer-

ence-choosing taking into account the effects of tense, aspect, temporal adverbials and rhetorical relations. Dorr and Gaasterland [2002] presented the enhanced one in addition considering the connecting words. But they are theoretical in nature and heavily dependent on languages. Currently, the static time-value mechanism [Mani and Wilson, 2000; Wu et al., 2005; Wu et al., 2005] and the static choosing-rules mechanism [Vozov, 2001; Jang et al., 2004; Lin et al., 2008] for reference time choosing are applied into some systems widely. Nevertheless, as the discussion in section 1, these two ways are not adaptable to universal Implicit Times. In addition, Vicente-Diez et al. [2008; 2009] discussed the reference date for relative times, but the alternative rules are not effective in experiments. Lin et al. [2008] considered the condition that there is no report time or publication time when choosing reference time.

Referring to the defuzzification, TIMEX2 Standard [Ferro et al., 2005] takes the X placeholder to express fuzzy times' value, so the related works [Jang et al., 2004; Lin et al., 2008; Vicente-Diez and Martinez, 2009] almost follow this vague expressing way. However, this method can not address the actual situation that the fuzzy time is referred to by other times. Based on the human cognitive psychology, Anderson et al. [1983] presented a classical scenario-time shifting model that discussed the time includes the fuzzy time is the clue to scenario shifting when people reading. Inspired by this issue and based on our experiments, we find all times in a same scenario own strong dependences in temporal granularity, which can effectively help us determine granularity in defuzzification. And more details are discussed in section 4.2.

Aiming at solving these challenges above, we establish a temporal expression normalization system for real texts, which improves the accuracy of temporal reference normalization remarkably by the dynamic-choosing mechanism.

3 Reference Time Dynamic-choosing Mechanism

3.1 Referential feature in Implicit Time

In this paper, we define the Implicit Time consists of the modifier and the temporal noun which is modified by modifiers. And here we extend the modifier based on the TIMEX2 Standard, which include verb, conjunction, adverb and preposition that quantify or modify temporal nouns. For example, "ten days" is a temporal noun, but "ten days ago" is modified after adding the modifier "ago".

Meanwhile we find no matter how long or how many modifiers modify the temporal noun, the whole temporal expression holds the original temporal reference inferred from the temporal noun. Moreover, the key point of normalizing temporal expressions is choosing the appropriate reference time according to the real context rather than deciding the right direction or computing the measurable offset. For instance, with regard to these two Implicit Times in Figure 1, "after one week" and "this Monday", we can achieve the referential direction easily from the modifiers through some mapping rules. Meanwhile, the offsets are able to be understood directly by machine with pattern matching. But for the reference time, we must build the context-depending reference reasoning to trace it. The reference link is described as Figure 2 shows.

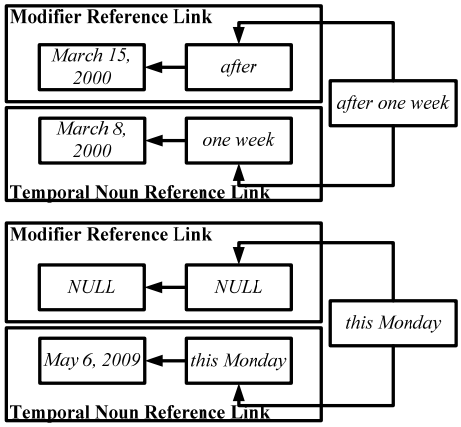

Figure 2. Example of reference link

From the reference reasoning, we can see the full temporal reference comes from two parts: modifier reference and temporal noun reference. Because the former is inferred from the latter, the temporal noun reference reasoning plays more important roles in normalization. In other words, the reference reasoning of the whole Implicit Time strongly depends on the temporal noun. Furthermore, in the practical operation, we indeed take the report time or the nearest narrative time in text above as the reference time of the temporal noun when normalizing a whole Implicit Time. Therefore, we consider the classi-

fication of the Implicit Time based on the classes of temporal noun's reference time. Basically we tag the Implicit Time as the same class as its temporal noun's under classifying temporal nouns into two classes according to the referential feature.

(1) *Global Temporal Noun*: Global Temporal Noun takes the report time or publication time of the document as the reference time when normalizing. Basically, it is independent of the local context.

(2) *Local Temporal Noun*: Local Temporal Noun makes reference to the nearest narrative time in text above in normalization due to depending on the local context.

Table 1 and 2 give some examples of Global Temporal Noun and Local Temporal Noun in real texts.

Consequently, here we denote the Implicit Time consists of the Global Temporal Noun and the modifier(s) by *Global Time* or GT, and accordingly the Local Temporal Noun corresponds to *Local Time* or LT.

Class	Sub-class	Examples
Global Temporal Noun	year	*last year*
	month	*next month*
	day	*this Friday*
	hour	*tonight*
	fuzzy	*lately*[2]

Table 1. Common Global Temporal Noun expressions

Class	Sub-class	Examples
Local Temporal Noun	year	*that year*
	month	*October*
	day	*the second day*
	hour	*morning*
	fuzzy	*then*
	duration	*one month*

Table 2. Common Local Temporal Noun expressions

3.2 Naïve Bayesian Classifier

A variety of machine learning classifiers are designed to resolve the classification problem, such as SVM classifier, ME classifier and the Decision Tree family. But the performance of these classifiers is greatly depending on the features selection. Based on the observation and analysis in our experiments, we find the referential feature holds in the temporal noun is hard to express with some explicit denotations. For example, "that year" and "this year" are nearly identical in surface feature, but the former is locally context-depending while the latter is locally context-free. So the Naïve Bayesian Classifier that assumes independence among feature denotations is suitable to be applied to our method.

We take the single word in the temporal noun as the object attribute x_i after removing the Explicit Time in the whole text. Given the class label c, the classifier learns the conditional probability of each attribute x_i from training data. Meanwhile, achieving the practical instance of X, classification is then performed by applying Bayes rules to compute the probability of c, and then predicting the class with the highest posterior probability.

$$c_o = \arg\max_c grade(c \mid x_1, x_2, \cdots, x_n) \quad x_i \in X \quad (1)$$

$$grade(c \mid x_1, x_2, \cdots, x_n) = \frac{p(c \mid x_1, x_2, \cdots, x_n)}{p(\bar{c} \mid x_1, x_2, \cdots, x_n)} \quad (2)$$

Applying Bayes rules to (2), we have:

$$grade(c \mid x_1, x_2, \cdots, x_n) = \frac{p(x_1, x_2, \cdots, x_n \mid c)p(c)}{p(x_1, x_2, \cdots, x_n \mid \bar{c})p(\bar{c})} = \frac{\prod_{i=1}^{n} p(x_i \mid c)p(c)}{\prod_{i=1}^{n} p(x_i \mid \bar{c})p(\bar{c})} \quad (3)$$

Actually, we estimate $p(x_i \mid c)$ and $p(x_i \mid \bar{c})$ by Maximum Likelihood Estimation (MLE) from training data with Dirichlet Smoothing method [Li et al., 2004].

$$p(x_i \mid c) = \frac{num(x_i, c) + \mu}{\sum_{j=1}^{n} num(x_j, c) + \mu \cdot n} \quad (4)$$

$$p(x_i \mid \bar{c}) = \frac{num(x_i, \bar{c}) + \mu}{\sum_{j=1}^{n} num(x_j, \bar{c}) + \mu \cdot n} \quad (5)$$

3.3 Reference Time Choosing

In our approach, there is a reference time table is used to hold full reference times for the whole text, and we need to update and maintain it dynamically after each normalizing processing.

[2] Some single temporal adverbs are taken as temporal noun, e.g. recently, currently and so on.

The time table consists of two parts: Global Reference Time and Local Reference Time.

(1) *Global Reference Time*: Global Reference Time (GRT) is a type of reference time which is referred to by the Global Time. Specifically, it is the report time or the publication time of the document.

(2) *Local Reference Time*: Local Reference Time (LRT) is made reference to by the Local Time. It will be updated dynamically after each normalizing.

Figure 3 shows a sample of the interaction between reference times and target times.

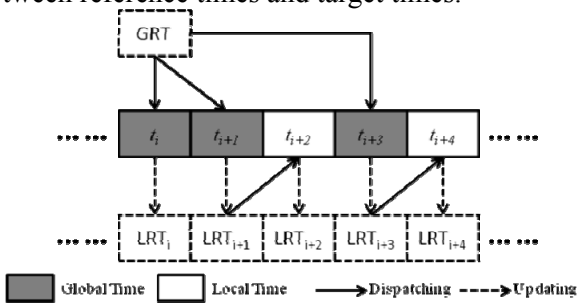

Figure 3. Interaction between reference times and target times

In Figure 3, we notice that different classes of time dynamically and automatically choose references based on their respective classes rather than do it using the fixed value or the inconsiderate rule under the static mechanism. And the reference time table is updated in real time finishing each normalizing, which makes the temporal situation compliable with dynamically changeable contexts.

4 Temporal Expression Normalization

4.1 Basic Normalizing Algorithm

In the beginning, we need to achieve the report time (RT) or the publication time (PT) of the document to initialize the GRT and LRT. Additionally, the fuzzy time can be referred to by other times in the normalization, but we must solve the defuzzification problem before taking it as the reference time. With respect to this issue, we will discuss it in the next section. Consequently, the practical normalizing algorithm is as follows.

```
Algorithm: TimeNormalize
Input: temporal expression t_i in text
Output: regular time list TList
Begin
  //initialize the GRT and LRT with RT or PT of this
  document
  GRT ← Initialize (RT|PT)
  LRT ← Initialize (RT|PT)
  for each t_i in text do
    //segment t_i into modifier and temporal noun
    t_i' ← SegmentTemporal (t_i)
    if IsExplicitTime (t_i) is true
      //update the time table with t_i
      LRT ← UpdateTime (t_i)
      //insert t_i into regular time list directly
      TList ← InsertList (t_i)
    else
      if IsLocalTime (t_i') is true
       //retrieve the latest LRT from time table and then
        normalize t_i'
        T_i ← RegularizeTemporal (t_i' , LRT)
      else
        //retrieve GRT from time table and then
         normalize t_i'
        T_i ← RegularizeTemporal (t_i' , GRT)
      LRT ← UpdateTime (T_i)
      end if
    TList ← InsertList (T_i)
    end if
  return TList
End Begin
```

4.2 Temporal Expression Defuzzification

In general, the defuzzification for fuzzy times faces two problems: deciding granularity and choosing offset. Here we introduce some knowledge on the human cognitive psychology and the empirical method to figure out these two issues respectively. Based on the scenario-time shifting model referred in related works, we get the conclusion that once the scenario is shifting, the time is shifting. More specifically, the time shifting is reflected in the temporal granularity between two different scenarios. So referring to writers, they will choose a few temporal expressions own the same granularity to render the coherent temporal dimensionality in one scenario in order to avoid generating improper scenario shifting for readers. Figure 4 describes the variation process of the temporal granularity between two different scenarios through scenario-time shifting.

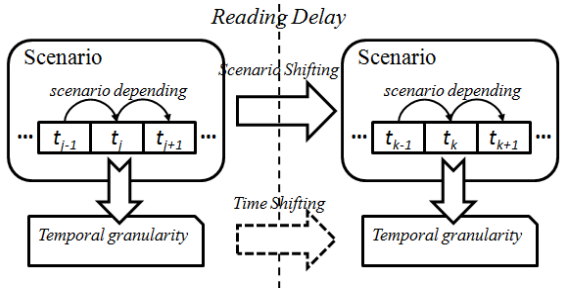

Figure 4. Variation process of temporal granularity

As conveyed in Figure 4, temporal expressions in the same scenario are constrained by the scenario depending. Hence fuzzy times should keep pace with scenario-correlative times in granularity. For example, two sentences in different scenarios:

"He was in Hong Kong *yesterday*, but now he is in Beijing."

"He was in Hong Kong *last year*, but now he is in Beijing."

Obviously, the first "now" means "today" in that scenario, and it has the same temporal granularity with "yesterday". Meanwhile it will be more appropriate for the second "now" choosing "year" as the temporal granularity than choosing "day" because of the dependence to the scenario-correlative time. In narrative, the paragraph is normally considered as the minimum unit of the scenario, so scenario-correlative relations should stand on the one paragraph at least.

But for the first temporal expression in the paragraph, we need to think about two specific conditions: when it appears in the first paragraph and in the non-first paragraph if it is a fuzzy time. Because there is no scenario shifting to the first paragraph, we employ a dictionary to initialize the algorithm when the first time included in the first paragraph is fuzzy time. The defuzzification process is outlined as follows.

Algorithm: *TempGranuarityDefuzzify*
Input: temporal expression t_i in text
Output: precise-granularity time t_i'
Begin
  //obtain the granularity of t_i
  granularity ← `GetGranularity` (t_i)
  //decide whether t_i is a fuzzy time
  if *granularity* is **not null**
    t_i' ← t_i
  else
    if t_i is **not** first temporal expression in current paragraph
      //assign the former's granularity to the t_i
      granularity ← `GetGranularity` (t_{i-1})
    else
      if t_i is **not** included in first paragraph
        //decide which granularity is assigned to t_i between t_{i-1} and t_{i+1}
        if `IsSameGranularity` (`GetGranularity` (t_{i-1}), `GetGranularity` (t_{i+1})) is **not true**
          granularity ← `GetGranularity` (`CoarserCompare` (t_{i-1}, t_{i+1}))
        else
          granularity ← `GetGranularity` (t_{i+1})
        end if
      else
        //retrieve default granularity from dictionary
        granularity ← `FindGranularityInDict` (t_i)
      end if
    end if
  //retrieve default offset from dictionary
  offset ← `FindOffsetInDict` (t_i)
  //update and intact all temporal attributes of t_i
  t_i' ← `ModifyTimeAttribute` (t_i, *granularity*, *offset*)
  end if
  return t_i'
End Begin

It's possible for the first temporal expression to correlate with forenamed times in last paragraph in real texts, so we choose the coarser granularity for the fuzzy time when appearing conflicts in granularity between the last temporal expression and the next temporal expression. Additionally, an empirical fuzzy time dictionary is constructed as the default in order to figure out the offset problem. For example, "lately" is denoted in dictionary as below.

Lately
Common synonyms: *recently*, *latterly*, *late*, *of late*
Default granularity: *day*
Default offset: *7 units*

Finishing the defuzzification for the whole text, the basic normalizing algorithm is evoked then. In the experiments, we find that the temporal expression defuzzified can clearly improve the accuracy of reference times besides discovering the implicit temporal information much more.

5 Evaluation

5.1 Setup

Because the normalization for temporal expressions is independent of the language [Wilson et al., 2001], we take the formal Chinese news[3] as

[3] People's Daily news corpus (January, 1998), supported by Institute of Computational Linguistics (ICL), Peking University.

the experimental corpus, which consist of 3148 Chinese news articles. The data collection contains 2,816,612 characters/967,884 words and 21,176 manually annotated temporal nouns. Among this corpus, 2518 articles (80%) include 13,835 temporal expressions are used as training data for the classification, and the rest (20%) as test data. Then the whole corpus is tested for the normalization. Event-anchored expressions are relevant with a specific event and it is hard to represent the exact meaning of them, so in our system, event-anchored expressions are not normalized.

5.2 Results

Results on Implicit Times classification: We firstly choose some temporal expressions classified in advance by crafted, and manually extend them in expressing patterns as the original training samples. For example, "last month" will extend to "this month" and "next month", which all belong to Global Times. Actually there are only 16,104 temporal expressions in our experiment because integrated temporal expressions in corpus are segmented into several parts, and we combine them together again before operating. Using classifier trained by training data, we get 2,264 Global Times and 998 Local Times from testing collections, where there are 1,705 Global Times and 804 Local Times are correct respectively by manual statistics. Table 3 gives the details of classification.

From the experiment data, we find the precision and the recall almost below 80%, and the classification performance is not expected. The reason is that we do not consider some special application situations beforehand, which result in classifying errors. For example, the Global Time should be taken as the Local Time when it appears in the dialog or speech that marks boundaries by a pair of quotation marks. So we introduce some revising patches shown in Table 4 to deal with this issue. Here the second and the fourth patches make corresponding temporal expressions be treated as non-target times that need not be processed. In addition, Time Set and Non-Specific are taken as the other classes except the Implicit Time and the Explicit Time. The final results with revising patches are shown in Table 5. Obviously, revising patches make the classification be more adapted for the real texts, and the performance evaluation is promising.

Class	#Correct	Precision (%)	Recall (%)	F-measure (%)
Global Time	1705	75.31	78.64	76.94
Local Time	804	80.56	79.45	80.00
Sum/Average	2509	77.94	79.05	78.47

Table 3. Results of classification

ID	Patch Type	Patterns	Operations
1	Dialog/Speech	"XXX"	Time → LT
2	Book/Movie	《XXX》 *XXX*	Be omitted
3	Time Set	quantifier + XXX	Time → others
4	Proper Noun	e.g. October Revolution	Be omitted
5	Non-Specific	e.g. childhood	Time → others

Table 4. Revising patches for classification

Class	#Correct	Precision (%)	Recall (%)	F-measure (%)
Global Time	1879	88.69	86.67	87.67
Local Time	918	90.55	90.71	90.63
Sum/Average	2797	89.62	88.69	89.15

Table 5. Results of classification with revising patches

Results on temporal expression normalization: For evaluating our algorithm objectively, we compare the experiment result with other two methods on the same testing corpus. The first compared method which is adopted in many traditional systems [Li et al., 2004; Wu et al., 2005] applies the static time-value mechanism to determine the reference time. The nearest narrative time [Lin et al., 2008; Vicente-Diez and Martinez, 2009] that represents the static choosing-rules mechanism is taken as the second compared method. Table 6 presents the results.

Method	Average referent updating/ article	Accuracy (%)	Errors	
			Referent (%)	Others (%)
STVM	0	68.42	22.84	8.74
SCRM	7.8	76.19	11.25	12.56
Our method	4.2	83.55	7.33	9.12

*STVM: Static Time-Value Mechanism
SCRM: Static Choosing-Rules Mechanism

Table 6. Results of normalization

The data shows that our method exceeds the compared ones evidently. The accuracy increases by 15.13% at most, and the errors by referent decreases by 3.92% at least. In contrast to the SCRM, we avoid the limitation that SCRM only concentrates on the nearest distance for choosing referent. Meanwhile, because the SCRM pays no attention to the normalization for fuzzy temporal expressions, the error by others (e.g. granularity) is greater than ours. Additionally, the STVM method applies the report time or the publication time of the document as the reference time for the whole text, so there is no referent updating in process. We mark all errors as referent errors as long as they involve with false reference time in results analysis, therefore, the STVM gets the highest referent errors ratio.

With respect to the defuzzification, we evaluate it on fuzzy times separately. All defuzzified fuzzy times are assessed by human, and then decided whether they are acceptable to the context. The evaluation results are shown in Table 7.

Type	#Acceptable	Acceptable ratio (%)	As referent (%)
Global Time	687	80.14	18.39
Local Time	159	92.61	6.43
Sum/Average	846	86.38	12.41

Table 7. Evaluations on temporal expression defuzzification

For the fuzzy temporal expression in Local Time, it is much fewer and easier than the one in Global Time in number and expression respectively, so the defuzzification in Local Times achieves more expected results. On the other hand, the fuzzy time in Global Time is often the first temporal expression in the first paragraph, and the corresponding dictionary-based method certainly affects the experiment results. According to the percentages that the temporal expressions defuzzified successfully account for in the all reference times, it demonstrates that the defuzzification makes contributions to the referential normalization besides discovering the internal temporal information in the fuzzy time.

6 Conclusion

In this paper, we present an approach to automatically normalizing temporal expressions under the reference time dynamic-choosing mechanism. The referential feature in temporal nouns is applied to classify Implicit Times. Based on this, different classes of times can be normalized according to their respective classes. Meanwhile, we introduce the scenario-time shifting model to deal with the defuzzification problem. The experiment shows that our approach achieves more promising evaluation results, and makes the automatic normalization more adaptable to real texts than the prior works. However, the neglect on the event-anchored expression certainly restricts the whole system in applications, so the event-anchored expression will be our research focus in future.

Abstract

Existing works indicate that the absence of explicit discourse connectives makes it difficult to recognize implicit discourse relations. In this paper we attempt to overcome this difficulty for implicit relation recognition by automatically inserting discourse connectives between arguments with the use of a language model. Then we propose two algorithms to leverage the information of these predicted connectives. One is to use these predicted implicit connectives as additional features in a supervised model. The other is to perform implicit relation recognition based only on these predicted connectives. Results on Penn Discourse Treebank 2.0 show that predicted discourse connectives help implicit relation recognition and the first algorithm can achieve an absolute average f-score improvement of 3% over a state of the art baseline system.

1 Introduction

Discourse relation analysis is to automatically identify discourse relations (e.g., explanation relation) that hold between arbitrary spans of text. This analysis may be a part of many natural language processing systems, e.g., text summarization system, question answering system. If there are discourse connectives between textual units to explicitly mark their relations, the recognition task on these texts is defined as *explicit discourse relation recognition*. Otherwise it is defined as *implicit discourse relation recognition*.

Previous study indicates that the presence of discourse connectives between textual units can greatly help relation recognition. In Penn Discourse Treebank (PDTB) corpus (Prasad et al., 2008), the most general senses, i.e., Comparison (Comp.), Contingency (Cont.), Temporal (Temp.) and Expansion (Exp.), can be disambiguated in explicit relations with more than 90% f-scores based only on the discourse connectives explicitly used to signal the relation (Pitler and Nenkova., 2009b).

However, for implicit relations, there are no connectives to explicitly mark the relations, which makes the recognition task quite difficult. Some of existing works attempt to perform relation recognition without hand-annotated corpora (Marcu and Echihabi, 2002), (Sporleder and Lascarides, 2008) and (Blair-Goldensohn, 2007). They use unambiguous patterns such as [Arg1, *but* Arg2] to create synthetic examples of implicit relations and then use [Arg1, Arg2] as an training example of an implicit relation. Another research line is to exploit various linguistically informed features under the framework of supervised models, (Pitler et al., 2009a) and (Lin et al., 2009), e.g., polarity features, semantic classes, tense, production rules of parse trees of arguments, etc.

Our study on PDTB test data shows that the average f-score for the most general 4 senses can reach 91.8% when we simply mapped the ground truth implicit connective of each test instance to its most frequent sense. It indicates the importance of connective information for implicit relation recognition. However, so far there is no previous study attempting to use such kind of connective information for implicit relation. One possi-

Coling 2008: Poster Volume, pages 1507–1514,
Beijing, August 2010

ble reason is that implicit connectives do not exist in unannotated real texts. Another evidence of the importance of connectives for implicit relations is shown in PDTB annotation. The PDTB annotation consists of inserting a connective expression that best conveys the inferred relation by the readers. Connectives inserted in this way to express inferred relations are called *implicit connectives*, which do not exist in real texts. These evidences inspire us to consider two interesting research questions:
(1) Can we automatically predict implicit connectives between arguments?
(2) How to use the predicted implicit connectives to build an automatic discourse relation analysis system?

In this paper we address these two questions as follows: (1) We insert appropriate discourse connectives between two textual units with the use of a language model. Here we train the language model on large amount of raw corpora without the use of any hand-annotated data. (2) Then we present two algorithms to use these predicted connectives for implicit relation recognition. One is to use these connectives as additional features in a supervised model. The other is to perform relation recognition based only on these connectives.

We performed evaluation of the two algorithms and a baseline system on PDTB 2.0 corpus. Experimental results showed that using predicted discourse connectives as additional features can significantly improve the performance of implicit discourse relation recognition. Specifically, the first algorithm achieved an absolute average f-score improvement of 3% over a state of the art baseline system.

The rest of this paper is organized as follows. Section 2 describes the two algorithms for implicit discourse relation recognition. Section 3 presents experiments and results on PDTB data. Section 4 reviews related work. Section 5 concludes this work.

2 Our Algorithms for Implicit Discourse Relation Recognition

2.1 Prediction of implicit connectives

Explicit discourse relations are easily identifiable due to the presence of discourse connectives between arguments. (Pitler and Nenkova., 2009b) showed that in PDTB corpus, the most general senses, i.e., Comparison (Comp.), Contingency (Cont.), Temporal (Temp.) and Expansion (Exp.), can be disambiguated in explicit relations with more than 90% f-scores based only on discourse connectives.

But for implicit relations, there are no connectives to explicitly mark the relations, which makes the recognition task quite difficult. PDTB data provides *implicit connectives* that are inserted between paragraph-internal adjacent sentence pairs not marked by any of explicit connectives. The availability of ground-truth implicit connectives makes it possible to evaluate the contribution of these connectives for implicit relation recognition. Our initial study on PDTB data show that the average f-score for the most general 4 senses can reach 91.8% when we obtained the sense of each test example by mapping each ground truth implicit connective to its most frequent sense. We see that connective information is an important knowledge source for implicit relation recognition. However these implicit connectives do not exist in real texts. In this paper we overcome this difficulty by inserting a connective between two arguments with the use of a language model.

Following the annotation scheme of PDTB, we assume that each implicit connective takes two arguments, denoted as *Arg1* and *Arg2*. Typically, there are two possible positions for most of implicit connectives[1], i.e., the position before Arg1 and the position between Arg1 and Arg2. Given a set of possible implicit connectives $\{c_i\}$, we generate two synthetic sentences, c_i+Arg1+Arg2 and Arg1+c_i+Arg2 for each c_i, denoted as $S_{c_i,1}$ and $S_{c_i,2}$. Then we calculate the perplexity (an intrinsic score) of these sentences with the use of a language model, denoted as $PPL(S_{c_i,j})$. According

[1]For parallel connectives, e.g., *if*...*then*..., the two connectives will take the two arguments together, so there is only one possible combination for connectives and arguments.

to the value of $PPL(S_{c_i,j})$ (the lower the better), we can rank these sentences and select the connectives in top N sentences as implicit connectives for this argument pair. The language model may be trained on large amount of unannotated corpora that can be cheaply acquired, e.g., North American News corpus.

2.2 Using predicted implicit connectives as additional features

We predict implicit connectives on both training set and test set. Then we can use the predicted implicit connectives as additional features for supervised implicit relation recognition. Previous works exploited various linguistically informed features under the framework of supervised models. In this paper, we include 9 types of features in our system due to their superior performance in previous studies, e.g., polarity features, semantic classes of verbs, contextual sense, modality, inquirer tags of words, first-last words of arguments, cross-argument word pairs, ever used in (Pitler et al., 2009a), production rules of parse trees of arguments used in (Lin et al., 2009), and intra-argument word pairs inspired by the work of (Saito et al., 2006).

Here we provide the details of the 9 features, shown as follows:

Verbs: Similar to the work in (Pitler et al., 2009a), the verb features consist of the number of pairs of verbs in Arg1 and Arg2 if they are from the same class based on their highest Levin verb class level (Dorr, 2001). In addition, the average length of verb phrase and the part of speech tags of main verb are also included as verb features.

Context: If the immediately preceding (or following) relation is an explicit, its relation and sense are used as features. Moreover, we use another feature to indicate if Arg1 leads a paragraph.

Polarity: We use the number of positive, negated positive, negative and neutral words in arguments and their cross product as features. For negated positives, we locate the negated words in text span and then define the closely behind positive word as negated positive.

Modality: We look for modal words including their various tenses or abbreviation forms in both arguments. Then we generate a feature to indicate the presence or absence of modal words in both arguments and their cross product.

Inquirer Tags: Inquirer Tags extracted from General Inquirer lexicon (Stone et al., 1966) contains positive or negative classification of words. In fact, its fine-grained categories, such as Fall versus Rise, or Pleasure versus Pain, can indicate the relation between two words, especially for verbs. So we choose the presence or absence of 21 pair categories with complementary relation in Inquirer Tags as features. We also include their cross production as features.

FirstLastFirst3: We choose the first and last words of each argument as features, as well as the pair of first words, the pair of last words, and the first 3 words in each argument. In addition, we apply Porter's Stemmer (Porter, 1980) to each word before preparation of these features.

Production Rule: According to (Lin et al., 2009), we extract all the possible production rules from arguments, and check whether the rules appear in Arg1, Arg2 and both arguments. We remove the rules occurring less than 5 times in training data.

Cross-argument Word Pairs: We perform the Porter's stemming (Porter, 1980), and then group all words from Arg1 and Arg2 into two sets W_1 and W_2 respectively. Then we generate any possible word pair (w_i, w_j) ($w_i \in W_1$, $w_j \in W_2$). We remove the word pairs with less than 5 times.

Intra-argument Word Pairs: Let $Q_1 = (q_1, q_2, \ldots, q_n)$ be the word sequence of Arg1. The intra-argument word pairs for Arg1 is defined as $WP_1 = ((q_1, q_2), (q_1, q_3), \ldots, (q_1, q_n), (q_2, q_3), \ldots, (q_{n-1}, q_n))$. We extract all the intra-argument word pairs from Arg1 and Arg2 and remove word pairs appearing less than 5 times in training data.

2.3 Relation recognition based only on predicted implicit connectives

After the prediction of implicit connectives, we can address the implicit relation recognition task with the methods for explicit relation recognition due to the presence of implicit connectives, e.g., sense classification based only on connectives (Pitler and Nenkova., 2009b). The work of (Pitler and Nenkova., 2009b) showed that most

of connectives are unambiguous and it is possible to obtain high performance in prediction of discourse sense due to the simple mapping relation between connectives and senses. Given two examples:
(E1) She paid less on her dress, ***but*** it is very nice.
(E2) We have to harry up ***because*** the raining is getting heavier and heavier.
The two connectives, i.e., *but* in E1 and *because* in E2, convey Comparison and Contingency sense respectively. In most cases, we can easily recognize the relation sense by the appearance of discourse connective since it can be interpreted in only one way. That means, the ambiguity of the mapping between sense and connective is quite few.

We count the frequency of sense tags for each possible connective on PDTB training data for implicit relation. Then we build a sense recognition model by simply mapping each connective to its most frequent sense. Here we do not perform connective prediction on training data. During testing, we use the language model to insert implicit connectives into each test argument pair. Then we perform relation recognition by mapping each implicit connective to its most frequent sense.

3 Experiments and Results

3.1 Experiments

3.1.1 Data sets

In this work we used the PDTB 2.0 corpus for evaluation of our algorithms. Following the work of (Pitler et al., 2009a), we used sections 2-20 as training set, sections 21-22 as test set, and sections 0-1 as development set for parameter optimization. For comparison with the work of (Pitler et al., 2009a), we ran four binary classification tasks to identify each of the main relations (Cont., Comp., Exp., and Temp.) from the rest. For each relation, we used equal numbers of positive and negative examples as training data[2]. The negative examples were chosen at random from sections 2-20. We used all the instances in sections 21 and 22 as test set, so the test set is representative of the natural distribution. The numbers of positive and negative instances for each sense in different data sets are listed in Table 1.

Table 1: Statistics of positive and negative samples in training, development and test sets for each relation.

Relation	Train	Dev	Test
	Pos/Neg	Pos/Neg	Pos/Neg
Comp.	1927/1927	191/997	146/912
Cont.	3375/3375	292/896	276/782
Exp.	6052/6052	651/537	556/502
Temp.	730/730	54/1134	67/991

In this work we used LibSVM toolkit to construct four linear SVM models for a baseline system and the system in Section 2.2.

3.1.2 A baseline system

We first built a baseline system, which used 9 types of features listed in Section 2.2.

We tuned the numbers of firstLastFirst3, cross-argument word pair, intra-argument word pair on development set. Finally we set the frequency threshold at 3, 5 and 5 respectively.

3.1.3 Prediction of implicit connectives

To predict implicit connectives, we adopt the following two steps:(1) train a language model; (2) select top N implicit connectives.

Step 1: We used SRILM toolkit to train the language models on three benchmark news corpora, i.e., New York part in the BLLIP North American News, Xin and Ltw parts of English Gigaword (4th Edition). We also tried different values for n in n-gram model. The parameters were tuned on the development set to optimize the accuracy of prediction. In this work we chose 3-gram language model trained on NY corpus.

Step 2: We combined each instance's Arg1 and Arg2 with connectives extract from PDTB2 (100 in all). There are two types of connectives, single connective (e.g. *because* and *but*) and parallel connective (such as "*not only* ..., *but also*"). Since discourse connectives may appear not only ahead of the Arg1, but also between Arg1 and Arg2, we considered this case. Given a set of possible implicit connectives $\{c_i\}$, for single connective $\{c_i\}$, we constructed two synthetic sentences, c_i+Arg1+Arg2 and Arg1+c_i+Arg2. In case of

[2]Here the numbers of training and test instances for Expansion relation are different from those in (Pitler et al., 2009a). The reason is that we do not include instances of EntRel as positive examples.

parallel connective, we constructed one synthetic sentence like c_{i1}+Arg1+c_{i2}+Arg2.

As a result, we can get 198 synthetic sentences for each argument pair. Then we converted all words to lower cases and used the language model trained in the above step to calculate perplexity on sentence level. The perplexity scores were ranked from low to high. For example, we got the perplexity (*ppl*) for two sentences as follows:
(1) *but* this is an old story, we're talking about years ago before anyone heard of asbestos having any questionable properties.
ppl= 652.837
(2) this is an old story, *but* we're talking about years ago before anyone heard of asbestos having any questionable properties.
ppl= 583.514

We considered the combination of connectives and their position as final features like mid_*but*, first_*but*, where the features are binary, that is, the presence and absence of the specific connective.

According to the value of $PPL(S_{c_i,j})$ (the lower the better), we selected the connectives in top N sentences as implicit connectives for this argument pair. In order to get the optimal N value, we tried various values of N on development set and selected the minimum value of N so that the ground-truth connectives appeared in top N connectives. The final N value is set to 60 based on the trade-off between performance and efficiency.

3.1.4 Using predicted connectives as additional features

This system combines the predicted implicit connectives as additional features and the 9 types of features in an supervised framework. The 9 types of features are listed as shown in Section 2.2 and tuned on development set.

We combined predicted connectives with the best subset features from the development data set with respect to f-score. In our experiment of selecting best subset features, single features rather than the combination of several features achieved much higher scores. So we combine single features with predicted connectives as final features.

3.1.5 Using only predicted connectives for implicit relation recognition

We built two variants for the algorithm in Section 2.3. One is to use the data for explicit relations in PDTB sections 2-20 as training data. The other is to use the data for implicit relations in PDTB sections 2-20 as training data. Given training data, we obtained the most frequent sense for each connective appearing in the training data. Then given test data, we recognized the sense of each argument pair by mapping each predicted connective to its most frequent sense. In this work we conducted another experiment to see the upper-bound performance of this algorithm. Here we performed recognition based on ground-truth implicit connectives and used the data for implicit relations as training data.

3.2 Results

3.2.1 Result of baseline system

Table 2 summarizes the best performance achieved by the baseline system in comparison with previous state-of-the-art performance achieved in (Pitler et al., 2009a). The first two lines in the table show their best results using single feature and using combined feature subset. It indicates that the performance of using combined feature subset is higher than that using single feature alone.

From this table, we can find that our baseline system has a comparable result on Contingency and Temporal. On Comparison, our system achieved a better performance around 9% f-score higher than their best result. However, for Expansion, they expanded both training and testing sets by including EntRel relation as positive examples, which makes it impossible to perform direct comparison. Generally, our baseline system is reasonable and thus the consequent experiments on it are reliable.

3.2.2 Result of algorithm 1: using predicted connectives as additional features

Table 3 summarizes the best performance achieved by the baseline system and the first algorithm (i.e., baseline + Language Model) on test set. The second and third column show the best performance achieved by the baseline system and

Table 2: Performance comparison of the baseline system with the system of (Pitler et al., 2009a) on test set.

System	Comp. vs. Not F_1 (Acc)	Cont. vs. Other F_1 (Acc)	Exp. vs. Other F_1 (Acc)	Temp. vs. Other F_1 (Acc)
Using the best single feature (Pitler et al., 2009a)	21.01(52.59)	36.75(62.44)	71.29(59.23)	15.93(61.20)
Using the best feature subset (Pitler et al., 2009a)	21.96(56.59)	47.13(67.30)	76.42(63.62)	16.76(63.49)
The baseline system	30.72(78.26)	45.38(40.17)	65.95(57.94)	16.46(29.96)

the first algorithm using predicted connectives as additional features.

Table 3: Performance comparison of the algorithm in Section 2.2 with the baseline system on test set.

Relation	Features	Baseline F_1 (Acc)	Baseline+LM F_1 (Acc)
Comp.	Production Rule	**30.72**(78.26)	31.08(68.15)
	Context	24.66(42.25)	27.64(53.97)
	InquirerTags	23.31(73.25)	27.87(55.48)

	Verbs	25.00(53.50)	**31.79**(58.22)
Cont.	Prodcution Rule	**45.38**(40.17)	**47.16**(48.96)
	Context	37.61(44.70)	34.74(48.87)
	Polarity	35.57(50.00)	43.33(33.74)
	InquirerTags	38.04(41.49)	42.22(36.11)
	Modality	32.18(66.54)	35.26(55.58)
	Verbs	40.44(54.06)	42.04(32.23)
Exp.	Context	48.34(54.54)	68.32(53.02)
	FirstLastFirst3	**65.95**(57.94)	68.94(53.59)
	InquirerTags	61.29(52.84)	68.49(53.21)
	Modality	64.36(56.14)	68.9(52.55)
	Polarity	49.95(50.38)	68.62(53.40)
	Verbs	52.95(53.31)	**70.11**(54.54)
Temp.	Context	13.52(64.93)	16.99(79.68)
	FirstLastFirst3	15.75(66.64)	19.70(64.56)
	InquirerTags	8.51(83.74)	19.20(56.24)
	Modality	**16.46**(29.96)	19.97(54.54)
	Polarity	16.29(51.42)	**20.30**(55.48)
	Verbs	13.88(54.25)	13.53(61.34)

From this table, we found that this additional feature obtained from language model showed significant improvements in almost four relations. Specifically, the top two improvements are on Expansion and Temporal relations, which improved 4.16% and 3.84% in f-score respectively. Although on Comparison relation there is only a slight improvement (+1.07%), our two best systems both got around 10% improvements of f-score over a state-of-the-art system in (Pitler et al., 2009a). As a whole, the first algorithm achieved 3% improvement of f-score over a state of the art baseline system. All these results indicate that predicted implicit connectives can help improve the performance.

3.2.3 Result of algorithm 2: using only predicted connectives for implicit relation recognition

Table 4 summarizes the best performance achieved by the second algorithm in comparison with the baseline system on test set.

The experiment showed that the baseline system using just gold-truth implicit connectives can achieve an f-score of 91.8% for implicit relation recognition. It once again proved that implicit connectives make significant contributions for implicit relation recognition. This also encourages our future work on finding the most suitable connectives for implicit relation recognition.

From this table, we found that, using only predicted implicit connectives achieved an comparable performance to (Pitler et al., 2009a), although it was still a bit lower than our best baseline. But we should bear in mind that this algorithm only uses 4 features for implicit relation recognition and these 4 features are easy computable and fast run, which makes the system more practical in application. Furthermore, compared with other algorithms which require hand-annotated data for training, the performance of this second algorithm is acceptable if we take into account that no labeled data is used for model training.

3.3 Analysis

Experimental results on PDTB showed that using the predicted implicit connectives significantly improves the performance of implicit discourse relation recognition. Our first algorithm achieves an average f-score improvement of 3% over a state of the art baseline system. Specifically, for the relations: Comp., Cont., Exp., Temp., our first algorithm can achieve 1.07%, 1.78%, 4.16%, 3.84% f-score improvements over a state of the art baseline system. Since (Pitler et al., 2009a)

Table 4: Performance comparison of the algorithm in Section 2.3 with the baseline system on test set.

System	Comp. vs. Other F_1 (Acc)	Cont. vs. Other F_1 (Acc)	Exp. vs. Other F_1 (Acc)	Temp. vs. Other F_1 (Acc)
The baseline system	30.72(78.26)	45.38(40.17)	65.95(57.94)	16.46(29.96)
Our algorithm with training data for explicit relation	26.02(52.17)	35.72(51.70)	64.94(53.97)	13.76(41.97)
Our algorithm with training data for implicit relation	24.55(63.99)	16.26(70.79)	60.70(53.50)	14.75(70.51)
Sense recognition using gold-truth implicit connectives	94.08(98.30)	98.19(99.05)	97.79(97.64)	77.04(97.07)

used different selection of instances for Expansion sense[3], we cannot make a direct comparison. However, we achieve the best f-score around 70%, which provide 5% improvements over our baseline system. On the other hand, the second proposed algorithm using only predicted connectives still achieves promising results for each relation. Specifically, the model for the Comparison relation achieves an f-score of 26.02% (5% over the previous work in (Pitler et al., 2009a)). Furthermore, the models for Contingency and Temporal relation achieve 35.72% and 13.76% f-score respectively, which are comparable to the previous work in (Pitler et al., 2009a). The model for Expansion relation obtains an f-score of 64.95%, which is only 1% less than our baseline system which consists of ten thousands of features.

4 Related Work

Existing works on automatic recognition of discourse relations can be grouped into two categories according to whether they used hand-annotated corpora.

One research line is to perform relation recognition without hand-annotated corpora.

(Marcu and Echihabi, 2002) used a pattern-based approach to extract instances of discourse relations such as Contrast and Elaboration from unlabeled corpora. Then they used word-pairs between two arguments as features for building classification models and tested their model on artificial data for implicit relations.

There are other efforts that attempt to extend the work of (Marcu and Echihabi, 2002). (Saito et al., 2006) followed the method of (Marcu and Echihabi, 2002) and conducted experiments with combination of cross-argument word pairs and phrasal patterns as features to recognize implicit relations between adjacent sentences in a Japanese corpus. They showed that phrasal patterns extracted from a text span pair provide useful evidence in the relation classification. (Sporleder and Lascarides, 2008) discovered that Marcu and Echihabi's models do not perform as well on implicit relations as one might expect from the test accuracies on synthetic data. (Blair-Goldensohn, 2007) extended the work of (Marcu and Echihabi, 2002) by refining the training and classification process using parameter optimization, topic segmentation and syntactic parsing.

(Lapata and Lascarides, 2004) dealt with temporal links between main and subordinate clauses by inferring the temporal markers linking them. They extracted clause pairs with explicit temporal markers from BLLIP corpus as training data.

Another research line is to use human-annotated corpora as training data, e.g., the RST Bank (Carlson et al., 2001) used by (Soricut and Marcu, 2003), adhoc annotations used by (**?**), (Baldridge and Lascarides, 2005), and the Graph-Bank (Wolf et al., 2005) used by (Wellner et al., 2006).

Recently the release of the Penn Discourse TreeBank (PDTB) (Prasad et al., 2008) benefits the researchers with a large discourse annotated corpora, using a comprehensive scheme for both implicit and explicit relations. (Pitler et al., 2009a) performed implicit relation classification on the second version of the PDTB. They used several linguistically informed features, such as word polarity, verb classes, and word pairs, showing performance increases over a random classification baseline. (Lin et al., 2009) presented an implicit discourse relation classifier in PDTB with the use of contextual relations, constituent Parse Features, dependency parse features and cross-argument word pairs.

[3]They expanded the Expansion data set by adding randomly selected EntRel instances by 50%, which is considered to significantly change data distribution.

In comparison with existing works, we investigated a new knowledge source, implicit connectives, for implicit relation recognition. Moreover, our two models can exploit both labeled and unlabeled data by training a language model on unlabeled data and then using this language model to generate implicit connectives for recognition models trained on labeled data.

5 Conclusions

In this paper we use a language model to automatically generate implicit connectives and then present two methods to use these connectives for recognition of implicit relations. One method is to use these predicted implicit connectives as additional features in a supervised model and the other is to perform implicit relation recognition based only on these predicted connectives. Results on Penn Discourse Treebank 2.0 show that predicted discourse connectives help implicit relation recognition and the first algorithm achieves an absolute average f-score improvement of 3% over a state of the art baseline system.

Abstract

This paper presents a novel semi-supervised learning algorithm called Active Deep Networks (ADN), to address the semi-supervised sentiment classification problem with active learning. First, we propose the semi-supervised learning method of ADN. ADN is constructed by Restricted Boltzmann Machines (RBM) with unsupervised learning using labeled data and abundant of unlabeled data. Then the constructed structure is fine-tuned by gradient-descent based supervised learning with an exponential loss function. Second, we apply active learning in the semi-supervised learning framework to identify reviews that should be labeled as training data. Then ADN architecture is trained by the selected labeled data and all unlabeled data. Experiments on five sentiment classification datasets show that ADN outperforms the semi-supervised learning algorithm and deep learning techniques applied for sentiment classification.

1 Introduction

In recent years, sentiment analysis has received considerable attentions in Natural Language Processing (NLP) community (Blitzer et al., 2007; Dasgupta and Ng, 2009; Pang et al., 2002). Polarity classification, which determine whether the sentiment expressed in a document is positive or negative, is one of the most popular tasks of sentiment analysis (Dasgupta and Ng, 2009). Sentiment classification is a special type of text categorization, where the criterion of classification is the attitude expressed in the text, rather than the subject or topic. Labeling the reviews with their sentiment would provide succinct summaries to readers, which makes it possible to focus the text mining on areas in need of improvement or on areas of success (Gamon, 2004) and is helpful in business intelligence applications, recommender systems, and message filtering (Pang, et al., 2002).

While topics are often identifiable by keywords alone, sentiment classification appears to be a more challenge task (Pang, et al., 2002). First, sentiment is often conveyed with subtle linguistic mechanisms such as the use of sarcasm and highly domain-specific contextual cues (Li et al., 2009). For example, although the sentence "The thief tries to protect his excellent reputation" contains the word "excellent", it tells us nothing about the author's opinion and in fact could be well embedded in a negative review. Second, sentiment classification systems are typically domain-specific, which makes the expensive process of annotating a large amount of data for each domain and is a bottleneck in building high quality systems (Dasgupta and Ng, 2009). This motivates the task of learning robust sentiment models from minimal supervision (Li, et al., 2009).

Recently, semi-supervised learning, which uses large amount of unlabeled data together with labeled data to build better learners (Raina et al., 2007; Zhu, 2007), has drawn more attention in sentiment analysis (Dasgupta and Ng, 2009; Li, et al., 2009). As argued by several researchers (Bengio, 2007; Salakhutdinov and Hinton, 2007), deep architecture, composed of multiple levels of non-linear operations (Hinton et al., 2006), is expected to perform well in semi-supervised learning because of its capability of modeling hard artificial intelligent tasks. Deep Belief Networks (DBN) is a representative

Coling 2008: Poster Volume, pages 1515–1523,
Beijing, August 2010

deep learning algorithm achieving notable success for semi-supervised learning (Hinton, et al., 2006). Ranzato and Szummer (2008) propose an algorithm to learn text document representations based on semi-supervised auto-encoders that are combined to form a deep network.

Active learning is another way that can minimize the number of required labeled data while getting competitive result. Usually, the training set is chosen randomly. However, active learning choose the training data actively, which reduce the needs of labeled data (Tong and Koller, 2002). Recently, active learning had been applied in sentiment classification (Dasgupta and Ng, 2009).

Inspired by the study of semi-supervised learning, active learning and deep architecture, this paper proposes a novel semi-supervised polarity classification algorithm called Active Deep Networks (ADN) that is based on a representative deep learning algorithm Deep Belief Networks (DBN) (Hinton, et al., 2006) and active learning (Tong and Koller, 2002). First, we propose the ADN architecture, which utilizes a new deep architecture for classification, and an exponential loss function aiming to maximize the separability of the classifier. Second, we propose the ADN algorithm. It firstly identifies a small number of manually labeled reviews by an active learner, and then trains the ADN classifier with the identified labeled data and all of the unlabeled data.

Our paper makes several important contributions: First, this paper proposes a novel ADN architecture that integrates the abstraction ability of deep belief nets and the classification ability of backpropagation strategy. It improves the generalization capability by using abundant unlabeled data, and directly optimizes the classification results in training dataset using back propagation strategy, which makes it possible to achieve attractive classification performance with few labeled data. Second, this paper proposes an effective active learning method that integrates the labeled data selection ability of active learning and classification ability of ADN architecture. Moreover, the active learning is also based on the ADN architecture, so the labeled data selector and the classifier are based on the same architecture, which provides an unified framework for semi-supervised classification task. Third, this paper applies semi-supervised learning and active learning to sentiment classification successfully and gets competitive performance. Our experimental results on five sentiment classification datasets show that ADN outperforms previous sentiment classification methods and deep learning methods.

The rest of the paper is organized as follows. Section 2 gives an overview of sentiment classification. The proposed semi-supervised learning method ADN is described in Section 3. Section 4 shows the empirical validation of ADN by comparing its classification performance with previous sentiment classifiers and deep learning methods on sentiment datasets. The paper is closed with conclusion.

2 Sentiment Classification

Sentiment classification can be performed on words, sentences or documents, and is generally categorized into lexicon-based and corpus-based classification method (Wan, 2009). The detailed survey about techniques and approaches of sentiment classification can be seen in the book (Pang and Lee, 2008). In this paper we focus on corpus-based classification method.

Corpus-based methods use a labeled corpus to train a sentiment classifier (Wan, 2009). Pang et al. (2002) apply machine learning approach to corpus-based sentiment classification firstly. They found that standard machine learning techniques outperform human-produced baselines. Pang and Lee (2004) apply text-categorization techniques to the subjective portions of the sentiment document. These portions are extracted by efficient techniques for finding minimum cuts in graphs. Gamon (2004) demonstrate that using large feature vectors in combination with feature reduction, high accuracy can be achieved in the very noisy domain of customer feedback data. Xia et al. (2008) propose the sentiment vector space model to represent song lyric document, assign the sentiment labels such as light-hearted and heavy-hearted.

Supervised sentiment classification systems are domain-specific and annotating a large scale corpus for each domain is very expensive (Dasgupta and Ng, 2009). There are several solutions for this corpus annotation bottleneck.

The first type of solution is using old domain labeled examples to new domain sentiment clas-

sification. Blitzer et al. (2007) investigate domain adaptation for sentiment classifiers, which could be used to select a small set of domains to annotate and their trained classifiers would transfer well to many other domains. Li and Zong (2008) study multi-domain sentiment classification, which aims to improve performance through fusing training data from multiple domains.

The second type of solution is semi-supervised sentiment classification. Sindhwani and Melville (2008) propose a semi-supervised sentiment classification algorithm that utilizes lexical prior knowledge in conjunction with unlabeled data. Dasgupta and Ng (2009) firstly mine the unambiguous reviews using spectral techniques, and then exploit them to classify the ambiguous reviews via a novel combination of active learning, transductive learning, and ensemble learning.

The third type of solution is unsupervised sentiment classification. Zagibalov and Carroll (2008) describe an automatic seed word selection for unsupervised sentiment classification of product reviews in Chinese.

However, unsupervised learning of sentiment is difficult, partially because of the prevalence of sentimentally ambiguous reviews (Dasgupta and Ng, 2009). Using multi-domain sentiment corpus to sentiment classification is also hard to apply, because each domain has a very limited amount of training data, due to annotating a large corpus is difficult and time-consuming (Li and Zong, 2008). So in this paper we focus on semi-supervised approach to sentiment classification.

3 Active Deep Networks

In this part, we propose a semi-supervised learning algorithm, Active Deep Networks (ADN), to address the sentiment classification problem with active learning. Section 3.1 formulates the ADN problem. Section 3.2 proposes the semi-supervised learning of ADN without active learning. Section 3.3 proposes the active learning method of ADN. Section 3.4 gives the ADN procedure.

3.1 Problem Formulation

There are many review documents in the dataset. We preprocess these reviews to be classified, which is similar with Dasgupta and Ng (2009). Each review is represented as a vector of unigrams, using binary weight equal to 1 for terms present in a vector. Moreover, the punctuations, numbers, and words of length one are removed from the vector. Finally, we sort the vocabulary by document frequency and remove the top 1.5%. It is because that many of these high document frequency words are stopwords or domain specific general-purpose words.

After preprocess, every review can be represented by a vector. Then the dataset can be represented as a matrix:

$$\mathbf{X}=\left[\mathbf{x}^1,\mathbf{x}^2,\ldots,\mathbf{x}^{R+T}\right]=\begin{bmatrix} x_1^1, x_1^2,\ldots, x_1^{R+T} \\ x_2^1, x_2^2,\ldots, x_2^{R+T} \\ \vdots,\vdots,\ldots,\vdots \\ x_D^1, x_D^2,\ldots, x_D^{R+T} \end{bmatrix} \quad (1)$$

where R is the number of training samples, T is the number of test samples, D is the number of feature words in the dataset. Every column of $\mathbf{X}$ corresponds to a sample $\mathbf{x}$, which is a representation of a review. A sample that has all features is viewed as a vector in $\mathbb{R}^D$, where the i^{th} coordinate corresponds to the i^{th} feature.

The L labeled samples are chosen randomly from R training samples, or chosen actively by active learning, which can be seen as:

$$\mathbf{X}^L=\mathbf{X}^R(\mathbf{S}),\mathbf{S}=[s_1,s_2,...,s_L]\ 1\le s_i\le R \quad (2)$$

where $\mathbf{S}$ is the index of selected training reviews to be labeled manually.

Let $\mathbf{Y}$ be a set of labels corresponds to L labeled training samples and is denoted as:

$$\mathbf{Y}^L=\left[\mathbf{y}^1,\mathbf{y}^2,\ldots,\mathbf{y}^L\right]=\begin{bmatrix} y_1^1, y_1^2,\ldots, y_1^L \\ y_2^1, y_2^2,\ldots, y_2^L \\ \vdots,\vdots,\ldots,\vdots \\ y_C^1, y_C^2,\ldots, y_C^L \end{bmatrix} \quad (3)$$

where C is the number of classes. Every column of $\mathbf{Y}$ is a vector in $\mathbb{R}^C$, where the j^{th} coordinate corresponds to the j^{th} class.

$$y_j^i=\begin{cases}1 & \text{if } \mathbf{x}^i\in j^{\text{th}}\text{ class} \\ -1 & \text{if } \mathbf{x}^i\notin j^{\text{th}}\text{ class}\end{cases} \quad (4)$$

For example, if a review $\mathbf{x}$ is positive, y=[1, -1]'; else, $\mathbf{y}$ = [-1, 1]'.

We intend to seek the mapping function $\mathbf{X}^L\to\mathbf{Y}^L$ using the L labeled data and R+T-L unlabeled data. After training, we can determine $\mathbf{y}$ by the trained ADN while a new sample $\mathbf{x}$ is fed.

3.2 Semi-Supervised Learning

To address the problem formulated in section 3.1, we propose a novel deep architecture for ADN method, as show in Figure 1. The deep architecture is a fully interconnected directed belief nets with one input layer $\mathbf{h}^0$, N hidden layers $\mathbf{h}^1$, $\mathbf{h}^2$, …, $\mathbf{h}^N$, and one label layer at the top. The input layer $\mathbf{h}^0$ has D units, equal to the number of features of sample data $\mathbf{x}$. The label layer has C units, equal to number of classes of label vector $\mathbf{y}$. The numbers of units for hidden layers, currently, are pre-defined according to the experience or intuition. The seeking of the mapping function $\mathbf{X}^L \to \mathbf{Y}^L$, here, is transformed to the problem of finding the parameter space $\mathbf{W}=\{\mathbf{w}^1, \mathbf{w}^2,\ldots,\mathbf{w}^N\}$ for the deep architecture.

The semi-supervised learning method based on ADN architecture can be divided into two stages: First, AND architecture is constructed by greedy layer-wise unsupervised learning using RBMs as building blocks. All the unlabeled data together with L labeled data are utilized to find the parameter space $\mathbf{W}$ with N layers. Second, ADN architecture is trained according to the exponential loss function using gradient descent method. The parameter space $\mathbf{W}$ is retrained by an exponential loss function using L labeled data.

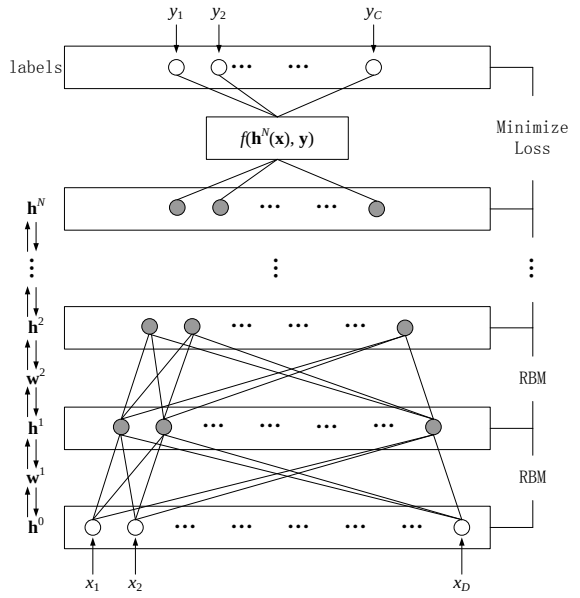

Figure 1. Architecture of Active Deep Networks

For unsupervised learning, we define the energy of the state ($\mathbf{h}^{k-1}$, $\mathbf{h}^k$) as:

$$E\left(\mathbf{h}^{k-1},\mathbf{h}^k;\theta\right)=-\sum_{s=1}^{D_{k-1}}\sum_{t=1}^{D_k} w_{st}^k h_s^{k-1} h_t^k - \sum_{s=1}^{D_{k-1}} b_s^{k-1} h_s^{k-1} - \sum_{t=1}^{D_k} c_t^k h_t^k \quad (5)$$

where $\theta=(\mathbf{w},\mathbf{b},\mathbf{c})$ are the model parameters: w_{st}^k is the symmetric interaction term between unit s in the layer $\mathbf{h}^{k-1}$ and unit t in the layer $\mathbf{h}^k$, k =1,…, N-1. b_s^{k-1} is the s^{th} bias of layer $\mathbf{h}^{k-1}$ and c_t^k is the t^{th} bias of layer $\mathbf{h}^k$. D_k is the number of unit in the k^{th} layer.

The probability that the model assigns to $\mathbf{h}^{k-1}$ is:

$$P\left(\mathbf{h}^{k-1};\theta\right)=\frac{1}{Z(\theta)}\sum_{\mathbf{h}^k}\exp\left(-E\left(\mathbf{h}^{k-1},\mathbf{h}^k;\theta\right)\right) \quad (6)$$

$$Z(\theta)=\sum_{\mathbf{h}^{k-1}}\sum_{\mathbf{h}^k}\exp\left(-E\left(\mathbf{h}^{k-1},\mathbf{h}^k;\theta\right)\right) \quad (7)$$

where $Z(\theta)$ denotes the normalizing constant. The conditional distributions over $\mathbf{h}^k$ and $\mathbf{h}^{k-1}$ are:

$$p\left(\mathbf{h}^k\mid\mathbf{h}^{k-1}\right)=\prod_t p\left(h_t^k\mid\mathbf{h}^{k-1}\right) \quad (8)$$

$$p\left(\mathbf{h}^{k-1}\mid\mathbf{h}^k\right)=\prod_s p\left(h_s^{k-1}\mid\mathbf{h}^k\right) \quad (9)$$

the probability of turning on unit t is a logistic function of the states of $\mathbf{h}^{k-1}$ and w_{st}^k:

$$p\left(h_t^k=1\mid\mathbf{h}^{k-1}\right)=\text{sigm}\left(c_t^k+\sum_s w_{st}^k h_s^{k-1}\right) \quad (10)$$

the probability of turning on unit s is a logistic function of the states of $\mathbf{h}^k$ and w_{st}^k:

$$p\left(h_s^{k-1}=1\mid\mathbf{h}^k\right)=\text{sigm}\left(b_s^{k-1}+\sum_t w_{st}^k h_t^k\right) \quad (11)$$

where the logistic function is:

$$\text{sigm}(\eta)=1/1+e^{-\eta} \quad (12)$$

The derivative of the log-likelihood with respect to the model parameter $\mathbf{w}^k$ can be obtained by the CD method (Hinton, 2002):

$$\frac{\partial \log p(\mathbf{h}^{k-1})}{\partial w_{st}}=\left\langle h_s^{k-1}h_t^k\right\rangle_{P_0}-\left\langle h_s^{k-1}h_t^k\right\rangle_{P_M} \quad (13)$$

where $\langle\cdot\rangle_{P_0}$ denotes an expectation with respect to the data distribution and $\langle\cdot\rangle_{P_M}$ denotes a distribution of samples from running the Gibbs sampler initialized at the data, for M full steps.

The above discussion is based on the training of the parameters between two hidden layers with one sample data $\mathbf{x}$. For unsupervised learning, we construct the deep architecture using all labeled data with unlabeled data by inputting them one by one from layer $\mathbf{h}^0$, train the parameter between $\mathbf{h}^0$ and $\mathbf{h}^1$. Then $\mathbf{h}^1$ is constructed, we

can use it to construct the up one layer $\mathbf{h}^2$. The deep architecture is constructed layer by layer from bottom to top, and in each time, the parameter space $\mathbf{w}^k$ is trained by the calculated data in the k-1th layer.

According to the $\mathbf{w}^k$ calculated above, the layer $\mathbf{h}^k$ can be got as below when a sample $\mathbf{x}$ is fed from layer $\mathbf{h}^0$:

$$h_t^k(\mathbf{x}) = \mathrm{sigm}(c_t^k + \sum_{s=1}^{D_{k-1}} w_{st}^k h_s^{k-1}(\mathbf{x})) \quad t = 1,\ldots,D_k \quad k = 1,\ldots,N-1 \quad (14)$$

The parameter space $\mathbf{w}^N$ is initialized randomly, just as backpropagation algorithm. Then ADN architecture is constructed. The top hidden layer is formulated as:

$$h_t^N(\mathbf{x}) = c_t^N + \sum_{s=1}^{D_{N-1}} w_{st}^N h_s^{N-1}(\mathbf{x}) \quad t = 1,\ldots,D_N \quad (15)$$

For supervised learning, the ADN architecture is trained by L labeled data. The optimization problem is formulized as:

$$\arg\min_{\mathrm{h}^N} \quad \mathrm{f}\left(\mathrm{h}^N\left(\mathbf{X}^L\right), \mathbf{Y}^L\right) \quad (16)$$

where

$$\mathrm{f}\left(\mathrm{h}^N\left(\mathbf{X}^L\right), \mathbf{Y}^L\right) = \sum_{i=1}^{L}\sum_{j=1}^{C} \mathrm{T}\left(\mathrm{h}_j^N\left(\mathbf{x}^i\right) y_j^i\right) \quad (17)$$

and the loss function is defined as

$$\mathrm{T}(r) = \exp(-r) \quad (18)$$

In the supervised learning stage, the stochastic activities are replaced by deterministic, real valued probabilities. We use gradient-descent through the whole deep architecture to retrain the weights for optimal classification.

3.3 Active Learning

Semi-supervised learning allows us to classify reviews with few labeled data. However, annotating the reviews manually is expensive, so we want to get higher performance with fewer labeled data. Active learning can help to choose those reviews that should be labeled manually in order to achieving higher classification performance with the same number of labeled data. For such purpose, we incorporate pool-based active learning with the ADN method, which accesses to a pool of unlabeled instances and requests the labels for some number of them (Tong and Koller, 2002).

Given an unlabeled pool $\mathbf{X}^R$ and a initial labeled data set $\mathbf{X}^L$ (one positive, one negative), the ADN architecture $\mathbf{h}^N$ will decide which instance in $\mathbf{X}^R$ to query next. Then the parameters of $\mathbf{h}^N$ are adjusted after new reviews are labeled and inserted into the labeled data set. The main issue for an active learner is the choosing of next unlabeled instance to query. In this paper, we choose the reviews whose labels are most uncertain for the classifier. Following previous work on active learning for SVMs (Dasgupta and Ng, 2009; Tong and Koller, 2002), we define the uncertainty of a review as its distance from the separating hyperplane. In other words, reviews that are near the separating hyperplane are chosen as the labeled training data.

After semi-supervised learning, the parameters of ADN are adjusted. Given an unlabeled pool $\mathbf{X}^R$, the next unlabeled instance to be queried are chosen according to the location of $\mathbf{h}^N(\mathbf{X}^R)$. The distance of a point $\mathbf{h}^N(\mathbf{x}^i)$ and the classes separation line $h_1^N = h_2^N$ is:

$$\mathbf{d}^i = \left|h_1^N\left(\mathbf{x}^i\right) - h_2^N\left(\mathbf{x}^i\right)\right| / \sqrt{2} \quad (19)$$

The selected training reviews to be labeled manually are given by:

$$s = \left\{ j : \mathbf{d}^j = \min\left(\mathbf{d}\right)\right\} \quad (20)$$

We can select a group of most uncertainty reviews to label at each time.

The experimental setting is similar with Dasgupta & Ng (2009). We perform active learning for five iterations and select twenty of the most uncertainty reviews to be queried each time. Then the ADN is re-trained on all of labeled and unlabeled reviews so far with semi-supervised learning. At last, we can decide the label of reviews $\mathbf{x}$ according to the output $\mathbf{h}^N(\mathbf{x})$ of the ADN architecture as below:

$$y_j = \begin{cases} 1 & \text{if } h_j^N(\mathbf{x}) = \max\left(\mathbf{h}^N(\mathbf{x})\right) \\ -1 & \text{if } h_j^N(\mathbf{x}) \neq \max\left(\mathbf{h}^N(\mathbf{x})\right) \end{cases} \quad (21)$$

As shown by Tong and Koller (2002), the BalanceRandom method, which randomly sample an equal number of positive and negative instances from the pool, has much better performance than the regular random method. So we incorporate this "Balance" idea with ADN method. However, to choose equal number of positive and negative instances without labeling the entire pool of instances in advance may not be practicable. So we present a simple way to approximate the balance of positive and negative reviews. At first, count the number of positive and negative labeled data respectively. Second,

for each iteration, classify the unlabeled reviews in the pool and choose the appropriate number of positive and negative reviews to let them equally.

3.4 ADN Procedure

The procedure of ADN is shown in Figure 2. For the training of ADN architecture, the parameters are random initialized with normal distribution. All the training data and test data are used to train the ADN with unsupervised learning. The training set $\mathbf{X}^R$ can be seen as an unlabeled pool. We randomly select one positive and one negative review in the pool to input as the initial labeled training set that are used for supervised learning. The number of units in hidden layer $D_1 \cdots D_N$ and the number of epochs Q are set manually based on the dimension of the input data and the size of training dataset. The iteration times I and the number G of active choosing data for each iteration can be set manually based on the number of labeled data in the experiment.

For each iteration, the ADN architecture is trained by all the unlabeled data and labeled data in existence with unsupervised learning and supervised learning firstly. Then we choose G reviews from the unlabeled pool based on the distance of these data from the separating line. At last, label these data manually and add them to the labeled data set. For the next iteration, the ADN architecture can be trained on the new labeled data set. At last, ADN architecture is retrained by all the unlabeled data and existing labeled data. After training, the ADN architecture is tested based on Equation (21).

The proposed ADN method can active choose the labeled data set and classify the data with the same architecture, which avoid the barrier between choosing and training with different architecture. More importantly, the parameters of ADN are trained iteratively on the label data selection process, which improve the performance of ADN. For the ADN training process: in unsupervised learning stage, the reviews can be abstracted; in supervised learning stage, ADN is trained to map the samples belong to different classes into different regions. We combine the unsupervised and supervised learning, and train parameter space of ADN iteratively. The proper data that should be labeled are chosen in each iteration, which improves the classification performance of ADN.

Active Deep Networks Procedure

Input: data $\mathbf{X}$
number of units in every hidden layer $D_1 \cdots D_N$
number of epochs Q
number of training data R
number of test data T
number of iterations I
number of active choose data for every iteration G
Initialize: $\mathbf{W}$ = normally distributed random numbers
$\mathbf{X}^L$ = one positive and one negative reviews

for i = 1 to I
Step 1. Greedy layer-wise training hidden layers using RBM
for n = 1 to N-1
for q = 1 to Q
for k = 1 to $R+T$
Calculate the non-linear positive and negative phase according to (10) and (11).
Update the weights and biases by (13).
end for
end for
end for
Step 2. Supervised learning the ADN with gradient descent
Minimize $f(h^N(\mathbf{X}),\mathbf{Y})$ on labeled data set $\mathbf{X}^L$, update the parameter space $\mathbf{W}$ according to (16).
Step 3. Choose instances for labeled data set
Choose G instances which near the separating line by (20)
Add G instances into the labeled data set $\mathbf{X}^L$
end
Train ADN with Step 1 and Step 2.

Output: ADN $h^N(\mathbf{x})$

Figure 2. Active Deep Networks Procedure.

4 Experiments

4.1 Experimental Setup

We evaluate the performance of the proposed ADN method using five sentiment classification datasets. The first dataset is MOV (Pang, et al., 2002), which is a widely-used movie review dataset. The other four dataset contain reviews of four different types of products, including books (BOO), DVDs (DVD), electronics (ELE), and kitchen appliances (KIT) (Blitzer, et al., 2007; Dasgupta and Ng, 2009). Each dataset includes 1,000 positive and 1,000 negative reviews.

Similar with Dasgupta and Ng (2009), we divide the 2,000 reviews into ten equal-sized folds randomly and test all the algorithms with cross-validation. In each folds, 100 reviews are random selected as training data and the remaining 100 data are used for test. Only the reviews in the training data set are used for the selection of labeled data by active learning.

The ADN architecture has different number of hidden units for each hidden layer. For greedy

layer-wise unsupervised learning, we train the weights of each layer independently with the fixed number of epochs equal to 30 and the learning rate is set to 0.1. The initial momentum is 0.5 and after 5 epochs, the momentum is set to 0.9. For supervised learning, we run 10 epochs, three times of linear searches are performed in each epoch.

We compare the classification performance of ADN with five representative classifiers, i.e., Semi-supervised spectral learning (Spectral) (Kamvar et al., 2003), Transductive SVM (TSVM), Active learning (Active) (Tong and Koller, 2002), Mine the Easy Classify the Hard (MECH) (Dasgupta and Ng, 2009), and Deep Belief Networks (DBN) (Hinton, et al., 2006). Spectral learning, TSVM, and Active learning method are three baseline methods for sentiment classification. MECH is a new semi-supervised method for sentiment classification (Dasgupta and Ng, 2009). DBN (Hinton, et al., 2006) is the classical deep learning method proposed recently.

4.2 ADN Performance

For MOV dataset, the ADN structure used in this experiment is 100-100-200-2, which represents the number of units in output layer is 2, in 3 hidden layers are 100, 100, and 200 respectively. For the other four data sets, the ADN structure is 50-50-200-2. The number of unit in input layer is the same as the dimensions of each datasets. All theses parameters are set based on the dimension of the input data and the scale of the dataset. Because that the number of vocabulary in MOV dataset is more than other four datasets, so the number of units in previous two hidden layers for MOV dataset are more than other four datasets. We perform active learning for 5 iterations. In each iteration, we select and label 20 of the most uncertain points, and then re-train the ADN on all of the unlabeled data and labeled data annotated so far. After 5 iterations, 100 labeled data are used for training.

The classification accuracies on test data in cross validation for five datasets and six methods are shown in Table 1. The results of previous four methods are reported by Dasgupta and Ng (2009). For ADN method, the initial two labeled data are selected randomly, so we repeat thirty times for each fold and the results are averaged. For the randomness involved in the choice of labeled data, all the results of other five methods are achieved by repeating ten times for each fold and then taking average on results.

Through Table 1, we can see that the performance of DBN is competitive with MECH. Since MECH is the combination of spectral clustering, TSVM and Active learning, DBN is just a classification method based on deep neural network, this result proves the good learning ability of deep architecture. ADN is a combination of semi-supervised learning and active learning based on deep architecture, the performance of ADN is better than all other five methods on five datasets. This could be contributed by: First, ADN uses a new architecture to guide the output vector of samples belonged to different regions of new Euclidean space, which can abstract the useful information that are not accessible to other learners; Second, ADN use an exponential loss function to maximize the separability of labeled data in global refinement for better discriminability; Third, ADN fully exploits the embedding information from the large amount of unlabeled data to improve the robustness of the classifier; Fourth, ADN can choose the useful training data actively, which also improve the classification performance.

Type	MOV	KIT	ELE	BOO	DVD
Spectral	67.3	63.7	57.7	55.8	56.2
TSVM	68.7	65.5	62.9	58.7	57.3
Active	68.9	68.1	63.3	58.6	58.0
MECH	76.2	74.1	70.6	62.1	62.7
DBN	71.3	72.6	73.6	64.3	66.7
ADN	**76.3**	**77.5**	**76.8**	**69.0**	**71.6**

Table 1. Test Accuracy with 100 Labeled Data for Five Datasets and Six Methods.

4.3 Effect of Active Learning

To test the performance of our proposed active learning method, we conduct following additional experiments.

Passive learning: We random select 100 reviews from the training fold and use them as labeled data. Then the proposed semi-supervised

learning method of ADN is used to train and test the performance. Because of randomness, we repeat 30 times for each fold and take average on results. The test accuracies of passive learning for five datasets are shown in Table 2. In comparison with ADN method in Table 1, we can see that the proposed active learning method yields significantly better results than randomly chosen points, which proves effectiveness of proposed active learning method.

Fully supervised learning: We train a fully supervised classifier using all 1,000 training reviews based on the ADN architecture, results are also shown in Table 2. Comparing with the ADN method in Table 1, we can see that employing only 100 active learning points enables us to almost reach fully-supervised performance for three datasets.

Type	MOV	KIT	ELE	BOO	DVD
Passive	72.2	75.0	75.0	66.0	67.9
Supervised	77.2	79.4	79.1	69.3	72.1

Table 2. Test Accuracy of ADN with different experiment setting for Five Datasets.

4.4 Semi-Supervised Learning with Variance of Labeled Data

To verify the performance of semi-supervised learning with different number of labeled data, we conduct another series of experiments on five datasets and show the results on Figure 3. We run ten-fold cross validation for each dataset. Each fold is repeated ten times and the results are averaged.

We can see that ADN can also get a relative high accuracy even by using just 20 labeled reviews for training. For most of the sentiment datasets, the test accuracy is increasing slowly while the number of labeled review is growing. This proves that ADN reaches good performance even with few labeled reviews.

5 Conclusions

This paper proposes a novel semi-supervised learning algorithm ADN to address the sentiment classification problem with a small number of labeled data. ADN can choose the proper training data to be labeled manually, and fully exploits the embedding information from the large amount of unlabeled data to improve the robustness of the classifier. We propose a new architecture to guide the output vector of samples belong to different regions of new Euclidean space, and use an exponential loss function to maximize the separability of labeled data in global refinement for better discriminability. Moreover, ADN can make the right decision about which training data should be labeled based on existing unlabeled and labeled data. By using unsupervised and supervised learning iteratively, ADN can choose the proper training data to be labeled and train the deep architecture at the same time. Finally, the deep architecture is re-trained using the chosen labeled data and all the unlabeled data. We also conduct experiments to verify the effectiveness of ADN method with different number of labeled data, and demonstrate that ADN can reach very competitive classification performance just by using few labeled data. This results show that the proposed ADN method, which only need fewer manual labeled reviews to reach a relatively higher accuracy, can be used to train a high performance sentiment classification system.

Abstract

The field of information retrieval still strives to develop models which allow semantic information to be integrated in the ranking process to improve performance in comparison to standard bag-of-words based models. A conceptual model has been adopted in general-purpose retrieval which can comprise a range of concepts, including linguistic terms, latent concepts and explicit knowledge concepts. One of the drawbacks of this model is that the computational cost is significant and often intractable in modern test collections. Therefore, approaches utilising concept-based models for re-ranking initial retrieval results have attracted a considerable amount of study. This method enjoys the benefits of reduced document corpora for semantic space construction and improved ranking results. However, fitting such a model to a smaller collection is less meaningful than fitting it into the whole corpus. This paper proposes a dual-space model which incorporates external knowledge to enhance the space produced by the latent concept method. This model is intended to produce global consistency across the semantic space: similar entries are likely to have the same re-ranking scores with respect to the latent and manifest concepts. To illustrate the effectiveness of the proposed method, experiments were conducted using test collections across different languages. The results demonstrate that the method can comfortably achieve improvements in retrieval performance.

1 Introduction

Information retrieval often suffers from the so called *"vocabulary mismatch"* problem. A document may be semantically relevant to a query despite the fact that the specific query terms used and the terms found in the document completely or partially differ (Furnas et al., 1987). Consequently, overlap with respect to linguistic terms should not be a necessary condition in query-document similarity and methods relying on the bag-of-words model can display poor performance as a result. In order to overcome the vocabulary mismatch problem, several solutions have been suggested which exploit semantic relations between text units. Among these methods, the latent model, the explicit model and the mixed model are commonly employed.

The latent model (Landauer et al., 1998; Blei et al., 2003) tries to directly model the internal structure of "topics" or "concepts" in the text data, thus building meaningful groups beyond single words. Typically some form of dimension reduction (Fodor, 2002) is applied to the data matrix to find such latent dimensions which correspond to concepts. In contrast, the explicit model (Gabrilovich and Markovitch, 2007) indexes texts according to an external knowledge base. Typically the meaning of a piece of text is represented as a weighted vector of knowledge-based concepts derived from ex-

Coling 2008: Poster Volume, pages 1524–1532,
Beijing, August 2010

ternal resources such as ODP[1] or Wikipedia[2] articles. The mixed model (Serban et al., 2005) extends the bag-of-words vector by adding external categories derived from WordNet or similar thesaurus. Based upon these definitions, the explicit model and the mixed model are similar in nature but differ in their use of external knowledge sources.

Models such as those described above, however, have well documented drawbacks. Firstly, these methods are very computationally complex. In the latent model, complexity grows linearly with the number of dimensions and the number of documents. For example, the computational cost of singular value decomposition (SVD) is significant; no successful experiment has been reported with over one million documents (Manning et al., 2008). This has been the biggest obstacle to the widespread adoption of this kind of method. For the explicit and mixed model, the dimensions of projecting documents into the external knowledge space are often limited to ten thousand (Potthast et al., 2008) in order to facilitate the large size of the test collections used. Another problem with the explicit model is that the documents are often distributed over thousands of dimensions in which the semantic relatedness will degrade dramatically. For example, in (Sorg and Cimiano, 2008) when the whole Wikipedia collection is adopted to build the space, one document is mapped to ten thousand dimensions, in which it may only have very few truly semantically related dimensions. The means of identifying these dimensions is not reported and this may significantly influence the retrieval performance.

Therefore, researchers started to consider integrating the aforementioned models into smaller, controlled document collections to overcome these shortcomings and assist the retrieval process. (Zhou and Wade, 2009b) proposed a Latent Dirichlet Allocation (LDA)-based method to model the latent structure of "topics" deduced from the initial retrieval results. The scores obtained from this process are then combined with initial ranking scores to produce a re-ranked list of results that are superior to original ordering. The method also enjoys the benefits of fast and tractable latent semantic computation and successfully avoids the incremental build problem (Landauer et al., 1998) which commonly exists in latent semantic analysis (LSA) techniques.

There is an important factor, however, that needs to be taken into account when applying this method. Due to the smaller corpus size, fitting a latent model into this corpus is less meaningful than fitting the same model into a large, web-scale corpus. This means that some form of justification has to be applied to achieve better performance. A simple approach to address this problem is to directly apply the explicit or mixed model into a controlled corpus to improve ranking performance. A similar problem will arise in the latent model in this single semantic space, resulting in limited improvements.

To address the challenges described above, this paper proposes a dual-space model which incorporates external knowledge to enhance the semantic space produced by the latent concept method. This model is intended to produce global consistency across the semantic space: *similar entries are likely to have the same re-ranking scores with respect to the latent and manifest concepts.* In other words: in this model, if a group of documents deal with the same topic induced from a dual semantic space which shares a strong similarity with a query, the documents will get allocated similar ranking as they are more likely to be relevant to the query.

In the experiments carried out in this paper, the dual-space model is applied to ad-hoc document retrieval and compared with the initial language model-based ranker and single-space model exploiting latent and explicit features. The results show that the explicit model could only bring minor improvements over the initial ranker. The latent model delivered more significant improvements than the explicit model. Both, however, are outperformed by the dual-space model.

The main contribution of this paper is to propose a dual-space semantic model for the re-ranking problem, which aims to improve precision, especially of the most highly ranked results. Other contributions of the paper include proposing a novel way of applying the explicit model to the re-ranking problem, and performing a systematic comparison between different models.

The rest of this paper is organised as follows. Related work on re-ranking and concept-based methods is briefly summarised in Section 2. Section 3 describes the latent space model and explicit space model used in the framework developed by this research, Section 4 presents details of how to build the dual-space model. In Section 5 a report is provided on a series of experiments performed over three different test collections written in English, French and German. This report includes details of the results obtained. Finally, Section 6 concludes the paper and speculates on future work.

2 Related Work

There exist several strands of related work in the areas of re-ranking and concept-based document retrieval.

A family of work on the structural re-ranking paradigm over different sized document corpora was proposed to refine initial ranking scores. Kurland and Lee performed re-ranking based on measures of centrality in the graph formed by the generation of links induced by language model scores, through a weighted version of the PageRank algorithm (Kurland and Lee, 2005) and a HITS-style cluster-based approach (Kurland and Lee, 2006). Zhang et al. (Zhang et al., 2005) proposed a similar method to improve web search based on a linear combination of results from text search and authority ranking. The graph, which they named an "affinity graph", shares strong similarities with Kurland and Lee's work where the links are induced by a modified version of cosine similarity using the vector space model. Diaz (Diaz, 2005) used score regularisation to adjust document retrieval rankings from an initial retrieval by a semi-supervised learning method. Deng et al. (Deng et al., 2009) further developed this method by building a latent space graph based on content and explicit link information. Unlike their approach this research attempts to model the explicit information directly.

The latent concept retrieval model has a long history in information retrieval. (Dumais, 1993; Dumais, 1995) conducted experiments with latent semantic indexing (LSI) on TREC[3] documents and tasks. These experiments achieved precision at, or above, that of the median TREC participant. On about 20% of TREC topics this system was the top scorer, and reportedly slightly better than average results in comparison to standard vector spaces for LSI at about 350 dimensions. (Hofmann, 1999) provides an initial probabilistic extension of the basic latent semantic indexing technique. A more satisfactory formal basis for a probabilistic latent variable model for dimensionality reduction is the LDA model (Blei et al., 2003), which is generative and assigns probabilities to documents outside of the training set. Wei and Croft (Wei and Croft, 2006) presented the first large-scale evaluation of LDA, finding it to significantly outperform the query likelihood model. (Zhou and Wade, 2009b; Zhou and Wade, 2009a) successfully applied this method to document re-ranking and achieved significant improvement over language model-based ranking and various graph-based re-ranking methods.

The explicit concept model has recently attracted much attention in the information retrieval community. Notably, explicit semantic analysis (ESA) has been proposed as an approach to computing semantic relatedness between words and thus, has a natural application in this field (Gabrilovich and Markovitch, 2007). In essence, ESA indexes documents with respect to the Wikipedia article space, indicating how strongly a given word in the document is associated to a specific Wikipedia article. In this model, each article is regarded as a concept, an analogical unit used in the latent model. As in the latent model, two words or texts can be semantically related in spite of not having any words in common. Specifically, this method has been widely adopted in cross-language information retrieval (CLIR) as an approach to resolving an extreme case of the vocabulary mismatch problem, where queries and documents are written in different languages (Potthast et al., 2008). (Anderka et al., 2009) showed that this approach has comparable performance to linguistic matching methods. (Cimiano et al., 2009) compared this method with a latent concept model based on LSI/LDA and concluded that it will outperform the latent model if trained on Wikipedia articles.

3 Latent and Explicit Models

In this section, an overview of the problem addressed by this paper is presented and the latent and explicit document re-ranking models are described in more detail. This section also demonstrates how these models can be used in a re-ranking setting.

3.1 Problem Definition

Let $\mathbb{D} = \{d_1, d_2, \dots, d_n\}$ denote the set of documents to be retrieved. Given a query q, a set of initial results $\mathbb{D}_{init} \in \mathbb{D}$ of top documents are returned by a standard information retrieval model (initial ranker). However, typically the performance of the initial ranker can be improved upon. The purpose of the re-ranking method developed by this research is to re-order a set of documents $\mathbb{D}'_{init}$ so as to improve retrieval accuracy at the most highly ranked results.

3.2 Latent Concept Model

The specific method used here is borrowed from (Zhou and Wade, 2009b), which is based on the LDA model. The topic mixture is drawn from a conjugate Dirichlet prior that remains the same for all documents. The process of generating a document corpus is as follows:

1) Pick a multinomial distribution $\vec{\varphi}_z$ for each topic k from a Dirichlet distribution with hyperparameter $\vec{\beta}$.
2) For each document d, pick a multinomial distribution $\vec{\theta}_d$, from a Dirichlet distribution with hyperparameter $\vec{\alpha}$.
3) For each word token w in document d, pick a topic $z \in \{1 \dots k\}$ from the multinomial distribution $\vec{\theta}_d$.
4) Pick word w from the multinomial distribution $\vec{\varphi}_z$.

LDA possesses fully consistent generative semantics by treating the topic mixture distribution as a k-parameter hidden random variable. LDA offers a new and interesting framework to model a set of documents. The documents and new text sequences (for example, queries) can easily be connected by "mapping" them to the topics in the corpus.

In a re-ranking setting, the probability that a document d generates w is estimated using a mixture model LDA. It uses a convex combination of a set of component distributions to model observations. In this model, a word w is generated from a convex combination of some hidden topics z:

$$LDA_d(w) = \sum_{z=1}^{k} p(w|z)p(z|d)$$

where each mixture model $p(w|z)$ is a multinomial distribution over terms that correspond to one of the latent topics z. This could be generated to give a distribution on a sequence of text:

$$LDA_d(w_1 w_2 \dots w_n) \stackrel{\text{def}}{=} \prod_{j=1}^{n} LDA_d(w_j)$$

Then the distance between a query and a document based on this model can be obtained. The method used here adopts the KL divergence (Baeza-Yates and Ribeiro-Neto, 1999) between the query terms and document terms to compute a Re-Rank score RS_{LDA}^{KL}:

$$RS_{LDA}^{KL} = -D(MLE_q(\cdot)||LDA_d(\cdot))$$

The final score is then obtained through a linear combination of the re-ranking scores based on the initial ranker and the latent document re-ranker, shown as follows:

$$RS_{Latent}^{LDA} = \lambda \cdot OS + (1 - \lambda) \cdot RS_{LDA}^{KL}$$

where OS denotes original scores returned by the initial ranker and λ is a parameter that can be tuned with $\lambda = 1$ meaning no re-ranking is performed.

Another well-known approach to the latent model is the LSI method. It is based on SVD, a technique from linear algebra. This method has not been reported anywhere previously for re-ranking purposes. It has been included here to compare the effectiveness of different latent approaches. As a full SVD is a loss-free decomposition of a matrix M, which is decomposed into two orthogonal matrices U and V and a diagonal matrix Σ. Estimating less singular values and their corresponding singular vectors leads to reduced dimensions resembling latent concepts so that documents are no longer represented by terms but by concepts. New documents (queries) are represented in terms of concepts by folding them into the LSI model. Next, cosine similarities may be used to compute the similarity between a query and a document to obtain RS_{LSI}^{COS} and combine it with the original score to produce the final re-ranking score:

Collection	Contents	Language	Num of docs	Size	Queries
BL (CLEF2009)	British Library Data	English (Main)	1,000,100	1.2 GB	50
BNF (CLEF2009)	Bibliothèque Nationale de France	French (Main)	1,000,100	1.3 GB	50
ONB (CLEF2009)	Austrian National Library	German (Main)	869,353	1.3 GB	50

Table 1. Statistics of test collections

$$RS_{latent}^{LSI} = \lambda' \cdot OS + (1-\lambda') \cdot RS_{LSI}^{COS}$$

3.3 Explicit Concept Model

As an example of explicit concept model (Gabrilovich and Markovitch, 2007), explicit semantic analysis attempts to index or classify a given text t with respect to a set of explicitly given external categories. The basic idea is to take as input a document d and map it to a high-dimensional, real-valued vector space. This space is spanned by a Wikipedia database $W_l = \{a_1, \ldots, a_n\}$.This mapping is given by the following function:

$$\Phi_l : T \to \mathbb{R}^{|W_l|}$$
$$\Phi_l(t) \coloneqq \langle v_1, \ldots, v_{|W_l|} \rangle$$

Where $|W_l|$ is the number of articles in Wikipedia W_l corresponding to language l. The value v_i in the vector t expresses the strength of association between t and the Wikipedia article a_i and is defined as the cosine similarity:

$$RS_{ESA}^{COS} = \frac{\langle t, a_i \rangle}{\| t \| \| a_i \|}$$

As pointed out in section 1, documents are often distributed over thousands of dimensions in which the semantic relatedness will degrade dramatically. The main purpose is to find the most relevant dimensions with respect to queries. To apply this method to re-ranking, W_l is limited to the number of highly relevant documents for a given query. In other words, the entire set of Wikipedia articles in language l is retrieved, and only return a specific number of documents as in W_l. This modification will also lead to fast computation of scores compared to scanning through the whole Wikipedia collection.

Similar to the latent model described above, the final ranking score is defined as:

$$RS_{Explicit}^{ESA} = \mu \cdot OS + (1-\mu) \cdot RS_{ESA}^{COS}$$

4 Dual space model

Armed with the latent and explicit models, the dual-space model proposed by this paper is now described. In order to make a direct connection between the two models, the key point is to make the dimensions comparable across different models. The detail presented on the latent and explicit concept models in the previous section did not describe how to define a specific number of dimensions. A simple assumption is taken here in the dual-space model: the number of dimensions produced by the explicit model has to correspond to the number of dimensions induced by the latent model. As the same group of documents are being mapped into two different semantic spaces, it is assumed that the concepts induced by the latent model reflect the hidden structures in this document collection. Therefore, the same phenomenon should be observed when applying the explicit model and vice-versa. Based on this assumption, the dual-space model could be conducted so as to make a constraint:

$$|W_l| = k$$

and the final ranking score for this dual space is:

$$RS_{dual}^{LDA} = \varsigma \cdot OS + (1-\varsigma-\tau) \cdot RS_{LDA}^{KL} + \tau \cdot RS_{ESA}^{COS}$$

or

$$RS_{dual}^{LSI} = \varsigma \cdot OS + (1-\varsigma-\tau) \cdot RS_{LSI}^{COS} + \tau \cdot RS_{ESA}^{COS}$$

4 Experiments and Results

In this section, an empirical study of the effectiveness of the dual-space model over three data collections written in English, French and German is presented.

4.1 Experimental Setup

The text corpus used in the experiment described below consisted of elements of the CLEF-2008[4] and CLEF-2009 European Library (TEL) collections[5] written in English, French and German. These collections are described in greater detail in Table 1. All of the documents in the experiment were indexed using the Terrier toolkit[6]. Prior to indexing, Porter's stemmer and a stopword list[7] were used for the English documents. A French and German analyser[8] is used to analyse French and German documents.

It is worth noting that the CLEF TEL data is actually multilingual: all collections to a greater or lesser extent contain records pointing to documents in other languages. However this is not a major problem because the majority of documents in the test collection are written in the primary language of those test collections (BL-English, BNF-French, ONB-German). Please refer to (Ferro and Peters, 2009) for a more detailed discussion about this data. These collections were chosen to test the scalability of the proposed method in different settings and over different languages.

The CLEF-2008 and CLEF-2009 query sets were also used. Both query sets consist of 50 topics in each language being tested. The CLEF-2008 queries written in English were used in training the parameters and all of the CLEF-2009 queries were used in the experiment for testing purposes. Each topic is composed of several parts, including: *Title*, *Description* and *Narrative*. *Title+Description* combinations were chosen as queries. The queries are processed similarly to the treatment of the test collections. The relevance judgments are taken from the judged pool of top retrieved documents by various participating retrieval systems from previous CLEF workshops. The initial ranker used in this study is the classic vector space model. This was selected to facilitate the LSI and ESA models used and the main purpose of the experiments is to compare different models in addition to demonstrating the effectiveness of the dual-space model.

A Wikipedia database in English, French and German was used as an explicit concept space. Only those articles that are connected via cross-language links between all three Wikipedia databases were selected. A snapshot was obtained on the 29/11/2009, which contained an aligned collection of 220,086 articles in all three languages.

The following evaluation metrics were chosen to measure the effectiveness of the various approaches: mean average precision (MAP), the precision of the top 5 documents (Prec@5), the precision of the top 10 documents (Prec@10), normalised discounted cumulative gain (NDCG) and Bpref. Statistically-significant differences in performance were determined using a paired t-test at a confidence level of 95%.

4.2 Parameter Tuning

Three primary categories of parameter combinations need to be determined in the experiments. For the latent re-ranking experiments, the parameters λ, λ' must be defined. For the explicit model the parameter μ must be chosen. For both models, the weights ς, τ have to be determined. In addition, the number of dimensions $|W_l|$ and k must be specified. Settings for these parameters were optimised with respect to MAP over the BL collection using CLEF-2008 English queries and were applied to all three collections. This optimisation was not conducted for the other metrics used.

The search ranges for these two parameters were:

$\lambda, \lambda', \mu, \varsigma, \tau$: 0.1, 0.2, …, 0.9

$|W_l|, k$: 5, 10, 15, …, 40

Note that parameters ς and τ are the weights assigned to the latent model and the explicit model in the dual-space model. The choice of one will have direct influence over another. As it turned out, for many instances, the optimal value of λ, λ' with respect to MAP was either 0.3 or 0.4, suggesting the initial retrieval scores still contain valuable information. In contrast, parameter μ shows no obvious difference in performance when the value is above 0.1. With this observation, when setting the parameters ς and τ more weight is assigned to the latent model rather than the explicit model. The optimal

[4] The test collections used in CLEF-2008 and CLEF-2009 are in fact identical.

Table 2. Experimental Results. For each evaluation setting, statistically significant differences between different methods and the initial ranker are indicated by star. Bold highlights the best results over all algorithms.

value of k was between 25 and 35 for the LDA based model and between 5 and 15 for the LSI based model. Although this demonstrates a relatively large variance, the differences in terms of MAP have remained small and statistically insignificant. $\mathbb{D}_{init}$ is set to 50 in all results reported.

4.3 Results

Primary Evaluation The main experimental results, which describe the performance of the different re-ranking algorithms on the CLEF document collection, are shown in Table 2. The first four rows in each test collection specify the most important measurements because this research is particularly interested in performance over the most highly ranked results. As illus-

trated by the data, the initial ranker was always the lowest performer in terms of nearly all measurements. This indicates the need for re-ranking. Using the method computed by the explicit space always led to an improvement in retrieval effectiveness. But this improvement is only minor in comparison to the other two models and the results are often statistically insignificant. When the re-ranking score was calculated using the latent model, retrieval effectiveness always exceeded initial ranker and the explicit model. There was a noticeable improvement in retrieval effectiveness in the English collection (BL, statistically significant results were often observed), but a modest increase for the other two collections (BNF and ONB).

The empirical results obtained using the dual space model are very promising. Pleasingly, both the LDA+ESA and LSI+ESA models outperformed the basic latent and explicit space model in the majority of retrieval runs, with the best scores relating to the LSI-based models. An important phenomenon is that statistically significant improvements are always recorded in the metrics which measure the most highly ranked results. An even more exciting observation is that in many cases, the dual-space model, even though tuned for MAP, can outperform various baselines and other models for all the evaluation metrics, with statistically significant improvements in many runs.

Another observation that can be drawn from Table 2 is that the relative performance tends to be stable across test collections written in different languages. This indicates a promising future for studying document structure with respect to latent and explicit semantic space for re-ranking purposes.

The Comparison of Latent Methods Table 2 also shows a side-by-side comparison of the various performance measurements between the latent model used in this research on the CLEF-2009 BL test collection. The LSI-based method appeared to outscore the LDA-based method in the latent model in the vast majority of cases, while the difference between the various scorings was fairly marginal as both methods deliver statistically significant results. For the dual-space model, similar results were observed. A possible reason is that the initial ranker used was based on the vector space model and LSI is also vector based. It shows that more research with respect to the latent model selection will be necessary in the future.

Effectiveness of Explicit Methods As part of experimental objectives of this research, it was also necessary to test the newly developed explicit model for re-ranking. In the parameter tuning section, the explicit model displayed no obvious difference in terms of combination effectiveness. However, some variations could be observed when applying different dimensions where statistically significant results often appear in lower dimensions. This confirms the need to find more relevant dimensions, both for performance and efficiency purposes.

5 Conclusion and Future Work

This paper proposed and evaluated a dual-space document re-ranking method for re-ordering the initial retrieval results. The key to refining the results is the global consistency over the semantic space, which leverages latent and explicit semantic information and results in state-of-art performance. This paper also proposed a novel way to apply the explicit model to the re-ranking problem, and performed a systematic comparison between different models.

Further investigation is planned in many research directions. It has been shown that the latent model-based retrieval is a promising method for ranking the whole corpus. There is a desire to call for a direct comparison between ranking and re-ranking using the proposed algorithmic variations. Future work will also include identifying improvements upon linear combination for engineering different models. At the same time, there exist a sufficient number of latent and explicit semantic techniques which will be explored to compare their performance.

Abstract

String-based metrics of automatic machine translation (MT) evaluation are widely applied in MT research. Meanwhile, some linguistic motivated metrics have been suggested to improve the string-based metrics in sentence-level evaluation. In this work, we attempt to change their original calculation units (granularities) of string-based metrics to generate new features. We then propose a powerful string-based automatic MT evaluation metric, combining all the features with various granularities based on SVM rank and regression models. The experimental results show that i) the new features with various granularities can contribute to the automatic evaluation of translation quality; ii) our proposed string-based metrics with multiple granularities based on SVM regression model can achieve higher correlations with human assessments than the state-of-art automatic metrics.

1 Introduction

The automatic machine translation (MT) evaluation has aroused much attention from MT researchers in the recent years, since the automatic MT evaluation metrics can be applied to optimize MT systems in place of the expensive and time-consuming human assessments. The state-of-art strategy to automatic MT evaluation metrics estimates the system output quality according to its similarity to human references. To capture the language variability exhibited by different reference translations, a tendency is to include deeper linguistic information into machine learning based automatic MT evaluation metrics, such as syntactic and semantic information (Amigò et al., 2005; Albrecht and Hwa, 2007; Giménez and Màrquez, 2008). Generally, such efforts may achieve higher correlation with human assessments by including more linguistic features. Nevertheless, the complex and variously presented linguistic features often prevents the wide application of the linguistic motivated metrics.

Essentially, linguistic motivated metrics introduce additional restrictions for accepting the outputs of translations (Amigó et al., 2009). With more linguistic features attributed, the model is actually capturing the sentence similarity in a finer granularity. In this sense, the practical effect of employing various linguistic knowledge is changing the calculation units of the matching in the process of the automatic evaluation.

Similarly, the classical string-based metrics can be changed in their calculation units directly. For example, the calculation granularity in BLEU (Papineni et al., 2002) metric is word: n-grams are extracted on the basis of single word as well as adjacent multiple words. And the calculation granularity in PosBLEU (Popović and Ney, 2009) metric is Pos tag, which correlate well with the human assessments. Therefore, it is straight forward to apply the popular string-based automatic evaluation metrics, such as BLEU, to compute the scores of the systems outputs in the surface or linguis-

Beijing, August 2010

tic tag sequences on various granularities levels.

In this paper, we attempt to change the original calculation units (granularities) of string-based metrics to generate new features. After that, we propose a powerful string-based automatic MT evaluation metric, combining all the features with various granularities based on SVM rank (Joachims, 2002) and regression (Drucker et al., 1996) models. Our analysis indicates that: i) the new features with various granularities can contribute to the automatic evaluation of translation quality; ii) our proposed string-based metrics with multiple granularities based on SVM regression model can achieve higher correlations with human assessments than the state-of-art automatic metrics .

The remainder of this paper is organized as follows: Section 2 reviews the related researches on automatic MT evaluation. Section 3 describes some new calculation granularities of string-based metrics on sentence level. In Section 4, we propose string-based metrics with multiple granularities based on SVM rank and regression models. In Section 5, we present our experimental results on different sets of data. And conclusions are drawn in the Section 6.

2 Related Work on Automatic Machine Translation Evaluation

The research on automatic string-based machine translation (MT) evaluation is targeted at a widely applicable metric of high consistency to the human assessments. WER (Nießen et al., 2000), PER (Tillmann et al., 1997), and TER (Snover et al., 2006) focuses on word error rate of translation output. GTM (Melamed et al., 2003) and the variants of ROUGE (Lin and Och, 2004) concentrate on matched longest common substring and discontinuous substring of translation output according to the human references. BLEU (Papineni et al., 2002) and NIST (Doddington, 2002) are both based on the number of common n-grams between the translation hypothesis and human reference translations of the same sentence. BLEU and NIST are widely adopted in the open MT evaluation campaigns; however, the NIST MT evaluation in 2005 indicates that they can even error in the system level (Le and Przybocki, 2005). Callison-Burch et al. (2006) detailed the deficits of the BLEU and other similar metrics, arguing that the simple surface similarity calculation between the machines translations and the human translations suffers from morphological issues and fails to capture what are important for human assessments.

In order to attack these problems, some metrics have been proposed to include more linguistic information into the process of matching, e.g., Meteor (Banerjee and Lavie, 2005) metric and MaxSim (Chan nad Ng, 2008) metrics, which improve the lexical level by the synonym dictionary or stemming technique. There are also substantial studies focusing on including deeper linguistic information in the metrics (Liu and Gildea, 2005; Owczarzak et al., 2006; Amigó et al., 2006; Mehay and Brew, 2007; Giménez and Màrquez, 2007; Owczarzak et al., 2007; Popovic and Ney, 2007; Giménez and Màrquez, 2008b).

A notable trend improving the string-based metric is to combine various deeper linguistic information via machine learning techniques in the metrics (Amigò et al., 2005; Albrecht and Hwa, 2007; Giménez and Màrquez, 2008). Such efforts are practically amount of introducing additional linguistic restrictions into the automatic evaluation metrics (Amigó et al, 2009), achiving a higher performance at the cost of lower adaptability to other languages owing to the language dependent linguistics features.

Previous work shows that including the new features into the evaluation metrics may benefit to describe nature language accurately. In this sense, the string-based metrics will be improved, if the finer calculation granularities are introduced into the metrics.

Our study analyzes the role of the calculation granularities in the performance of metrics. We find that the new features with various granularities can contribute to the automatic evaluation of translation quality. Also we propose a powerful string based automatic MT evaluation metric with multiple granularities combined by SVM. Finally, we seek a finer feature set of metrics with multiple calculation granularities.

3 The New Calculation Granularities of String-based Metrics on Sentence Level

The string-based metrics of automatic machine translation evaluation on sentence level adopt a common strategy: taking the sentences of the documents as plain strings. Therefore, when changing the calculation granularities of the string-based metrics we can simplify the information of new granularity with plain strings. In this work, five kinds of available calculation granularities are defined: "Lexicon", "Letter", "Pos", "Constitute" and "Dependency".

Lexicon: The calculation granularity is common word in the sentences of the documents, which is popular practice at present.

Letter: Split the granularities of "Lexical" into letters. Each letter is taken as a matching unit.

Pos: The Pos tag of each "Lexicon" is taken as a matching unit in this calculation granularity.

Constitute: Syntactic Constitutes in a tree structure are available through the parser tools. We use Stanford Parser (Klein and Manning, 2003a; Klein and Manning, 2003b) in this work. The Constitute tree is changed into plain string, travelling by BFS (Breadth-first search traversal) [1].

Dependency: Dependency relations in a dependency structure are also available through the parser tools. The dependency structure can also be formed in a tree, and the same processing of being changed into plain string is adopted as "Constitute".

The following serves as an example:

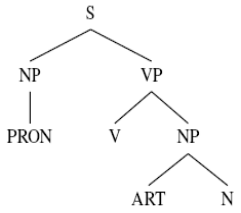
Sentence:

I have a dog

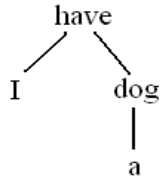
Pos tag:

I/PRON have/V a/ART dog/N

Constitute tree:



Dependency tree:



Then, we can change the sentence into the plain string in multiple calculation granularities as follows:

Lexicon string:

I have a dog

Letter string:

I h a v e a d o g

Pos string:

PRON V ART N

Constitute string:

PRON V ART N NP NP VP S

Dependency string:

a I dog have

The translation hypothesis and human reference translations are both changed into those strings of various calculation granularities. The strings are taken as inputs of the string-based automatic MT evaluation metrics. The outputs of each metric are calculated on different matching units.

4 String-based Metrics with Multiple Granularities Combined by SVM

Introducing machine learning methods to established MT evaluation metric is a popular trend. Our study chooses rank and regression support vector machine (SVM) as the learning model. Features are important for the SVM models.

Plenty of scores can be generated from the proposed metrics. In fact, not all these features are needed. Therefore, feature selection should be a necessary step to find a proper feature set and alleviate the language dependency by using fewer linguistic features.

Feature selection is an NP-Complete problem; therefore, we adopt a greedy selection algorithm called "Best One In" to find a local optimal feature set. Firstly, we select the feature among all the features which best correlates with the human assessments. Secondly, a feature among the rest features is added in to the feature set, if the correlation with the human assessments of the metric using new set is

[1] We also attempt some other traversal algorithms, including preorder, inorder and postorder traversal, the performance are proved to be similar.

the highest among all new metrics and higher than the previous metric in cross training corpus. The cross training corpus is prepared by dividing the training corpus into five parts. Each four parts of the five are for training and the rest one for testing; then, we integrate scores of the five tests as scores of cross training corpus. The five-fold cross training can help to overcome the overfitting. At the end, the feature selection stops, if adding any of the rest features cannot lead to higher correlation with human assessments than the current metric.

5 Experiments

5.1 The Impact of the Calculation Granularities on String-based Metrics

In this section, we use the data from NIST Open MT 2006 evaluation (LDC2008E43), which is described in Table 1. It consists of 249 source sentences that were translated by four human translators as well as 8 MT systems. Each machine translated sentence was evaluated by human judges for their adequacy on a 7-point scale.

	NIST 2002	**NIST 2003**	**NIST Open MT 2006**
LDC corpus	LDC2003 T17	LDC2006 T04	LDC2008 E43
Type	Newswire	Newswire	Newswire
Source	Chinese	Chinese	Arabic
Target	English	English	English
# of sentences	878	919	249
# of systems	3	7	8
# of references	4	4	4
Score	1-5, adequacy & fluency	1-5, adequacy & fluency	1-7 adequacy

Table 1: Description of LDC2006T04, LDC2003T17 and LDC2008E43

To judge the quality of a metric, we compute Spearman rank-correlation coefficient, which is a real number ranging from -1 (indicating perfect negative correlations) to +1 (indicating perfect positive correlations), between the metric's scores and the averaged human assessments on test sentences.

We select 21 features in "lexicon" calculation granularity and 11×4 in the other calculation granularities. We analyze the correlation with human assessments of the metrics in multiple calculation granularities. Table 2 lists the optimal calculation granularity of the multiple metrics on sentence level in the data (LDC2008E43).

Metric	**Granularity**
BLEU-opt	Letter
NIST-opt	Letter
GTM(e=1)	Dependency
TER	Letter
PER	Lexicon
WER	Dependency
ROUGE-opt	Letter

Table 2 The optimal calculation granularity of the multiple metrics

The most remarkable aspect is that not all the best metrics are based on the "lexicon" calculation granularities, such as the "letter" and "dependency". In other words, the granularities-shifted string-based metrics are promising to contribute to the automatic evaluation of translation quality.

5.2 Correlation with Human Assessments of String-based Metrics with Multiple Granularities Based on SVM Frame

We firstly train the SVM rank and regression models on LDC2008E43 using all the features ($21+11 \times 4$ species), without any selection. Secondly, the other two SVM rank and regression models are trained on the same data using the feature set via feature selection, which are described in Table 3. We have four string-based evaluation metrics with multiple granularities on rank and regression SVM frame "Rank_All, Regression_All, Rank_Select and Regression_Select". Then we apply the four metrics to evaluate the sentences of the test data (LDC2006T04 and LDC2003T17). The results of Spearman correlation with human assessments is summarized in Table 3. For comparison, the results from some state-of-art metrics (Papineni et al., 2002; Doddington,

2002; Melamed et al., 2003; Banerjee and Lavie, 2005; Snover et al., 2006; Liu and Gildea, 2005) and two machine learning methods (Albrecht and Hwa, 2007; Ding Liu and Gildea, 2007) are also included in Table 3. Of the two machine learning methods, both trained on the data LDC2006T04. The "Albrecht, 2007" score reported a result of Spearman correlation with human assessments on the data LDC2003T17 using 53 features, while the "Ding Liu, 2007" score reported that under five-fold cross validation on the data LDC2006T04 using 31 features.

	Feature number	**LDC 2003 T17**	**LDC 2006 T04**
Rank_All	65	0.323	0.495
Regression_All	65	**0.345**	0.507
Rank_Select	16	0.338	0.491
Regression_Select	8	0.341	**0.510**
Albrecht, 2007	53	0.309	--
Ding Liu, 2007	31	--	0.369
BLEU-opt[2]	--	0.301	0.453
NIST-opt	--	0.219	0.417
GTM(e=1)	--	0.270	0.375
METEOR[3]	--	0.277	0.463
TER	--	-0.250	-0.302
STM-opt	--	0.205	0.226
HWCM-opt	--	0.304	0.377

Table 3: Comparison of Spearman correlations with human assessments of our proposed metrics and some start-of-art metrics and two machine learning methods
"-opt" stands for the optimum values of the parameters on the metrics

Table 3 shows that the string-based meta-evaluation metrics with multiple granularities based on SVM frame gains the much higher Spearman correlation than other start-of-art metrics on the two test data and, furthermore, our proposed metrics also are higher than the machine learning metrics (Albrecht and Hwa, 2007; Ding Liu and Gildea, 2007).

The underlining is that our proposed metrics are more robust than the aforementioned two machine learning metrics. As shown in Table 1 the heterogeneity between the training and test data in our method is much more significant than that of the other two machine learning based methods.

In addition, the "Regression_Select" metric using only 8 features can achieve a high correlation rate which is close to the metric proposed in "Albrecht, 2007" using 53 features, "Ding Liu, 2007" using 31 features, "Regression_All" and "Rank_All" metrics using 65 features and "Rank_Select" metric using 16 features. What is more, "Regression_Select" metric is better than "Albrecht, 2007", and slightly lower than "Regression_All" on the data LDC2003T17; and better than both "Regression_All" and "Rank_All" metrics on the data LDC2006T04. That confirms that a small cardinal of feature set can also result in a metric having a high correlation with human assessments, since some of the features represent the redundant information in different forms. Eliminating the redundant information is benefit to reduce complexity of the parameter searching and thus improve the metrics performance based on SVM models. Meanwhile, fewer features can relieve the language dependency of the machine learning metrics. At last, our experimental results show that regression models perform better than rank models in the string-based metrics with multiple granularities based on SVM frame, since "Regression_Select" and "Regression_All" achieve higher correlations with human assessments than the others.

5.3 Reliability of Feature Selection

The motivation of feature selection is keeping the validity of the feature set and alleviating the language dependency. We also look forward to the higher Spearman correlation on the test data with a small and proper feature set.

We use SVM-Light (Joachims, 1999) to train our learning models using NIST Open MT 2006 evaluation data (LDC2008E43), and test on the two sets of data, NIST's 2002 and 2003 Chinese MT evaluations. All the data are described in Table 1. To avoid the bias in the distributions of the two judges' assessments in NIST's 2002 and 2003 Chinese MT evaluations, we normalize the scores following (Blatz et al., 2003).

[2] The result is computed by mteval11b.pl.
[3] The result is computed by meteor-v0.7.

We trace the process of the feature selection. The selected feature set of the metric based on SVM rank includes 16 features and that of the metric based on SVM regression includes 8 features. The selected features are listed in Table 4. The values in Table 4 are absolute Spearman correlations with human assessments of each single feature score. The prefixes "C_", "D_", "L_", "P_", and "W_" represent "Constitute", "Dependency", "Letter", "Pos" and "Lexicon" respectively.

Rank	spearman	Regression	spearman

Table 4: Feature sets of SVM rank and regression

Table 4 shows that 8 features are selected from 65 features in the process of feature selection based on SVM regression while 16 features based on SVM rank. Fewer features based on SVM regression are selected than SVM rank. Only one feature in feature set based on SVM regression does not occur in that based on SVM rank. The reason is that there are more complementary advantages between the common selected features.

Next, we will verify the reliability of our feature selection algorithm. Figure 1 and Figure 2 show the Spearman correlation values between our SVM-based metrics (regression and rank) and the human assessments on both training data (LDC2008E43) and test data (LDC2006T04 and LDC2003T17).

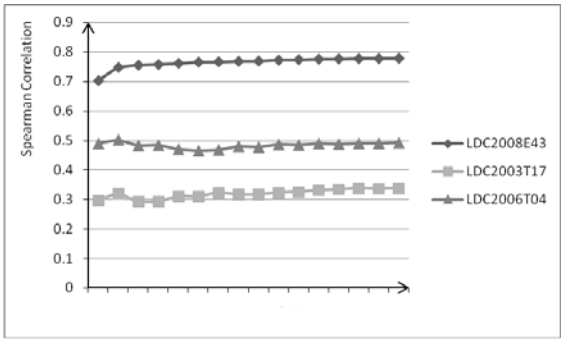

Figure 1: The Spearman correlation values between our **SVM rank** metrics and the human assessments on both training data and test data with the extension of the feature sets

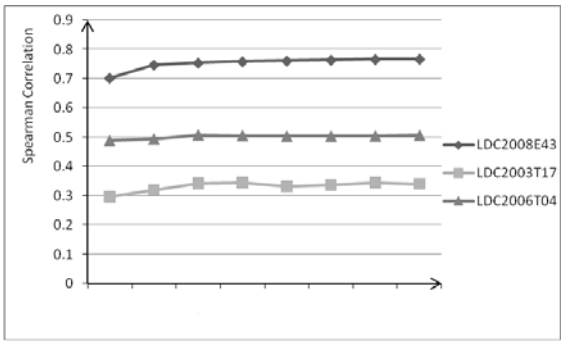

Figure 2: The Spearman correlation values between our **SVM regression** metrics and the human assessments on both training data and test data with the extension of the feature sets

From Figure 1 and Figure 2, with the extension of the feature sets, we can find that the tendency of correlation obtained by each metric based on SVM rank or regression roughly the same on both the training data and test data. Therefore, the two feature sets of SVM rank and regression models are reliable.

6 Conclusion

In this paper we propose an integrated platform for automatic MT evaluation by improving the string based metrics with multiple granularities. Our proposed metrics construct a novel integrated platform for automatic MT evaluation based on multiple features. Our key contribution consists of two parts: i) we suggest a strategy of changing the various complex features into plain string form. According to the strategy, the automatic MT evaluation frame are

much more clarified, and the computation of the similarity is much more simple, since the various linguistic features may express in the uniform strings with multiple calculation granularities. The new features have the same form and are dimensionally homogeneous; therefore, the consistency of the features is enhanced strongly. ii) We integrate the features with machine learning and proposed an effective approach of feature selection. As a result, we can use fewer features but obtain the better performance.

In this framework, on the one hand, string-based metrics with multiple granularities may introduce more potential features into automatic evaluation, with no necessarily of new similarity measuring method, compared with the other metrics. On the other hand, we succeed in finding a finer and small feature set among the combinations of plentiful features, keeping or improving the performance. Finally, we proposed a simple, effective and robust string-based automatic MT evaluation metric with multiple granularities.

Our proposed metrics improve the flexibility and performance of the metrics based on the multiple features; however, it still has some drawbacks: i) some potential features are not yet considered, e.g. the semantic roles; and ii) the loss of information exists in the process of changing linguistic information into plain strings. For example, the dependency label in the calculation granularity "Dependency" is lost when changing information into string form. Though the final results obtain the better performance than the other linguistic metrics, the performance is promising to be further improved if the loss of information can be properly dealt with.

Automatic Treebank Conversion via Informed Decoding

Abstract

In this paper, we focus on the challenge of automatically converting a constituency treebank (source treebank) to fit the standard of another constituency treebank (target treebank). We formalize the conversion problem as an *informed decoding* procedure: information from original annotations in a source treebank is incorporated into the decoding phase of a parser trained on a target treebank during the parser assigning parse trees to sentences in the source treebank. Experiments on two Chinese treebanks show significant improvements in conversion accuracy over baseline systems, especially when training data used for building the parser is small in size.

1 Introduction

Recent years have seen extensive applications of machine learning methods to natural language processing problems. Typically, increase in the scale of training data boosts the performance of machine learning methods, which in turn enhances the quality of learning-based NLP systems (Banko and Brill, 2001). However, annotating data by human is time consuming and labor intensive. For this reason, human-annotated corpora are considered as the most valuable resource for NLP.

In practice, there often exist more than one corpus for the same NLP tasks. For example, for constituent syntactic parsing (Collins, 1999; Charniak, 2000; Petrov et al., 2006) for Chinese, in addition to the most popular treebank Chinese Treebank (CTB) (Xue et al., 2002), there are also other treebanks such as Tsinghua Chinese Treebank (TCT) (Zhou, 1996). For the purpose of full use of readily available human annotations for the same tasks, it is significant if such corpora can be used jointly. Such attempt is especially significant for some languages that have limited size of labeled data. At first sight, a direct combination of multiple corpora is a way to this end. However, corpora created for the same NLP tasks are generally built by different organizations. Thus such corpora often follow different annotation standards and/or even different linguistic theories. We take CTB and TCT as a case study. Although both CTB and TCT are Chomskian-style treebanks, they have annotation divergences in at least two dimensions: a) CTB and TCT have dramatically different tag sets, including parts-of-speech and grammar labels, and the tags cannot be mapped one to one; b) CTB and TCT have distinct hierarchical structures. For example, the Chinese words "中国 (Chinese) 传统 (traditional) 文化 (culture)" are grouped as a flat noun phrase according to the CTB standard (right side in Fig. 1), but in TCT, the last two words are instead grouped together beforehand (left side in Fig. 1). The differences cause such treebanks of different annotation standard to be generally used independently.

In this paper, we focus on unifying multiple constituency treebanks of distinct annotation standards through treebank conversion. The task of treebank conversion is defined to be conversion of annotations in one treebank (source treebank) to

Coling 2008: Poster Volume, pages 1541–1549,
Beijing, August 2010

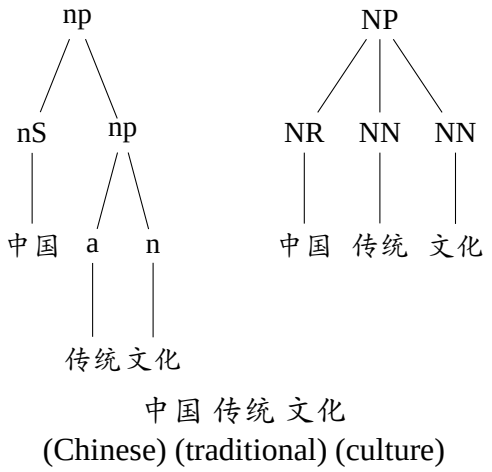

Figure 1: Example tree fragments with TCT (left) and CTB (right) annotations

fit the standard of another treebank (target treebank). To this end, we propose a language independent approach called *informed decoding* [1], in which a parser trained on a target treebank automatically assigns new parse trees to sentences in a source treebank with the aid of information derived from annotations in the source treebank. We conduct experiments on two open Chinese treebanks [2]: CTB and TCT. Experimental results show that our approach achieves significant improvements over baseline systems, especially when training data used for building the parser is small in size.

The rest of the paper is structured as follows. In Section 2 we describe previous work on treebank conversion. In Section 3, we describe in detail the informed decoding approach. Section 4 presents experimental results which demonstrate the effectiveness of our approach. Finally, Section 5 concludes our work.

2 Related Work

Previous work on treebank conversion can be grouped into two categories according to whether grammar formalisms of treebanks are identical. One type focuses on converting treebanks of different grammar formalisms. Collins et al. (1999) addressed constituent syntactic parsing on Czech using a treebank converted from a Prague dependency treebank, where conversion rules derived from head-dependent pairs and heuristic rules are applied. Xia and Palmer (2001) compared three algorithms for conversion from dependency structures to phrase structures. The algorithms expanded each node in input dependency structures into a projection chain, and labeled the newly inserted node with syntactic categories. The three algorithms differ only in heuristics adopted to build projection chains. Xia et al. (2008) automatically extracted conversion rules from a target treebank and proposed strategies to handle the case when more than one conversion rule are applicable. Instead of using conversion rules, Niu et al. (2009) proposed to convert a dependency treebank to a constituency one by using a parser trained on a constituency treebank to generate k-best lists for sentences in the dependency treebank. Optimal conversion results are selected from the k-best lists. There also exists work in the reverse direction: from a constituency treebank to a dependency treebank (Nivre, 2006; Johansson and Nugues, 2007).

Relatively few efforts have been put on conversion between treebanks that have the same grammar formalisms but follow different annotation standards. Wang et al. (1994) applied a similar framework as in (Niu et al., 2009) to convert from a simple constituency treebank to a more informative one. The basic idea is to apply a parser built on a target treebank to generate k-best lists for sentences in the source treebank. Then, a matching metric is defined on the number of identical bracketing spans between two trees. Such a function computes a score for each parse tree in a k-best list and its corresponding parse tree in the source treebank. Finally, the parse tree with the highest score in a k-best list is selected to be the conversion result. The difference between our work and (Wang et al., 1994) is that, instead of using trees from the source treebank to select parse trees from k-best lists, we propose to use such trees to guide the decoding phase of the parser built on the target treebank. Making use of the source treebank in such a novel way is believed to be the major contribution of our work.

[1] The terminology *decoding* is referred to the parsing phase of a parser.

[2] Note that although we use Chinese treebanks, our approach is language independent.

3 Treebank Conversion via Informed Decoding

The task of treebank conversion is defined to convert parse trees in a source treebank to fit the standard of a target treebank. In the informed decoding approach, treebank conversion proceeds in two steps: 1) build a parser on a target treebank; 2) apply the parser to decode sentences in a source treebank with the aid of information derived from the source treebank. For convenience, parse trees in a source treebank are referred to as *source trees* and corresponding, trees from a target treebank are referred to as *target trees*. Moreover, a parser built on a target treebank is referred to as *target parser*. In the following sections, we first describe motivation of our work and then present details of the informed decoding approach.

3.1 Motivation

We use the example in Fig. 2 to illustrate why original annotations in a source treebank can help in treebank conversion. The figure depicts three tree fragments for the Chinese words 发 *(pay)* 了 *(already)* 一 *(one)* 天 *(day)* 的 *(of)* 工资*(salary)*, among which Fig. 2(a) and Fig. 2(b) are tree fragments of the CTB standard and Fig. 2(c) is a tree fragment of the TCT standard. From the figure, we can see that these Chinese words actually have (at least) two plausible interpretations of the meaning. In Fig. 2(a), the words mean *pay salary for one-day work* while in Fig. 2(b), the words mean *spend one day on paying salary*. If Fig. 2(c) is a source tree to be converted into the CTB standard, then Fig. 2(b) will be rejected since it conflicts with Fig. 2(c) with respect to tree structures. Note that structures reflect underlying sentence meaning. On the other hand, although Fig. 2(a) also has (minor) differences in tree structures from Fig. 2(c), it is preferred as the conversion result[3]. From the example we can get inspired by the observation that original annotations in a source treebank are informative and necessary to converting parse trees in the source treebank.

In general, conversion like that from Fig. 2(c) to Fig. 2(a) requires sentence-specific conversion rules which are difficult to obtain in practice. In order to make use of information provided by original annotations in a source treebank, Wang et al. (1994) proposed a selecting-from-k-best approach where source trees are used to select one "optimal" parse tree from each k-best list generated by a target parser. In this paper, we instead incorporate information of original annotations into the parsing phase. The underlying motivation is two-fold:

- The decoding phase of a parser is essentially a search process. Due to the extreme magnitude of searching space, pruning of search paths is practically necessary. If reliable information is provided to guide the pruning of search paths, more efficient parsing and better results are expected.

- Selecting-from-k-best works on the basis of k-best lists. Unfortunately, we often see very few variations in k-best lists. For example, 50-best trees present only 5 to 6 variations (Huang, 2008). The lack of diversities in k-best lists makes information from the source treebank less effective in selecting parse trees. By contrast, incorporating such information into decoding makes the information affect the whole parse forest.

3.2 Formalization of Information from Source Treebank

In this paper, information from a source treebank translates into two strategies which help a target parser to prune illegal partial parse trees and to rank legal partial parse trees higher. Following are the two strategies:

- Pruning strategy: despite distinctions existing between annotation standards of a source treebank and a target treebank, a source treebank indeed provides treebank conversion with indicative information on bracketing structures and grammar labels. So when a partial parse tree is generated, it should be examined against the corresponding source tree. Unless the partial parse tree does *not conflict* with any constituent in the source tree, it should be pruned out.

[3]Note that we don't deny existence of annotation distinctions between the treebanks, but we aim to make use of what they both agree on. We assume that consensus is the majority.

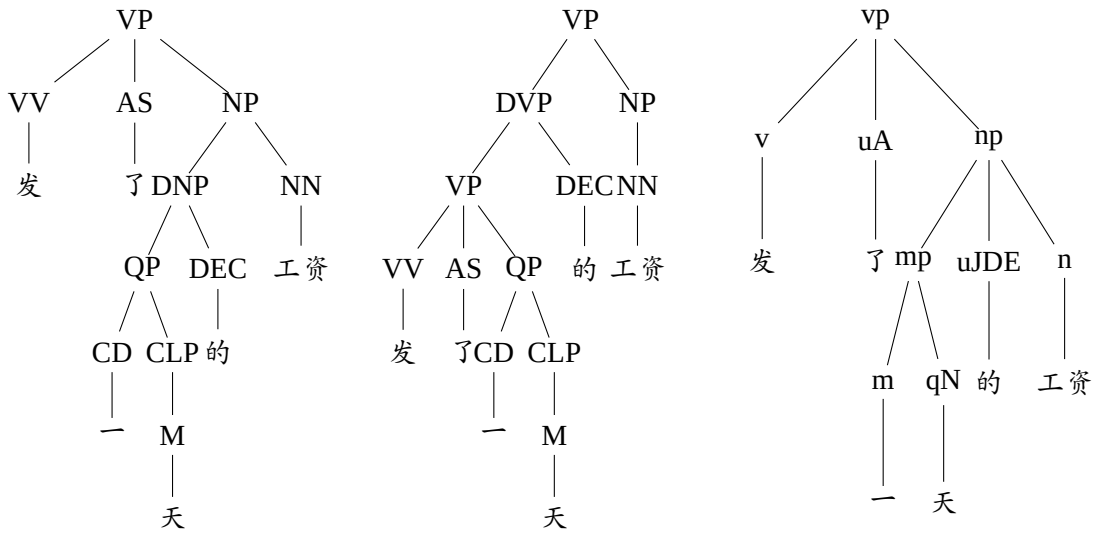

Figure 2: tree fragments of words 发 了 一 天 的 工资: (a) and (b) show two plausible tree fragments of the words using the CTB standard; (c) shows a tree fragment of the TCT standard which has the same interpretation as (a).

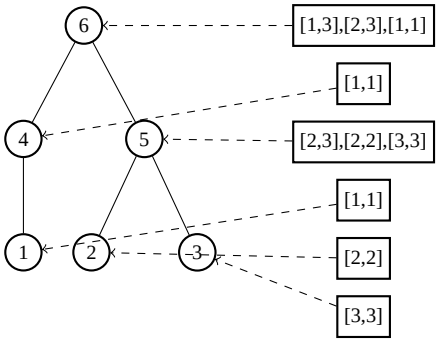

Figure 3: Constituent set of a synthetic parse tree

- Rescoring strategy: in practice, decoding is often a local optimal search process. In some cases even if a correct parse tree exits in the parse forest, parsers may fail to rank it to the top position. Rescoring strategy is used to increase scores for partial parse trees which are confidently thought to be valid.

3.2.1 Pruning Strategy

The pruning strategy used in this paper is based on the concept of *conflict* which is defined in two dimensions: structures and grammar labels. Since a tree structure can be equivalently represented as its span (interval of word indices) set, we can check whether two trees conflict by checking their spans. See Fig. 3 for an illustration of spans of a tree. Following are criteria determining whether two trees conflict in their structures.

- If one node in tree A is raised to be a child of the node's grandfather in tree B, and the grandfather has more than two children, then tree A and tree B conflict in structures.
- If tree A has a span $[a, b]$ and tree B has a span $[m, k]$ and these two spans satisfy the condition of either $a < m \leq b < k$ or $m < a \leq k < b$, then tree A and B conflict in structures.

Fig. 4 illustrates criteria mentioned above, where Fig. 4(a) is compatible (not conflict) with Fig. 4(b) although they have different structures. But Fig. 4(a) conflicts with Fig. 4(c) (according to criterion 1; node 3 is raised) and (d) (according to criterion 2).

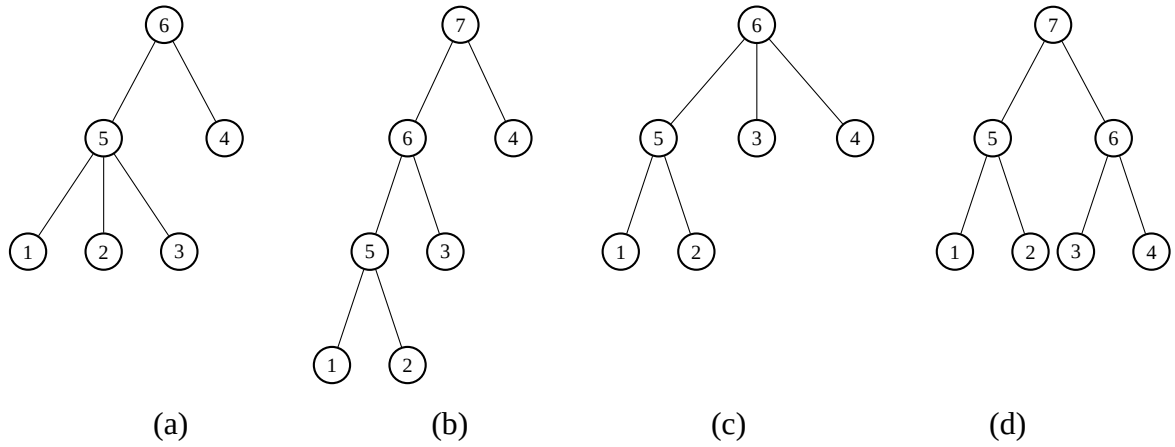

Figure 4: Illustrating example of the concept of *conflict*: (a) and (b) are compatible (not conflict); (a) conflicts with (c) (condition 1) and (d) (condition 2)

For the dimension of grammar labels, we manually construct a mapping between label sets (POS tags excluded) of source and target treebanks. Such a mapping is frequently a many-to-many mapping. Two labels are said to be conflicting if they are from different label sets and they cannot be mapped.

By combining these two strategies, two parse trees (of different standards) which yield the same sentence are said to be conflicting if they conflict in both structures and labels. Note that we describe pruning strategy for the case of two parse trees. In informed decoding process, this strategy is actually applied to every partial parse tree generated during decoding.

3.2.2 Rescoring Strategy

As mentioned above, despite that the pruning strategy helps in improving conversion accuracy, we are faced with the problem of how to rank valid parse trees higher in a parse forest. To solve the problem, we adjust the scores of those partial parse trees that are considered to be confidently "good". The criteria which is used to judge "goodness" of a partial parse are listed as follows:

- The partial parse tree can find in the source tree a constituent that has the same structure as it.
- When the first criterion is satisfied, grammar categories of this partial parse should not conflict with the grammar categories of its counterpart.

In practice, we use a parameter λ to adjust the score.

$$P_{new}(e) = \lambda * P(e) \quad (1)$$

Here e represents any partial tree that is rescored, and $P(e)$ and $P_{new}(e)$ refer to original and new scores, respectively.

3.3 Parsing Model

Theoretically all parsing models are applicable in informed decoding, but we prefer to adopt a CKY-style parser for two reasons: CKY style parsers are dynamically bottom-up and always have edges (or parsing items) belonging to the same span stacked together in the same chart[4] cell. The property of CKY-style parsers being dynamically bottom-up can make the pruning strategy efficient by avoiding rechecking subtrees that have already been checked. The property of stacking edges in the same chart cell makes CKY-style parsers easily portable to the situaiton of informed decoding. In this paper, Collins parser (Collins, 1999) is used. Algorithm 1 presents the extended version of the decoding algorithm used in Collins parser. What the algorithm needs to do is to generate edges for each span. And before edges are allowed to enter the chart, pruning conditions

[4]Data structure used to store paring items that are not pruned

Algorithm 1 CKY-style decoding
Argument: a parsing decoder
a sentence to be parsed and corresponding source tree

Begin
Steps:
1. initialization steps
2. for span from 2 to sentence_length **do**
for start from 1 to (sentence_length-span+1) **do**
end := (start + span - 1)
for each edge e for span [start, end] **do**
generate(e**, start, end)**
prune(e**, start, end)**
rescore(e**, start, end)**

End

Subroutine:
generate: generates an edge which belongs to the span [start, end].
prune: apply *pruning strategy* to check whether the edge should be pruned.
rescore: apply *rescoring strategy* to weight the edge.
add_edge: add the edge into *chart*.

should be checked in *prune* subroutine and rescoring should be conducted in *rescore* subroutine with respect to the corresponding source tree.

4 Experiments

4.1 Experimental Setup

In this paper, we conduct two groups of experiments in order to evaluate 1) treebank conversion accuracy and 2) how much newly generated data can boost syntactic parsing accuracy. For the experiments of treebank conversion, Penn Chinese Treebank (CTB) 5.1 is used as the target treebank. That is, the CTB standard is the one we are interested in. Following the conventional data splitting of CTB5.1, articles 001-270 and 400-1151 (18,100 sentences, 493,869 words) are used for training, articles 271-300 (348 sentences, 8,008 words) are used as test data, and articles 301-325 (352 sentences, 6,821 words) are used as development data [5]. Moreover, in order to directly evaluate conversion accuracy, we randomly sampled 150 sentences from the CTB test set and have three annotators manually label sentences of these parse trees according to the standard of Tsinghua Chinese Treebank (TCT). Thus each of the 150 sentences has two parse trees, following the CTB and TCT standard, respectively. For convenience of reference, the set of 150 parse trees of the CTB standard is referred to as *Sample-CTB* and its counterpart which follows the TCT standard is referred to as *Sample-TCT*. In such setting, the experiments of treebank conversion is designed to use the informed decoding approach to convert Sample-TCT to the standard of CTB and conversion results are evaluated with respect to Sample-CTB. The CTB training data (or portion of it) is used as target training data on which parsers are trained for conversion.

For the experiments of syntactic parsing, the TCT corpus is used as the source treebank. The TCT corpus contains 27,268 sentences and 587,298 words, which are collected from the literature and newswire domains. In this group of experiments, the CTB training data is again used as target training data and the whole TCT corpus is converted using the informed decoding approach. The newly-gained parse trees are used as additional training data for syntactic parsing on the CTB test data. One thing worth noting in the experiments is that, using Collins parser to convert the TCT corpus requires Part-of-Speech tags of the CTB standard be assigned to sentences in TCT ahead of conversion being conducted. To this end, instead of using POS taggers, we use the *label correspondence learning* method described in (Zhu and Zhu, 2009) in order to get high POS tagging accuracy.

For all the experiments in this paper, *bracketing F1* is used as the performance metric, provided by the EVALB program [6]. λ in Eq.1 is set to 3.0 since it provides best conversion results in our experiments.

4.2 Experiments on Conversion

The setup of conversion experiments is described above. In the experiments, we use two representative baseline systems. One, named *directly parsing (DP)* converts Sample-TCT by directly parsing using Collins parser which is trained on target training data, and the other is the method proposed in (Wang et al., 1994) (hereafter referred to as *Wang94*). For the latter baseline, we use Berkeley parser (Petrov et al., 2006) instead of

[5] Development set is not used in this paper.

Table 3: Conversion results with respect to different grammar categories

Collins parser. The reason is that we want to build a strong baseline since Berkeley parser is able to generate better k-best lists than Collins parser does (Zhang et al., 2009). In detail, Wang94 proceeds in two steps: 1) use Berkeley parser to generate k-best lists for sentences in Sample-TCT; 2) select a parse tree from each k-best list with respect to original annotations in Sample-TCT. Here we set k to 50. Table 1 reports F1 scores of the baseline systems and our informed decoding approach with varying size of target training data. The first row of the table represents fractions of the CTB training data which are used as target training data. For example, 40% means 7,240 parse trees (of 18,100) in the CTB training data are used. To relieve the effect of ordering, we randomly shuffled parse trees in the CTB training data.

From the table, we can see that our approach performs significantly better than DP and Wang94. In detail, when 100% CTB training data is used as target training data, 2.95% absolute improvement is achieved. When the size of target training data decreases, absolute improvements of our approach over baseline systems are further enlarged. More interestingly, decreasing in target training data only results in marginal decrement in conversion accuracy of our approach. This is of significant importance in the situation where target treebank is small in size.

In order to evaluate the accuracy of conversion methods on different span lengths, we compare the results of Wang94 and informed decoding produced by using 100% CTB training data. Table 2 shows the statistics.

From the results we can see that our approach performs significantly better on long spans and achieves marginally lower accuracy on small ones. But notice that the informed decoding approach is implemented on the base of Collins parser and that Wang94 works on the basis of Berkeley parser. Taking the performance gap of Collins parser and Berkeley parser, we actually can conclude that on small spans, our approach is able to achieve results comparable with or even better than Wang94. We can also infer from the observation that our approach can outperform Wang94 when converting parse trees which yield long sentences.

Another line of analysis is to compare the results of Wang94 and our approach, with respect to different grammar categories. Table 3 lists five grammar categories in which our approach achieves most improvements. For categories *NP* and *VP*, absolute improvements are 1.1% and 1.4% respectively. Take into account large amounts of instances of *NP* and *VP*, the improvements are also quite significant.

4.3 Experiments on Parsing

Before doing the experiments of parsing, we first converted the whole TCT corpus using 100% CTB training data as target training data. Using the newly-gained data only as training data for Collins parser, we can get F1 score 75.4% on the CTB test data. We can see that the score is much lower than the accuracy achieved by using the CTB training data (75.4% vs. 82.04%). Possible reasons that result in lower accuracy includes: 1) divergences in word segmentation standards between TCT and CTB; 2) divergences of domains of TCT and CTB; 3) conversions errors in newly-gained data. Although the newly-gained

data cannot replace the CTB training data thoroughly, we would like to use it as additional training data besides the CTB training data. Following experiments aim to examine effectiveness of the newly-gained data when used as additional training data.

In the first parsing experiment, the TCT corpus is converted using portions of the CTB training data. As in the conversion experiments, parse trees in the CTB training data are randomly ordered before splitting of the training set. For each portion, newly-gained data together with the portion of the CTB training data are used to train a new parser. Evaluation results on the CTB test data are presented in Table 4.

Ratio	20%	40%	60%	80%	100%
Collins	75.74	77.65	79.43	81.22	82.04
Collins+	**78.86**	**79.52**	**80.06**	**81.77**	**82.38**

Table 4: Parsing accuracy with new data added in

Here in Table 4, the first row represents ratios of parse trees from the CTB training data. For example, 40% means the first 40% parse trees in the CTB training data are used. The *Collins* row represents the results of only using portions of the CTB training data, and the *Collins+* row contains the results achieved with enlarged training data. From the results, we find that new data indeed provides complementary information to the CTB training data, especially when the training data is small in size. But benefits of Collins parser gained from additional training data level out with the increment of the training data size. Actually if techniques like corpus weighting (Niu et al., 2009) are applied to weight differently training data and the additional data, higher parsing accuracy is reasonably expected.

Another obversion from Table 4 is that the parser trained on 40% CTB training data plus additional training data achieves higher accuracy than using 60% CTB training data. We incrementally add labeled training data and automatic training data respectively to 40% CTB training data. The purpose of this experiment is to see the magnitude of automatic training data which can achieve the same effect as labeled training data does. The results are depicted in Table 5.

# of Added Data	2k	4k	6k	8k
Labeled Data	78.51	79.52	80.01	81.37
Auto Data	78.23	79.11	79.85	79.67

Table 5: Parsing accuracy with new data added in

From the results we see that accuracy gaps between using labeled data and using automatic data get large with the increment of added data. One possible reason is that more noise is taken when more data is added. This observation further verifies that refining techniques like corpus weighting are necessary for using automatically-gained data.

5 Conclusions

In this paper we proposed an approach called informed decoding for the task of conversion between treebanks which have different annotation standards. Experiments which evaluate conversion accuracy directly showed that our approach significantly outperform baseline systems. More interestingly we found that the size of target training data have limited effect on the conversion accuracy of our approach. This is extremely important for languages which lack enough treebanks in whose standards we are interested.

We also added newly-gained data to target training data to check whether new data can boost parsing results. Experiments showed additional training data provided by treebank conversion could boost parsing accuracy.

Imposing Hierarchical Browsing Structures onto Spoken Documents

Abstract

This paper studies the problem of imposing a known hierarchical structure onto an unstructured spoken document, aiming to help browse such archives. We formulate our solutions within a dynamic-programming-based alignment framework and use minimum error-rate training to combine a number of global and hierarchical constraints. This pragmatic approach is computationally efficient. Results show that it outperforms a baseline that ignores the hierarchical and global features and the improvement is consistent on transcripts with different WERs. Directly imposing such hierarchical structures onto raw speech without using transcripts yields competitive results.

1 Introduction

Though speech has long served as a basic method of human communication, revisiting and browsing speech content had never been a possibility before human can record their own voice. Recent technological advances in recording, compressing, and distributing such archives have led to the consistently increasing availability of spoken content.

Along with this availability comes a demand for better ways to browse such archives, which is inherently more difficult than browsing text. In relying on human beings' ability to browse text, a solution is therefore to reduce the speech browsing problem to a text browsing task through technologies that can automatically convert speech to text, i.e., the automatic speech recognition (ASR). Research along this line has implicitly changed the traditional speaking-for-hearing and writing-for-reading construals: now speech can be *read* through its transcripts, though it was not originally intended for this purpose, which in turn raises a new set of problems.

The efficiency and convenience of reading spoken documents are affected by at least two facts. First, the quality of transcripts can impair browsing efficiency, e.g., as shown in (Stark et al., 2000; Munteanu et al., 2006), though if the goal is only to browse salient excerpts, recognition errors on the extracts can be reduced by considering the confidence scores assigned by ASR (Zechner and Waibel, 2000; Hori and Furui, 2003).

Even if transcription quality is not a problem, browsing transcripts is not straightforward. When intended to be read, written documents are almost always presented as more than uninterrupted strings of text. Consider that for many written documents, e.g., books, indicative structures such as section/subsection headings and tables-of-contents are standard constituents created manually to help readers. Structures of this kind, however, are rarely aligned with spoken documents.

In this paper, we are interested in addressing the second issue: adding hierarchical browsable structures to speech transcripts. We define a hierarchical browsable structure as a set of nested labelled bracketing which, when placed in text, partition the document into labeled segments. Examples include the sequence of numbered section headings in this paper, or the hierarchical slide/bullet structure in the slides of a presentation.

Coling 2008: Poster Volume, pages 1550–1557,
Beijing, August 2010

An ideal solution to this task would directly infer both the hierarchical structure and the labels from unstructured spoken documents. However, this is a very complex task, involving the analysis of not only local but also high-level discourse over large spans of transcribed speech. Specifically for spoken documents, spoken-language characteristics as well as the lack of formality and thematic boundaries in transcripts violate many conditions that a reliable algorithm (Marcu, 2000) relies on and therefore make the task even harder.

In this paper, we aim at a less ambitious but naturally occurring problem: imposing a known hierarchical structure, e.g., presentation slides, onto the corresponding document, e.g., presentation transcripts. Given an ordered, nested set of topic labels, we must place the labels so as to correctly segment the document into appropriate units. Such an alignment would provide a useful tool for presentation browsing, where a user could easily navigate through a presentation by clicking on bullets in the presentation slides. The solution to this task should also provide insights and techniques that will be useful in the harder structure-inference task, where hierarchies and labels are not given.

We present a dynamic-programming-based alignment framework that considers global document features and local hierarchical features. This pragmatic approach is computationally efficient and outperforms a baseline alignment that ignores the hierarchical structure of bullets within slides. We also explore the impact of speech recognition errors on this task. Furthermore, we study the feasibility of directly aligning a structure to raw speech, as opposed to a transcript.

2 Related work

Topic/slide boundary detection The previous work most directly related to ours is research that attempts to find *flat* structures of spoken documents, such as topic and slide boundaries. For example, the work of (Chen and Heng, 2003; Ruddarraju, 2006; Zhu et al., 2008) aims to find slide boundaries in the corresponding lecture transcripts. Malioutov et al. (2007) developed an approach to detecting topic boundaries of lecture recordings by finding repeated acoustic patterns. None of this work, however, has involved hierarchical structures that exist at different levels of a document.

In addition, researchers have also analyzed other multimedia channels, e.g., video (Liu et al., 2002; Wang et al., 2003; Fan et al., 2006), to detect slide transitions. Such approaches, however, are unlikely to find semantic structures that are more detailed than slide transitions, e.g., the bullet hierarchical structures that we are interested in.

Building tables-of-contents on written text A notable effort going further than topic segmentation is the work by Branavan et al. (2007), which aims at the ultimate goal of building tables-of-contents for written texts. However, the authors assumed the availability of the hierarchical structures and the corresponding text spans. Therefore, their problem was restricted to generating titles for each span. Our work here can be thought of as the inverse problem, in which the title of each section is known, but the corresponding segments in the spoken documents are unknown. Once the correspondence is found, an existing hierarchical structure along with its indicative titles is automatically imposed on the speech recordings. Moreover, this paper studies spoken documents instead of written text. We believe it is more attractive not only because of the necessity of browsing spoken content in a more efficient way but also the general absence of helpful browsing structures that are often available in written text, as we have already discussed above.

Rhetoric analysis In general, analyzing discourse structures can provide thematic skeletons (often represented as trees) of a document as well as relationship between the nodes in the trees. Examples include the widely known discourse parsing work by Marcu (2000). However, when the task involves the understanding of high-level discourse, it becomes more challenging than just finding local discourse conveyed on small spans of text; e.g., the latter is more likely to benefit from the presence of discourse markers. Specifically for spoken documents, spoken-language characteristics as well as the absence of formality and thematic boundaries in transcripts pose additional

difficulty. For example, the boundaries of sentences, paragraphs, and larger text blocks like sections are often missing. Together with speech recognition errors as well as other speech characteristics such as speech disfluences, they will impair the conditions on which an effective and reliable algorithm of discourse analysis is often built.

3 Problem formulation

We are given a speech sequence $U = u_1, u_2, ..., u_m$, where u_i is an utterance. Depending on the application, u_i can either stand for the audio or transcript of the utterance. We are also given a corresponding hierarchical structure. In our work, this is a sequence of lecture slides containing a set of slide titles and bullets, $B = \{b_1, b_2, ..., b_n\}$, organized in a tree structure $T(\Re, \aleph, \Psi)$, where $\Re$ is the root of the tree that concatenates all slides of a lecture; i.e., each slide is a child of the root $\Re$ and each slide's bullets form a subtree. In the rest of this paper, the word *bullet* means both the title of a slide (if any) and any bullet in it. $\aleph$ is the set of nodes of the tree (both terminal and non-terminals, excluding the root $\Re$), each corresponding to a bullet b_i in the slides. Ψ is the edge set. With the definitions, our task is herein to find the triple (b_i, u_k, u_l), denoting that a bullet b_i starts from the kth utterance u_k and ends at the lth. Constrained by the tree structure, the text span corresponding to an ancestor bullet contains those corresponding to its descendants; i.e., if a bullet b_i is the ancestor of another bullet b_j in the tree, the acquired boundary triples (b_i, u_{k1}, u_{l1}) and (b_j, u_{k2}, u_{l2}) should satisfy $u_{k1} \leq u_{k2}$ and $u_{l1} \geq u_{l2}$. In implementation, we only need to find the starting point of a bullet, i.e., a pair (b_i, u_k), since we know the tree structure in advance and therefore we know that the starting position of the next sibling bullet is the ending boundary for the current bullet.

4 Our approaches

Our task is to find the correspondence between slide bullets and a speech sequence or its transcripts. Research on finding correspondences between parallel texts pervades natural language processing. For example, aligning bilingual sentence pairs is an essential step in training machine translation models. In text summarization, the correspondence between human-written summaries and their original texts has been identified (Jing, 2002), too. In speech recognition, forced alignment is applied to align speech and transcripts. In this paper, we keep the general framework of alignment in solving our problem.

Our solution, however, should be flexible to consider multiple constraints such as those conveyed in hierarchical bullet structures and global word distribution. Accordingly, the model proposed in this paper depends on two orthogonal strategies to ensure efficiency and richness of the model. First of all, we formulate all our solutions within a classic dynamic programming framework to enforce computational efficiency (section 4.1). On the other hand, we explore the approach to incorporating hierarchical and global features into the alignment framework (Section 4.2). The associated parameters are then optimized with Powell's algorithm (Section 4.3).

4.1 A pre-order walk of bullet trees

We formulate our solutions within the classic dynamic-programming-based alignment framework, dynamic time warping (DTW). To this end, we need to sequentialize the given hierarchies, i.e., bullet trees. We propose to do so through a pre-order walk of a bullet tree; i.e., at any step of a recursive traversal of the tree, the alignment model always visits the root first, followed by its children in a left-to-right order. This sequentialization actually corresponds to a reasonable assumption: words appearing earlier on a given slide are spoken earlier by the speaker. The pre-order walk is also used by (Branavan et al., 2007) to reduce the search space of their discriminative table-of-contents generation. Our sequentialization strategy can be intuitively thought of as removing indentations that lead each bullet. As shown in Figure 1, the right panel is a bullet array resulting from a pre-walk of the slide in the left panel. In our baseline model, the resulted bullet array is directly aligned with lecture utterances.

Other orders of bullet traversal could also be considered, e.g., when speech does not strictly follow bullet orders. In general, one can regard our

task here as a tagging problem to allow further flexibility on bullet-utterance correspondence, in which bullets are thought of as tags. However, considering the fact that bullets are created to organize speech and in most cases they correspond to the development of speech content monotonically, this paper focuses on addressing the problem in the alignment framework.

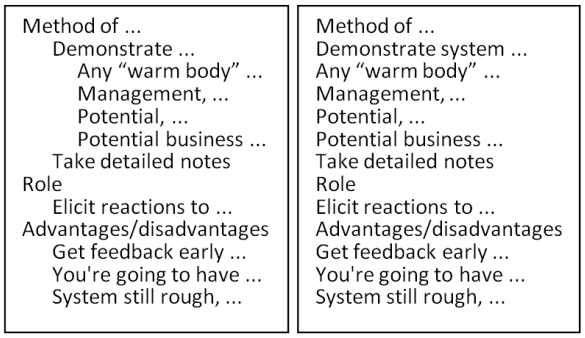

Figure 1: A pre-order walk of a bullet tree.

4.2 Incorporating hierarchical and global features

Our models should be flexible enough to consider constraints that could be helpful, e.g., the hierarchical bullet structures and global word distribution. We propose to consider all these constraints in the phase of estimating similarity matrices. To this end, we use two levels of similarity matrices to capture local tree constraints and global word distributions, respectively.

First of all, information conveyed in the hierarchies of bullet trees should be considered, such as the potentially discriminative nature between two sibling bullets (Branavan et al., 2007) and the relationships between ancestor and descendant bullets. We incorporate them in the bullet-utterance similarity matrices. Specifically, when estimating the similarity between a bullet b_i and an utterance u_j, we consider local tree constraints based on where the node b_i is located on the slide. We do so by accounting for first and second-order tree features. Given a bullet, b_i, we first represent it as multiple vectors, one for each of the following: its own words, the words appearing in its parent bullet, grandparent, children, grandchildren, and the bullets immediately adjacent to b_i. That is, b_i is now represented as 6 vectors of words (we do not discriminate between its left and right siblings and put these words in the same vector). Similarity between the bullet b_i and an utterance u_j is calculated by taking a weighted average over the similarities between each of the 6 vectors and the utterance u_j. A linear combination is used and the weights are optimized on a development set.

Global property of word distributions could be helpful, too. A general term often has less discriminative power in the alignment framework than a word that is localized to a subsection of the document and is related to specific subtopics. For example, in a lecture that teaches introductory computer science topics, aligning a general term "computer" should receive a smaller weight than aligning some topic-specific terms such as "automaton." The latter word is more likely to appear in a more narrow text span. It is not straightforward to directly calculate *idf* scores unless a lecture is split into smaller segments in some way. Instead, in our models, the distribution property of a word is considered in word-level similarity matrices with the following formula.

$$sim(w_i, w_j) = \begin{cases} 0 & : i \neq j \\ 1 - \lambda \frac{var(w_i)}{\max_k(var(w_k))} & : i = j \end{cases}$$

Aligning different words receives no bonus, while matching the same word between bullets and utterances receives a score of 1 minus a distribution penalty, as shown in the formula above. The function $var(w_i)$ calculates the standard variance of the positions where the word w_i appears. Divided by the maximal standard variance of word positions in the same lecture, the score is normalized to [0,1]. This distribution penalty is weighted by λ, which is tuned in a development set. Again, a general term is expected to have a larger positional variance.

Once a word-level matrix is acquired, it is combined with the bullet-utterance level matrix discussed above. Specifically, when measuring the similarity between a word vector (one of the 6 vectors) and the transcripts of an utterance, we sum up the word-level similarity scores of all matching words between them, normalize the resulted score by the length of the vector and utterance, and then renormalize it to the range

[0, 1] within the same spoken document. The final bullet-utterance similarity matrix is incorporated into the pre-order-walk suquentialization discussed above, when alignment is conducted.

4.3 Parameter optimization

Powell's algorithm (Press et al., 2007) is used to find the optimal weights for the constraints we incorporated above, to directly minimize the objective function, i.e., the P_k and WindowDiff scores that we will discuss later. As a summary, we have 7 weights to tune: a weight for each of the following: parent bullet, grandparent, adjacent siblings, children, grandchildren, and the current bullet, plus the word distribution penalty λ. The values of these weights are determined on a development set.

Note that the model we propose here does not exclude the use of further features; instead, many other features, such as smoothed word similarity scores, can be easily added to this model. We are conservative on our model complexity here, in terms of number of weights need to be tuned, for the consideration of the size of data that we can used to estimate these weights. Finally, with all the 7 weights being determined, we apply the standard dynamic time warping (DTW).

5 Experimental set-up

5.1 Data

We use a corpus of lectures recorded at a large research university. The correspondence between bullets and speech utterances are manually annotated in a subset of this lecture corpus, which contains approximately 30,000 word tokens in its manual transcripts. Intuitively, this roughly equals a 120-page double-spaced essay in length. The lecturer's voice was recorded with a head-mounted microphone with a 16kHz sampling rate and 16-bit samples. Students' comments and questions were not recorded. The speech is split into utterances by pauses longer than 200ms, resulting in around 4000 utterances. There are 119 slides that are composed of 921 bullets. A subset containing around 25% consecutive slides and their corresponding speech/transcripts are used as our development set to tune the parameters discussed earlier; the rest data are used as our test set.

5.2 Evaluation metric

We evaluate our systems according to how well the segmentation implied by the inferred bullet alignment matches that of the manually annotated gold-standard bullet alignment. Though one may consider that different bullets may be of different importance, in this paper we do not use any heuristics to judge this and we treat all bullets equally in our evaluation. We evaluate our systems with the P_k and WindowDiff metrics (Malioutov et al., 2007; Beeferman et al., 1999; Pevsner and Hearst, 2002). Note that for both metrics, the lower a score is, the better the performance of a system is. The P_k score computes the probability of a randomly chosen pair of words being inconsistently separated. The WindowDiff is a variant of P_k; it penalizes false positives and near misses equally.

6 Experimental results

6.1 Alignment performance

Table 1 presents the results on automatic transcripts with a 39% WER, a typical WER in realistic and uncontrolled lecture conditions (Leeuwis et al., 2003; Hsu and Glass, 2006). The transcripts were generated with the SONIC toolkit (Pellom, 2001). The acoustic model was trained on the Wall Street Journal dictation corpus. The language model was trained on corpora obtained from the Web through searching the words appearing on slides as suggested by (Munteanu et al., 2007).

	Pk	WindowDiff
UNI	0.481	0.545
TT	0.469	0.534
B-ALN	0.283	0.376
HG-ALN	0.266	0.359

Table 1: The P_k and WindowDiff scores of uniform segmentation (UNI), TextTiling (TT), baseline alignment (B-ALN), and alignment with hierarchical and global information (HG-ALN).

From Table 1, we can see that the model that

utilizes the hierarchical structures of slides and global distribution of words, i.e., the HG-ALN model, reduces both P_k and WindowDiff scores over the baseline model, B-ALN. As discussed earlier, the baseline is a re-implementation of standard dynamic time warping based only on a pre-order walk of the slides, while the HG-ALN model incorporates also hierarchical bullet constraints and global word distribution.

Table 1 also presents the performance of a typical topic segmentation algorithm, TextTiling (Hearst, 1997). Note that similar to (Malioutov et al., 2007), we force the number of predicted topic segments to be the target number, i.e., in our task, the number of bullets. The results show that both the P_k and WindowDiff scores of TextTiling are significantly higher than those of the alignment algorithms. Our manual analysis suggests that many segments are as short as several utterances and the difference between two consecutive segments is too subtle to be captured by a lexical cohesion-based method such as TextTiling. For comparison, We also present the results of uniform segmentation (UNI), which simply splits the transcript of each lecture evenly into segments with same numbers of words.

6.2 Performance under different WERs

Speech recognition errors within reasonable ranges often have very small impact on many spoken language processing tasks such as spoken language retrieval (Garofolo et al., 2000) and speech summarization (Christensen et al., 2004; Maskey, 2008; Murray, 2008; Zhu, 2010). To study the impact of speech recognition errors on our task here, we experimented with the alignment models on manual transcripts as well as on automatic transcripts with different WERs, including a 39% and a 46% WER produced by two real recognition systems. To increase the spectrum of our observation, we also overfit our ASR models to obtain smaller WERs at the levels of 11%, 19%, and 30%.

From Figure 2, we can see that at all levels of these different WERs, the HG-ALN model consistently outperforms the B-ALN system (the AUDIO model will be discussed below). The P_k and WindowDiff curves also show that the alignment performance is sensitive to recognition errors, particularly when the WER is in the range of 30%–45%, suggesting that the problem we study here can benefit from the improvement of current ASR systems in this range, e.g., the recent advance achieved in (Glass et al., 2007).

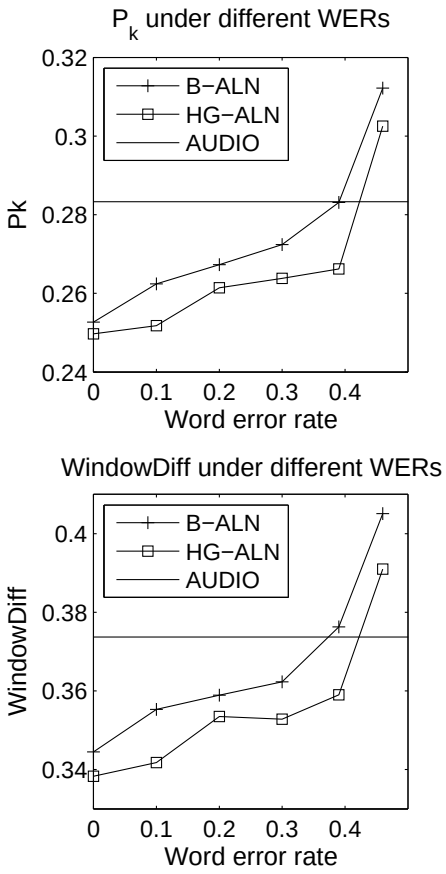

Figure 2: The impact of different WERs on the alignment models. The performance of an audio-based model (AUDIO) is also presented.

6.3 Imposing hierarchical structures onto raw speech

We can actually impose hierarchical structures directly onto raw speech, through estimating the similarity between bullets and speech. This enables navigation through the raw speech by using slides; e.g., one can hear different parts of speech by clicking a bullet. We apply keyword spotting to solve this problem, which detects the occurrences of each bullet word in the corresponding lecture audio.

In this paper, we use a token-passing based algorithm provided in the ASR toolkit SONIC (Pellom, 2001). Since the slides are given in advance, we manually add into the pronunciation dictionary the words that appear in slides but not in the pronunciation dictionary. To estimate similarity between a word vector (discussed earlier in Section 4.2) and an utterance, we sum up all keyword-spotting confidence scores assigned between them, normalize the resulted score by the length of the vector and the duration of the utterance, and then renormalize it to the range [0, 1] within the same spoken lecture.

We present the performance of our bullet-audio alignment model (AUDIO) in Figure 2 so that one can compare its effectiveness with the transcription based methods. The figure shows that the performance of the AUDIO model is comparable to the baseline transcription-based model, i.e., B-ALN, when the WERs of the transcripts are in the range of 37%–39%. The performance is comparable to the HG-ALN model when WERs are in the range of 42%–44%. Also, this suggests that incorporating hierarchical and global features compensates for the performance degradation of speech recognition in this range when the WER is 4%-6% higher.

Note that we did not observe that the performance is different when incorporating hierarchical information and global word distributions into the AUDIO model, so the AUDIO results in Figure 2 are the performance of both types of methods. The current keyword spotting component yields a high false-positive rate; e.g., it incorrectly reports many words that are acoustically similar to parts of other words that really appear in an utterance. This happened even when a high threshold is set. The noise impairs the benefit of hierarchical and distribution features.

7 Conclusions and discussions

This paper investigates the problem of imposing a known hierarchical structure onto an unstructured spoken document. Results show that incorporating local hierarchical constraints and global word distributions in the efficient dynamic programming framework yields a better performance over the baseline. Further experiments on a wide range of WERs confirm that the improvement is consistent, and show that both types of models are sensitive to speech recognition errors, particularly when WER increases to 30% and above. Moreover, directly imposing hierarchical structures onto raw speech through keyword spotting achieves competitive performance.

Abstract

We present a probabilistic, salience-based approach to the interpretation of pointing gestures together with spoken utterances. Our mechanism models dependencies between spatial and temporal aspects of gestures and features of utterances. For our evaluation, we collected a corpus of requests which optionally included pointing. Our results show that pointing information improves interpretation accuracy.

1 Introduction

DORIS (Dialogue Oriented Roaming Interactive System) is a spoken dialogue system designed for a household robot. In (Zukerman et al., 2008), we described *Scusi?* — a spoken language interpretation module which considers multiple sub-interpretations at different levels of the interpretation process, and estimates the probability of each sub-interpretation at each level (Section 2). This formalism is required for requests such as "Get me the blue cup" in the context of the scene depicted in Figure 1, where possible candidates are the three white cups, and the blue and purple tumblers, but it is unclear which is the intended object, as none of the alternatives match the request perfectly.

In this paper, we integrate pointing gestures into *Scusi?*'s probabilistic formalism. We adopt a salience-based approach, where we take into account spatial and temporal information to estimate the probability that a pointing gesture refers to an object. To evaluate our formalism, we collected a corpus of requests where people were allowed to point (Section 4). Our results show that when people point, our mechanism yields significant improvements in interpretation accuracy; and when pointing was artificially added to utterances where the people did not point, its effect on interpretation accuracy was reduced.

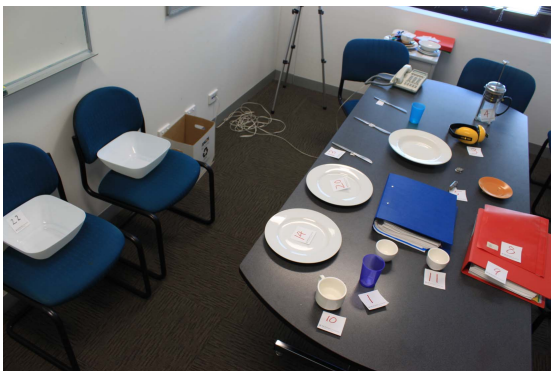

Figure 1: Experimental Setup

This paper is organized as follows. Section 2 outlines the interpretation of a spoken request and the estimation of the probability of an interpretation. Section 3 describes how pointing affects this probability. Our evaluation is detailed in Section 4. Related research is discussed in Section 5, followed by concluding remarks.

2 Interpreting Spoken Requests

Here we summarize our previous work on the interpretation of single-sentence requests (Makalic et al., 2008; Zukerman et al., 2008).

Coling 2008: Poster Volume, pages 1558–1566,
Beijing, August 2010

Scusi? processes spoken input in three stages: speech recognition, parsing and semantic interpretation. First, Automatic Speech Recognition (ASR) software (Microsoft Speech SDK 5.3) generates candidate hypotheses (texts) from a speech signal. The ASR produces up to 50 texts for a spoken utterance, where each text is associated with a probability. In the parsing stage, the texts are considered in descending order of probability. Charniak's probabilistic parser (`ftp://ftp.cs.brown.edu/pub/nlparser/`) is applied to each text, yielding up to 50 parse trees — each associated with a probability.

During semantic interpretation, parse trees are successively mapped into two representations based on Concept Graphs (Sowa, 1984). First *Uninstantiated Concept Graphs (UCGs)*, and then *Instantiated Concept Graphs (ICGs)*. UCGs are obtained from parse trees deterministically — one parse tree generates one UCG. A UCG represents syntactic information, where the concepts correspond to the words in the parent parse tree, and the relations are derived from syntactic information in the parse tree and prepositions. Each UCG can generate many ICGs. This is done by nominating different instantiated concepts and relations from the system's knowledge base as potential realizations for each concept and relation in a UCG. Instantiated concepts are objects and actions in the domain (e.g., `mug01`, `mug02` and `cup01` are possible instantiations of the uninstantiated concept "mug"), and instantiated relations are similar to semantic role labels (Gildea and Jurafsky, 2002). The interpretation process continues until a preset number of sub-interpretations (including texts, parse trees, UCGs and ICGs) has been generated or all options have been exhausted.

Figure 2 illustrates a UCG and an ICG for the request "get the large red folder on the table". The *intrinsic* features of an object (lexical item, colour and size) are stored in the UCG node for this object. *Structural* features, which involve two objects (e.g., "*folder*-on-*table*"), are represented as sub-graphs of the UCG (and the ICG).

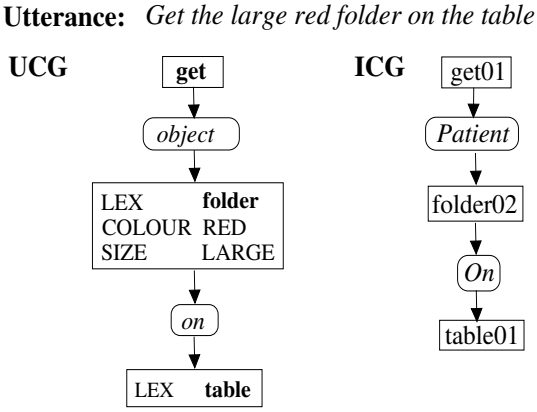

Figure 2: UCG and ICG for a sample utterance

2.1 Estimating the probability of an ICG

Scusi? ranks candidate ICGs according to their probability of being the intended meaning of a spoken utterance. Given a speech signal W and a context $\mathcal{C}$, the probability of an ICG I, $\Pr(I|W,\mathcal{C})$, is proportional to

$$\sum_{\Lambda} \Pr(T|W)\cdot\Pr(P|T)\cdot\Pr(U|P)\cdot\Pr(I|U,\mathcal{C}) \quad (1)$$

where T, P and U denote text, parse tree and UCG respectively. The summation is taken over all possible paths $\Lambda = \{P, U\}$ from the speech wave to the ICG, because a UCG and an ICG can have more than one ancestor. As mentioned above, the ASR and the parser return an estimate of $\Pr(T|W)$ and $\Pr(P|T)$ respectively; and $\Pr(U|P) = 1$, since the process of generating a UCG from a parse tree is deterministic. The estimation of $\Pr(I|U,\mathcal{C})$ is described in (Zukerman et al., 2008). Here we present the final equation obtained for $\Pr(I|U,\mathcal{C})$, and outline the ideas involved in its calculation.

$$\Pr(I|U,\mathcal{C}) \approx \prod_{k\in I} \Pr(u|k,\mathcal{C})\,\Pr(k|k_p,k_{gp})\,\Pr(k|\mathcal{C}) \quad (2)$$

where u is a node in UCG U, k is the corresponding instantiated node in ICG I, k_p is k's parent node, and k_{gp} is k's grandparent node. For example, *On* is the parent of `table01`, and `folder02` the grandparent in the ICG in Figure 2.

- $\Pr(u|k)$ is the "match probability" between the specifications for node u in UCG U and the intrinsic features of the corresponding node k in ICG I, i.e., the probability that a speaker who intended a particular object k gave the specifications in u.

- $\Pr(k|k_p, k_{gp})$ represents the structural probability of ICG I, where structural information is simplified to node trigrams, e.g., whether `folder02` is *On* `table01`.

- $\Pr(k|\mathcal{C})$ is the probability of a concept in light of the context, which includes information about domain objects, actions and relations.

Scusi? handles three intrinsic features: lexical item, colour and size; and two structural features: ownership and several locative relations (e.g., on, under, near). The match probability $\Pr(u|k)$ and the structural probability $\Pr(k|k_p, k_{gp})$ are estimated using a distance function between the requirements specified by the user and what is found in reality — the closer the distance between the specifications and reality, the higher the probability (for details see (Makalic et al., 2008)).

3 Incorporating Pointing Gestures

Pointing affects the salience of objects and the language used to refer to objects: objects in the temporal and spatial vicinity of a pointing gesture are more salient than objects that are farther away, and pointing is often associated with demonstrative determiners. Thus, the incorporation of pointing into *Scusi?* affects the following elements of Equation 2 (Section 2.1).

- $\Pr(k|\mathcal{C})$ – the context-based probability of an object (i.e., its salience) is affected by the time of a pointing gesture and the space it encompasses. For instance, if the user says "Get the cup" in the context of the scene in Figure 1, pointing around the time s/he said "cup", the gesture most likely refers to an object that may be called "cup". Further, among the candidate cups in Figure 1, those closer to the "pointing vector" have a higher probability.[1]

- $\Pr(u|k, \mathcal{C})$ – when pointing, people often use demonstrative determiners, e.g., "get me *that* cup". Also, people often use generic identifiers in conjunction with demonstrative determiners to refer to unfamiliar objects, e.g., "that thing" to refer to a vacuum tube (Figure 1).

These probabilities are estimated in Sections 3.1 and 3.2. Our calculations are based on information returned by the gesture recognition system described in (Li and Jarvis, 2009): gesture type, time, probability and relevant parameters (e.g., a vector for a pointing gesture). Since we focus on pointing gestures, we convert the probabilities expected from Li and Jarvis's system into the probability of Pointing and that of Not Pointing, which comprises all other gestures and no gesture (these hypotheses are returned at the same time).[2]

3.1 Calculating salience from pointing

When pointing is taken into account, the probability of object k is expressed as follows.

$$\begin{aligned}\Pr(k|\mathcal{C}) &= \Pr(k|\mathcal{P}, \mathcal{C}) \cdot \Pr(\mathcal{P}|\mathcal{C}) + \\ &\quad \Pr(k|\neg\mathcal{P}, \mathcal{C}) \cdot \Pr(\neg\mathcal{P}|\mathcal{C})\end{aligned} \tag{3}$$

where $\mathcal{P}$ designates Pointing, $\Pr(\mathcal{P}|\mathcal{C})$ and its complement are returned by the gesture recognition system, and $\Pr(k|\neg\mathcal{P}, \mathcal{C}) = \frac{1}{N}$ (N is the number of objects in the room, i.e., in the absence of pointing, we assume that all the objects in the room are equiprobable[3]).

As indicated above, we posit that pointing is spatially correlated with an intended object, and temporally correlated with a word referring to the intended object. Hence, we separate Pointing into two components: spatial (s) and temporal (t), obtaining $\langle \mathcal{P}_s, \mathcal{P}_t \rangle$. Thus

$$\begin{aligned}\Pr(k|\mathcal{P}, \mathcal{C}) &= \frac{\Pr(k, \mathcal{P}_t, \mathcal{P}_s, \mathcal{C})}{\Pr(\mathcal{P}, \mathcal{C})} \\ &= \frac{\Pr(\mathcal{P}_t|k, \mathcal{P}_s, \mathcal{C}) \cdot \Pr(k|\mathcal{P}_s, \mathcal{C}) \cdot \Pr(\mathcal{P}_s|\mathcal{C})}{\Pr(\mathcal{P}|\mathcal{C})}\end{aligned} \tag{4}$$

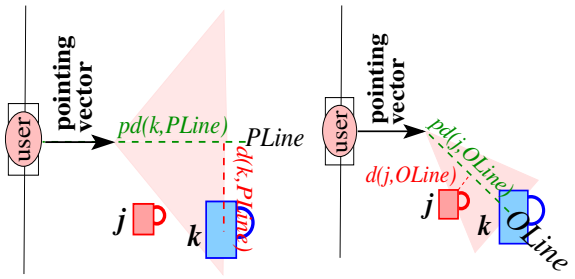
We assume that given k, $\mathcal{P}_t$ is conditionally independent from $\mathcal{P}_s$; and that $\Pr(\mathcal{P}_s|\mathcal{C}) = \Pr(\mathcal{P}|\mathcal{C})$, i.e., the spatial probability of a pointing gesture is the probability returned by the gesture system for the entire pointing hypothesis (time and space). This yields

$$\Pr(k|\mathcal{P}, \mathcal{C}) = \Pr(\mathcal{P}_t|k, \mathcal{C}) \cdot \Pr(k|\mathcal{P}_s, \mathcal{C}) \tag{5}$$

[1] At present, we assume that an utterance is associated with at most one pointing gesture, and that pointing pertains to objects. This assumption is supported by our user study (Section 4.1).

[2] Owing to timing limitations of the gesture recognition system (Section 4), we simulate its output.

[3] At present, we do not consider dialogue salience.



(a) Pointing (b) Occlusion

Figure 3: Spatial pointing and occlusion

where $\Pr(k|\mathcal{P}_s, \mathcal{C})$ and $\Pr(\mathcal{P}_t|k, \mathcal{C})$ are estimated as described in Section 3.1.1 and 3.1.2 respectively. This equation is smoothed as follows (and incorporated into Equation 3) to take into account objects that are (spatially or temporally) excluded from the pointing gesture.

$$\Pr'(k|\mathcal{P}, \mathcal{C}) = \frac{\Pr(k|\mathcal{P}, \mathcal{C}) + \frac{1}{N}}{1 + \sum_{j=1}^{N} \Pr(k_j|\mathcal{P}, \mathcal{C})} \quad (6)$$

3.1.1 Estimating $\Pr(k|\mathcal{P}_s, \mathcal{C})$

$\Pr(k|\mathcal{P}_s, \mathcal{C})$, the probability that the user intended object k when pointing to a location, is estimated using a conic Gaussian density function around *PLine*, the *Pointing Line* created by extending the pointing vector returned by the gesture identification system (Figure 3(a)).[4]

$$\Pr(k|\mathcal{P}_s, \mathcal{C}) = \frac{\alpha\theta_k}{\sqrt{2\pi}\sigma_{P_s}(pd)} e^{-\frac{d(k,PLine)^2}{2\sigma^2_{P_s}(pd)}} \quad (7)$$

where α is a normalizing constant; $\sigma_{P_s}(pd)$ is the standard deviation of the Gaussian cone as a function of $pd(k, PLine)$, the *projected distance* between the user's pointing hand and the projection of object k on *PLine*; $d(k, PLine)$ is the shortest distance between the center of object k and *PLine*; and θ_k is a factor that reduces the probability of object k if it is (partially) *occluded* (Figure 3(b)).

The ***projected distance*** pd takes into account the imprecision of pointing actions — a problem that is exacerbated by the uncertainty associated with sensing a pointing vector. A small angular error in the detected pointing vector yields a discrepancy in the distance between the pointing line and candidate objects. This discrepancy increases as $pd(k, PLine)$ increases. To compensate for this situation, we increase the variance of the Gaussian distribution linearly with the projected distance from the user's hand (we start with a small standard deviation of $\sigma_0 = 5$ mm at the user's fingers, attributed to sensor error). This allows farther objects with a relatively high displacement from the pointing vector to be encompassed in a pointing gesture (e.g., the larger mug in Figure 3(a)), while closer objects with the same displacement are excluded (e.g., the smaller mug). This yields the following equation for the variance.

$$\sigma^2_{P_s}(pd) = \sigma_0^2 + K \cdot pd(k, PLine)$$

where $K = 2.5$ mm is an empirically determined increase rate.

The ***occlusion factor*** θ_k reduces the probability of objects as they become more occluded. We approximate θ_k by considering the objects that are closer to the user than k, and estimating the extent to which these objects occlude k (Figure 3(b)). This estimate is a function of the position of these objects and their size — the larger an intervening object, the lower the probability that the user is pointing at k. These factors are taken into account as follows.

$$\Pr(j \text{ occl } k) = \frac{\gamma}{\sqrt{2\pi}\sigma_\theta(pd)} e^{-\frac{(d(j,OLine) - \frac{1}{2}\dim_{\min}(j))^2}{2\sigma^2_\theta(pd)}} \quad (8)$$

where γ is a normalizing constant; the numerator of the exponent represents the maximum distance from the edge of object j to the line between the user's hand and object k, denoted *Object Line* (*OLine*); and

$$\sigma^2_\theta(pd) = \frac{1}{2}\left(\sigma_0^2 + K \cdot pd(j, OLine)\right)$$

represents the variance of a cone from the user's hand to object k as a function of distance. In order to represent the idea that object j must be close to the Object Line to occlude object k, we use half the variance of that used for the "pointing cone", which yields a thinner "occlusion cone" (Figure 3(b)). θ_k is then estimated as 1 minus the

[4] Since this is a continuous density function, it does not directly yield a point probability. Hence, it is normalized on the basis of the largest possible returned value.

maximum occlusion caused by the objects that are closer to the user than k.

$$\theta_k = 1 - \max_{\forall j \ d(j,\text{hand}) < d(k,\text{hand})} \{\Pr(j \text{ occl } k)\} \quad (9)$$

3.1.2 Estimating $\Pr(\mathcal{P}_t|k,\mathcal{C})$

$\Pr(\mathcal{P}_t|k,\mathcal{C})$ is obtained as follows.

$$\Pr(\mathcal{P}_t|k,\mathcal{C}) = \sum_{i=1}^{n} \frac{\Pr(\mathcal{P}_t, k, W_i, \mathcal{C})}{\Pr(k,\mathcal{C})} \quad (10)$$

$$= \sum_{i=1}^{n} \frac{\Pr(k|\mathcal{P}_t, w_i, \mathcal{C}) \cdot \Pr(T(w_i)|\mathcal{P}_t, \mathcal{C}) \cdot \Pr(\mathcal{P}_t|\mathcal{C})}{\Pr(k|\mathcal{C})}$$

where n is the number of nouns in the user's utterance, and $W_i = \langle w_i, T(w_i)\rangle$ is a tuple comprising the ith noun and the mid point of the time when it was uttered.

We make the following assumptions.

- $\Pr(\mathcal{P}_t|\mathcal{C}) = 1$, as all the gesture hypotheses are returned at the same time;
- given $\mathcal{P}_t$, the timing of a word $T(w_i)$ is conditionally independent of $\mathcal{C}$; and
- given w_i, k is conditionally independent of the timing of the pointing gesture $\mathcal{P}_t$, i.e., $\Pr(k|\mathcal{P}_t, w_i, \mathcal{C}) = \Pr(k|w_i, \mathcal{C})$.

This probability is represented as

$$\Pr(k|w_i,\mathcal{C}) = \frac{\Pr(w_i|k) \cdot \Pr(k|\mathcal{C})}{\sum_{j=1}^{N} \{\Pr(w_i|k_j) \cdot \Pr(k_j|\mathcal{C})\}}$$

where N is the number of objects.

These assumptions yield

$$\Pr(\mathcal{P}_t|k,\mathcal{C}) = \sum_{i=1}^{n} \frac{\Pr(w_i|k) \cdot \Pr(T(w_i)|\mathcal{P}_t)}{\sum_{j=1}^{N} \{\Pr(w_i|k_j) \cdot \Pr(k_j|\mathcal{C})\}} \quad (11)$$

where $\Pr(T(w_i)|\mathcal{P}_t)$, the probability of the time of word w_i given the time of the pointing gesture, is obtained from the following Gaussian time distribution for pointing.

$$\Pr(T(w_i)|\mathcal{P}_t) = \frac{\beta}{\sqrt{2\pi}\sigma_{P_t}} e^{-\frac{(T(w_i)-PTime)^2}{2\sigma_{P_t}^2}} \quad (12)$$

where β is a normalizing constant, *PTime* is the time of the gesture, and σ_{P_t} is the standard deviation of the Gaussian density function, which is currently set to 650 msec (based on our corpus).

As in our previous work (Makalic et al., 2008), we estimate $\Pr(w_i|k)$ using the Leacock and Chodorow (1998) WordNet similarity metric. This metric also yields a match probability between most objects and generic words like "object, thing, here, there", enabling us to handle requests such as "Get that *thing* over *there*".

3.2 Calculating the probability of a referring expression

As mentioned in Section 2, the intrinsic features previously considered in *Scusi?* are lexical item, colour and size (Makalic et al., 2008). Pointing affects referring expressions in that people may point instead of generating complex descriptions, they may employ demonstrative determiners together with generic terms such as "thing" (especially when they are unfamiliar with the name of an object), and they may use demonstrative pronouns. The first two behaviours were exhibited in our user study (Section 4), but none of our trial participants used demonstrative pronouns.

To incorporate pointing into the calculation of $\Pr(u|k,\mathcal{C})$, we add determiners to *Scusi?*'s formalism for intrinsic features, which yields

$$\Pr(u|k,\mathcal{C}) = \Pr(u_{\text{lex}}, u_{\text{det}}, u_{\text{colr}}, u_{\text{size}}|k,\mathcal{C})$$

After adding weights for the intrinsic features (inspired by (Dale and Reiter, 1995)), and making some simplifying assumptions, we obtain

$$\Pr(u|k,\mathcal{C}) = \quad (13)$$
$$\Pr(u_{\text{lex}}|k,\mathcal{C})^{w_{lex}} \cdot \Pr(u_{\text{det}}|k,\mathcal{C})^{w_{det}} \cdot$$
$$\Pr(u_{\text{colr}}|k)^{w_{colr}} \cdot \Pr(u_{\text{size}}|u_{\text{lex}},k)^{w_{size}}$$

The estimation of $\Pr(u_{\text{lex}}|k,\mathcal{C})$, $\Pr(u_{\text{colr}}|k)$ and $\Pr(u_{\text{size}}|u_{\text{lex}},k)$ is described in (Makalic et al., 2008). Here we focus on $\Pr(u_{\text{det}}|k,\mathcal{C})$.

3.2.1 Estimating $\Pr(u_{\text{det}}|k,\mathcal{C})$

$\Pr(u_{\text{det}}|k,\mathcal{C})$ is estimated as follows.

$$\Pr(u_{\text{det}}|k,\mathcal{C}) = \frac{\Pr(k|u_{\text{det}},\mathcal{C}) \cdot \Pr(u_{\text{det}}|\mathcal{C})}{\Pr(k|\mathcal{C})} \quad (14)$$

$$= \frac{\Pr(k|u_{\text{det}},\mathcal{C})}{\Pr(k|\mathcal{C})} \left[\begin{array}{l} \Pr(u_{\text{det}}|\mathcal{P},\mathcal{C}) \cdot \Pr(\mathcal{P}|\mathcal{C}) + \\ \Pr(u_{\text{det}}|\neg\mathcal{P},\mathcal{C}) \cdot \Pr(\neg\mathcal{P}|\mathcal{C}) \end{array} \right]$$

where det = {def_article, indef_article, demonstr_this, demonstr_that}; $\Pr(\mathcal{P}|\mathcal{C})$ and $\Pr(\neg\mathcal{P}|\mathcal{C})$ are returned by the gesture system; $\Pr(u_{\text{det}}|\mathcal{P},\mathcal{C})$ and $\Pr(u_{\text{det}}|\neg\mathcal{P},\mathcal{C})$ are obtained from our corpus; and for now we assume that $\Pr(k|u_{\text{det}},\mathcal{C}) = \Pr(k|\mathcal{C})$.[5] This yields

$$\begin{aligned}\Pr(u_{\text{det}}|k,\mathcal{C}) = \Pr(u_{\text{det}}|\mathcal{P},\mathcal{C}) \cdot \Pr(\mathcal{P}|\mathcal{C}) + \\ \Pr(u_{\text{det}}|\neg\mathcal{P},\mathcal{C}) \cdot \Pr(\neg\mathcal{P}|\mathcal{C})\end{aligned} \quad (15)$$

4 Evaluation

To obtain a corpus, we conducted a user study whereby we set up a room with labeled objects (Figure 1), and asked trial participants to request 12 selected items from *DORIS* (the room included 33 items in total, including distractors, and one of the authors pretended to be *DORIS*). The objects were selected and laid out in the room to reflect a variety of conditions, e.g., common and rare objects (e.g., vacuum tube); unique, non-unique and similar objects (e.g., white cups); and objects placed near each other and far from each other.

We divided our corpus of requests into two parts: with and without pointing. *Scusi?*'s performance was tested on input obtained from the ASR and on textual input (perfect ASR). We considered two scenarios for each sub-corpus: Pointing, where our pointing mechanism was activated on the basis of a simulated pointing gesture,[6] and No-Pointing, where no pointing gesture was detected. This was done in order to test two hypotheses: (1) when people point, pointing information improves interpretation performance; and (2) when they do not point, even perfect pointing has little effect on interpretation performance.

Scusi? was set to generate at most 300 sub-interpretations in total (including texts, parse trees, UCGs and ICGs) for each spoken request, and at most 200 sub-interpretations for each textual request. On average, *Scusi?* takes 10 seconds to go from texts to ICGs. An interpretation was deemed successful if it correctly represented the speaker's intention, which was encoded in one or more *Gold ICG*s. These ICGs were manually constructed on the basis of the requested objects and the participants' utterances. Multiple Gold ICGs were allowed if there were several suitable actions and objects.

4.1 The Corpus

19 people participated in the trial, generating a total of 276 requests, of which 136 involved pointing gestures (3 participants were asked to repeat the experiment after it became clear that they were refraining from pointing, as they erroneously assumed they were not allowed to gesture). We filtered out 64 requests, which included concepts our system cannot yet handle, specifically "the end of the table", projective modifiers (e.g., "behind/left"), ordinals ("first/second"), references to groups of things (e.g., "six blue pens"), and zero- and one-anaphora. This yielded 212 requests, of which 105 involved pointing gestures.

In addition, the software we used has the following limitations: the gesture recognition system (Li and Jarvis, 2009) requires users to hold a gesture for 2 seconds, and the ASR system is speaker dependent and cannot recognize certain words (e.g., "mug", "bowl" and "pen"). To circumvent these problems, each pointing gesture was manually encoded into a time-stamped vector; and one of the authors read slightly sanitized versions of participants' utterances into the ASR: "can you", "please" and "DORIS" were omitted; long prepositional phrases were shortened (e.g., "the thing with wires *sticking out of it*"); and words that were problematic for the ASR were replaced (e.g., "pencil" was used instead of "pen").

There was some difference in the length of requests with and without pointing, but it wasn't as pronounced as reported in (Johnston et al., 2002): requests with/without pointing had 5.84/6.27 words on average. ASR performance was worse for the requests that had pointing, with the top ASR interpretation being correct for only 46% of these requests, compared to 57.5% for the requests without pointing. This difference may be attributed to the ASR having trouble with sentence constructs associated with pointing. Overall

[5] In the future, we will incorporate distance from the user to refine the probabilities of determiners.

[6] At present, we assume accurate pointing and gesture detection, and precise information regarding the position of objects. In the near future, we will study the sensitivity of our mechanism to pointing inaccuracies, and to errors in gesture detection and scene analysis.

	% Gold ICGs in top 1	% Gold ICGs in top 3	Avg adj rank (rank)	% Not found	Avg adj rank (rank) 20	% Not found 20

Table 1: *Scusi?*'s interpretation performance

the ASR returned the correct interpretation, at any rank, for 88% of the requests.

4.2 Results

Table 1 summarizes our results. Column 1 displays the test condition (sub-corpus with/without pointing, text/ASR, and with/without *Scusi?*'s pointing mechanism). Columns 2-3 show the percentage of utterances that had Gold ICGs whose probability was among the top 1 and top 3, e.g., in the sub-corpus with pointing, when *Scusi?*-Pointing was run on text, 82.9% of the utterances had Gold ICGs with the highest probability (top 1). The average *adjusted rank (AR)* and average *rank* of the Gold ICG appear in Column 4. The rank of an ICG I is its position in a list sorted in descending order of probability (starting from position 0), such that all equiprobable ICGs are deemed to have the same position. The adjusted rank of an ICG I is the mean of the positions of all ICGs that have the same probability as I. For example, if we have 4 equiprobable ICGs in positions 0-3, each has a rank of 0, but an adjusted rank of $\frac{r_{\text{best}}+r_{\text{worst}}}{2} = 1.5$. Column 5 shows the percentage of utterances that didn't yield a Gold ICG. Column 6 shows the average AR for interpretations with AR < 20 (and their average rank), and Column 7 shows the percentage of utterances that had AR ≥ 20 or were not found. We distinguish between Gold ICGs with ARs 0 to 19 and total Gold ICGs that were found, because a dialogue manager is likely to inspect the promising options, i.e., those with AR $< K$ (we assume $K = 20$). In addition, there is normally a trade-off between the number of Not Found Gold ICGs and average AR. ICGs that are not found by one approach but are found by another approach typically have a high (bad) rank when they are eventually found (Zukerman et al., 2008). Thus, an approach that fails to find such "difficult" ICGs usually yields a lower average AR than an approach that finds these ICGs. Capping the ARs of the found Gold ICGs at 20 clarifies the trade-off between average AR and Not Found.

Our results show that, as expected, the main role of pointing is in referent disambiguation. This is evident from the significant reduction in average AR-20 (Column 6) for the pointing and no-pointing sub-corpora, under the text/ASR input conditions. All the differences are statistically significant with $p < 0.01$.[7] Nonetheless, the improvements in average AR-20 obtained by artificially introduced pointing in the no-pointing sub-corpus are smaller for both text and ASR than the improvements obtained with actual pointing. We posit that this smaller impact is due to the fact that utterances without pointing are more descriptive than those with pointing, hence benefitting less from the disambiguating effect of pointing.

The Pointing condition has a seemingly adverse effect on the number of interpretations with top ranks (Columns 2-3). This is explained by the fact

[7]The differences were calculated using a paired t-test for all the Gold ICGs that were found in both configurations.

that all equiprobable interpretations have the same rank, which happens more often under the No-Pointing condition than under the Pointing condition (as pointing has a disambiguating effect).

Finally, under all conditions, the rank of the request at the 75%-ile is 0, which indicates creditable performance. The larger number of Not Found Gold ICGs for the ASR condition is expected, as the ASR failed to find 12% of the correct texts on average, performing worse for the pointing sub-corpus. The other Not Found Gold ICGs were mainly due to parsing preferences, and multiple parses for some utterances that had the word "thing" (which matched all objects).

5 Related Research

Gesture recognition systems endeavour to detect the gesture being made. Common approaches include Hidden Markov Models, e.g., (Nickel and Stiefelhagen, 2003), and Finite State Machines, e.g., (Li and Jarvis, 2009). Systems that focus on pointing also identify the target object, without recognizing the type of this object (Nickel and Stiefelhagen, 2003; Li and Jarvis, 2009).

Most of the research in gesture and speech integration focuses on pointing gestures, employing speech as the main input modality, and using semantic fusion to combine spoken input with gesture. Different approaches are used for gesture detection, e.g., vision (Stiefelhagen et al., 2004; Brooks and Breazeal, 2006) and sensor glove (Corradini et al., 2002); and for language interpretation, e.g., dedicated grammars (Stiefelhagen et al., 2004; Brooks and Breazeal, 2006) and keywords (Einstein and Christoudias, 2004). Fusion is variously implemented using heuristics based on temporal overlap (Bolt, 1980; Johnston et al., 2002), querying a gesture-sensing module when ambiguous referents are identified (Fransen et al., 2007), or unification to determine which elements can be merged (Corradini et al., 2002; Stiefelhagen et al., 2004). These are sometimes combined with search techniques coupled with penalties (Einstein and Christoudias, 2004; Brooks and Breazeal, 2006). With the exception of Bolt's system, these systems were tested on utterances that were quite short and constrained.

Our approach integrates spatial and temporal aspects of gesture into our probabilistic formalism (Zukerman et al., 2008), focusing on the effect of pointing on object salience. Other salience-based approaches are described in (Einstein and Christoudias, 2004; Huls et al., 1995). However, they are not directly comparable with our approach, as they use salience to weigh the importance of factors pertaining to gesture-speech alignment, but there is no uncertainty associated with the visual salience resulting from pointing.

Our use of a probabilistic parser enables us to handle more complex utterances than those considered by most speech-gesture systems (Section 2). At the same time, we do not yet handle speech disfluencies, which are currently handled by (Einstein and Christoudias, 2004; Stiefelhagen et al., 2004). Also, at present we do not consider the challenges pertaining to the real-time synchronization of the output of a gesture-sensing and a speech-recognition system (Stiefelhagen et al., 2004; Brooks and Breazeal, 2006).

6 Conclusion and Future Work

We have extended *Scusi?*, our spoken language interpretation system, to incorporate pointing gestures. Specifically, we have offered a formalism that takes into account relationships between aspects of gesture and spoken language to integrate information about pointing gestures into the estimation of the probability of candidate interpretations of an utterance. Our empirical evaluation shows that our formalism significantly improves interpretation accuracy.

In the future, we propose to refine our model of demonstrative determiners. We also intend to perform sensitivity analysis regarding the accuracy of the vision system, and that of the gesture recognition system. In addition, we will conduct user studies to gain insights with respect to conditions that influence the probability of pointing, e.g., type of object and its position relative to the speaker.
